Part 6 Molecular Networks

20
Modeling and Simulating Metabolic Networks

Stefan Schuster and David Fell

1 Introduction

This chapter gives an overview of various modeling and simulation techniques in the theoretical description of metabolic (biochemical) networks. While the term "modeling" refers to the establishment of a formal representation of the system or process under study, "simulation" stands for the numerical calculations performed with the model. As most biochemical systems subsist in stable stationary states, the modeling of such states is central to the field. However, oscillatory and other dynamics can also be modeled. First, the fundamentals are outlined: stoichiometry, balance equations and enzyme kinetics. Thereafter, the principles of metabolic pathway analysis are presented. Basic concepts such as conservation relations, nullspace, elementary modes and extreme pathways are explained. The added value of elementary-modes analysis by avoiding incorrect interpretations from graphic representations and by deducing novel interpretations of metabolism is illustrated by examples from carbon metabolism, e.g. in Crassulacean plants. Methods for constructing and using dynamic models of metabolic networks are outlined. Such models can often be simplified by the quasi-equilibrium and quasi-steady-state approximations. As an example of medium-scale analysis, we discuss the modeling of red blood cell metabolism. An outlook on current trends in the field concludes the chapter.

2 Fundamentals

2.1 Motivation

The phenomenon of life is tightly coupled to chemical reactions – autotrophic organisms fix CO_2 and convert it to organic compounds, while heterotrophic organisms degrade some of the organic compounds of their food to obtain energy and convert other constituents of the food into organism-specific compounds. At the level of living cells, this chemical transformation of substances is called metabolism (from the Greek: *meta* = within and *bole* = throwing). Most biochemical reactions are catalyzed by specific proteins – enzymes. Technologically relevant metabolic processes include the synthesis of antibiotics, dyes and perfumes, and the production of ethanol by yeast and of amino acids (in large quantities for food supplements) by bacteria. The understanding of these processes is, hence, of great economic importance. Moreover, it has medical relevance because many inherited single-gene diseases result from complete or partial enzyme deficiencies. For example, the complete lack of the enzyme phenylalanine 4-monooxygenase prevents formation of the amino acid tyrosine from the amino acid phenylalanine. This causes the disease phenylketonuria implying mental retardation, due to excessive accumulation of phenylalanine (e.g. Ref. [138]). The disease can be treated by a life-long, nearly phenylalanine-free diet. Partial lack of one or more enzymes causes the complex group of diseases known as mitochondrial cytopathies, one of which, for example, leads to progressive weakness and degeneration of skeletal muscles (ragged red muscle fiber disease). There are only palliative treatments for these disorders (e.g. Ref. [75]).

The metabolism in living cells is a very complex system due to the large number of reactions most of which convert more than one *reactant* (or *substrate*) into more than one *product*. Therefore, a graphical representation in which each reaction is an edge and each substance is a node leads to a network that is more complex than a graph in graph theory, where each edge would only connect two nodes (see also Chapter 43). Importantly, the metabolism of each cell forms a single, interconnected network. For plants and many microbes, the reason is obvious – they can create all their cell contents from one source of carbon. Although many metabolites have only one producing reaction and one consuming reaction, a significant minority are involved in large numbers of reactions. In fact, there appears to be a power-law distribution of connectivities of metabolites [60, 148], so even though the reason for this distribution remains controversial, metabolism forms a highly interconnected network. In addition to the conversion reactions, there are regulatory interactions superimposed on this network, where metabolites activate or inhibit the rates of reactions other than the ones in which they directly participate. As will be explained below, the velocities of biochemical reactions are usually nonlinear functions of the concentrations of substances (substrates, products and *effectors* – the general term for both activators and inhibitors).

For all these reasons, the dynamic behavior of metabolic systems cannot normally be understood intuitively – a mathematical description is needed, often called a model. In fact, nonintuitive behavior can arise in small networks with linear kinetics, as demonstrated by Braess' paradox [9], originally formulated in the context of traffic flows although it also arises in computer networks. In essence, the paradox demonstrates that the addition of a new link in the network in order to increase its capacity can actually lead to a decrease in the average transit velocity.

A model is a simplified representation of some observed system, process or feature. While the term *modeling* refers to the establishment of a formal representation of the system or process under study, *simulation* stands for the numerical calculations performed with the model. For a more detailed discussion of modeling and theory in biochemistry, see Ref. [51].

Mathematical modeling in biochemistry has traditionally focused on the description of stationary states and time courses by using kinetic models (e.g. Refs. [19, 32, 51]. Such models are aimed at predicting the system's dynamics on the basis of the knowledge of the structure in terms of reactions (see Section 2.2) of the network and the kinetic parameters of enzymes (see Section 2.4). Within the last 15 years, however, the focus has somewhat shifted, at least for large-scale models of metabolism, towards network modeling (e.g. Refs. [51, 57, 79, 92, 100, 129]), sometimes called *constraint-based modeling*. The main idea is to leave aside the many kinetic details, which are often unknown, and consider some basic constraints arising from the network structure and thermodynamic principles.

2.2 Stoichiometry

The stoichiometry of a reaction expresses the proportions of changes in mole numbers of the substances involved. For example, in the reaction $2H_2O_2 \rightarrow 2H_2O + O_2$ (catalyzed by the enzyme catalase) the proportion between consumption of hydrogen peroxide and production of oxygen is 2:1. This is expressed by the stoichiometric coefficients 2 and 1. To make a distinction between the substances on the left-hand side of the equation (in chemistry called reactants, in biochemistry often called substrates) and the substances on the right-hand side (products), the stoichiometric coefficients are taken to be negative for substrates and positive for products. Formally, one can write the reaction equation as $2H_2O + O_2 - 2H_2O_2 = 0$.

Of course, most metabolic models comprise more than one biochemical reaction. A concise way of representing the stoichiometric coefficients is to compile them in a matrix. In this matrix, usually rows correspond to metabolites and columns correspond to reactions. The matrix entries signify the multiplicities with which the respective metabolites occur in the respective reactions. The signs indicate the side of the reaction on which the metabolites occur. Consider, for example, the phosphorylation and subsequent isomerization of glucose:

$$\text{glucose} + \text{ATP} \leftrightarrow \text{glucose-6-phosphate} + \text{ADP} \tag{1a}$$

$$\text{glucose-6-phosphate} \leftrightarrow \text{fructose-6-phosphate} \tag{1b}$$

catalyzed by the enzymes hexokinase and phosphoglucoisomerase, respectively. These two reactions are part of the reaction system shown in Figure 1. The stoichiometry matrix corresponding to the above two reactions reads:

$$\mathbf{N} = \begin{pmatrix} -1 & 0 \\ -1 & 0 \\ 1 & -1 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}. \tag{2}$$

with the first and second column corresponding to hexokinase and phosphoglucoisomerase, respectively, and the rows (from top to bottom) correspond-

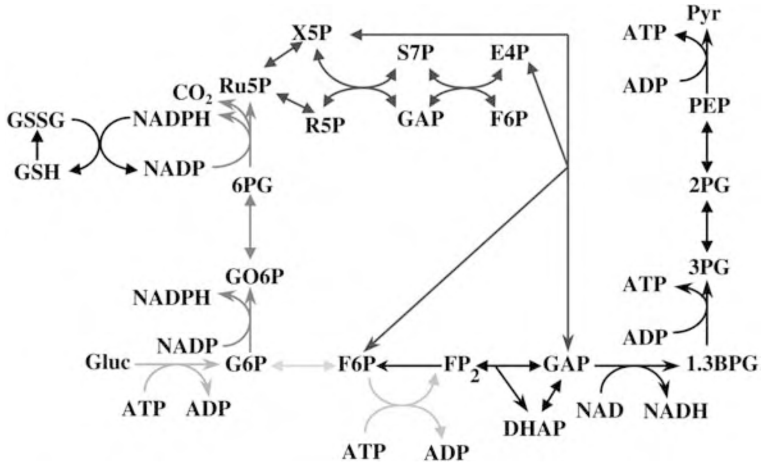

Figure 1 Part of sugar metabolism in various cell types. Abbreviations of metabolite names used in the text: F6P, fructose-6-phosphate; Gluc, glucose; G6P, glucose-6-phosphate, GSH/GSSG, reduced and oxidized forms of glutathione, respectively; Pyr, pyruvate. Red, hexokinase; green, phosphoglucoisomerase; orange, phosphofructokinase; blue (brown), reactions of oxidative (nonoxidative) pentose phosphate pathway.

ing to glucose, ATP, glucose-6-phosphate, ADP and fructose-6-phosphate. Since most substances are involved in only a few reactions, stoichiometric matrices are normally sparse, i.e. they involve a large number of zero entries.

2.3 Balance Equations

Metabolic systems are amenable to mathematical modeling because the law of mass conservation imposes some restrictions that can be expressed in very useful equations. In other processes, this law is also valid, but it does not play such a major role, e.g. in signal transduction systems, the flow of information (which is the focus of interest and which is not subject to conservation laws) is not coupled to the flow of mass (see Chapter 22).

Intuitively speaking, mass conservation implies that the temporal change in the concentration of each metabolite equals the sum of all reaction rates producing that metabolite minus all reaction rates consuming it. Using the stoichiometric coefficients, this can be written as:

$$\frac{\mathrm{d}S_i}{\mathrm{d}t} = \sum_{j=1}^{r} n_{ij} v_j \, , \tag{3}$$

where n_{ij} are the entries in the i-th row and j-th column of matrix $\mathbf{N}$. The symbols S_i and v_j stand for the concentration of the i-th metabolite, S_i, and the rate of the j-th reaction, respectively. r denotes the number of reactions. By gathering the S_i and v_j into vectors $\mathbf{S}$ and $\mathbf{v}$, respectively, Eq. (3) can concisely be written as:

$$\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}t} = \mathbf{N}\mathbf{v} \, . \tag{4}$$

In order to apply this equation in a meaningful way, a distinction should be made between two types of metabolites. *Internal metabolites* are those substances for which the dynamics of their concentrations can be described by Eq. (4) because they are internal to the model. As each model needs to be delimited somehow, some metabolites should form its *boundaries*, i.e. they participate both in reactions involved in the model and in additional (external) reactions. This, however, implies that these substances, which are usually called *external metabolites*, are not properly described by the respective component equations in Eq. (4). Therefore, the rows corresponding to external metabolites should be deleted from the stoichiometry matrix. The distinction between external and internal metabolites is meaningful to properly describe that biochemical networks are open systems, which exhibit a throughput of mass. In the glucose example given above (Eq. 1), all substances except glucose-6-phosphate take part in only one reaction of the model. In the living cell, however, they also participate in other reactions. Therefore, for this small didactic example, it is sensible to consider only glucose-6-phosphate as an internal metabolite. Thus, the stoichiometry matrix reduces to:

$$\mathbf{N} = (1 \ \ -1). \tag{5}$$

This allows one to make assertions about the steady state of the system (see Section 3.2).

2.4 Enzyme Kinetics

To be able to solve the differential equation system (4) analytically or, in most cases, numerically, the right-hand sides should also be expressed in terms of concentrations. This is feasible because the reaction rates do depend on the concentrations, $\mathbf{v} = \mathbf{v}(\mathbf{S})$. It is intuitively clear that the number of molecules converted in a reaction per time depends on the number of molecules present. This dependence is called the *rate law* or *reaction kinetics*. If the reaction is catalyzed by an enzyme, the term *enzyme kinetics* can be used (this term is also used for the entire discipline dealing with such rate laws.) The best known enzyme kinetics is a rate law called after the biochemists Michaelis and Menten [82]:

$$v = \frac{V_{\mathrm{max}} S}{K_{\mathrm{m}} + S}\,, \tag{6}$$

where V_{max} is the limiting rate (formerly maximal activity) and K_{m} is the Michaelis–Menten constant. It describes a unidirectional, monomolecular reaction, i.e. the conversion of one substance, S, into one other substance, P, without a reverse reaction. The italic symbol S denotes the concentration of S. This rate law can be understood very easily: for low substrate concentrations, it simplifies to a linear rate law, $v = V_{\mathrm{max}}/K_{\mathrm{m}} \times S$, which coincides with the usual mass action kinetics known from chemistry. For larger substrate concentrations, the reaction rate increases, but less than linearly, and for very high substrate levels, the reaction rate tends to an asymptotic value, the limiting rate, V_{max}. This is because the rate of formation of the product is proportional to the concentration of the enzyme-substrate complex (ES), which cannot exceed the total amount of the enzyme. This phenomenon is called saturation.

For bidirectional, monomolecular reactions, the Michaelis–Menten kinetics can be generalized to give (e.g. Refs. [19,124]):

$$v = \frac{V_{\mathrm{max}}^{+} S/K_{\mathrm{mS}} - V_{\mathrm{max}}^{-} P/K_{\mathrm{mP}}}{1 + S/K_{\mathrm{mS}} + P/K_{\mathrm{mP}}} \tag{7}$$

where V_{max}^{+} and V_{max}^{-} are the limiting rates of the substrate and product, respectively, and K_{mS} and K_{mP} are the Michaelis–Menten constants of the forward and backward rates, respectively. Bidirectionality means that a forward

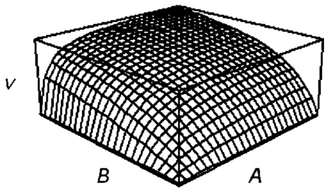

Figure 2 A 3-D plot of the reaction rate of an irreversible, bimolecular enzyme reaction versus the two substrate concentrations, A and B, according to the rate law Eq. (8). Note that any cross-section parallel to the A-axis (or B-axis) yields the plot of a standard Michaelis–Menten rate law (6) with respect to A (respectively B). Parameter values: $V_{\text{max}} = 2$, $K_{\text{iA}} = 1$, $K_{\text{mB}} = 0.5$, $K_{\text{mA}} = 0$.

reaction and a backward reaction proceed simultaneously. In enzyme kinetics, unidirectionality and bidirectionality of reactions are often equated with irreversibility and reversibility, respectively. However, in other applications, such as in network analysis (see Section 3), a reaction is called *irreversible* if it has a fixed net direction while it is allowed to have a backward reaction "underneath". A reaction is called *reversible* if the direction of the net flux can be reversed by changing substrate and/or product concentrations appropriately, although the boundary between irreversible and reversible is arbitrary (see Ref. [32] for a discussion).

Most biochemical reactions are not, however, monomolecular. Also, for these cases, Michaelis–Menten-type rate laws have been derived. Here, we give the rate law for an irreversible reaction with two substrates, A and B (e.g. Refs. [19,124]):

$$v = \frac{V_{\text{max}} \cdot A \cdot B}{K_{\text{iA}} \cdot K_{\text{mB}} + K_{\text{mB}} \cdot A + K_{\text{mA}} \cdot B + A \cdot B} \,. \tag{8}$$

The symbol K with different subscripts stands for phenomenological parameters depending on the rate constants of the elementary steps of enzyme catalysis. If Eq. (8) is derived by the quasi-equilibrium approximation, these parameters are dissociation constants of the enzyme–substrate complexes. For example, K_{mB} is the constant of dissociation of the complex EAB into EA and B. If Eq. (8) is derived by the quasi-steady-state approximation, the dependence is more complicated. In Figure 2, the dependence of the reaction rate on substrate concentrations according to Eq. (8) is plotted.

The various enzyme kinetic rate laws can be derived from the mass-action kinetic equations describing the elementary steps (such as the binding of substrate to the free enzyme). For the monomolecular reaction S → P, the scheme can be written as:

$$\text{E} + \text{S} \rightarrow \text{ES} \rightarrow \text{E} + \text{P}. \tag{9}$$

In the derivation, approximations need to be used, the most common being the quasi-steady-state approximation saying that the concentration of the enzyme–substrate complex is nearly constant in time. A plethora of enzyme kinetic rate laws have been derived, describing, among others, cooperativity, competitive, allosteric and uncompetitive inhibition, various forms of activation, etc. For monographs on enzyme kinetics, the reader is referred to Refs. [19, 124]. Cooperativity means that two or more substrate molecules have to bind to initiate the reaction. This leads to a sigmoidal curve of the rate law (e.g. Hill kinetics and Monod–Wyman–Changeux kinetics), i.e. the curve goes up sharply near an inflection point.

Interestingly, the various versions of Michaelis–Menten kinetics describe the respective enzyme reactions over the entire range of possible substrate concentrations (from zero through infinity) fairly well, provided the equation has been derived for a mechanism appropriate to the enzyme under consideration. In fact, the main motivation for deriving such equations was to diagnose enzyme mechanisms, not so much to describe the enzyme rate function. Such mechanistically derived equations contain many parameters whose values are rarely experimentally known. On the other hand, it is known from sensitivity analysis of model behavior that uncertainty about their exact value is unlikely to have much impact on simulations, so the equations are "over-specified" for use in modeling of cellular situations where the variation in concentration of metabolites is much less than in *in vitro* enzyme kinetics experiments. For this reason, it has been common to use simplified versions of the equations with fewer parameters [14, 156]. There is even a kinetic equation that copes with substrate, product and effector cooperativity, for which there is no satisfactory mechanistically derived justification [53]. In the same vein, simplified rate laws have been proposed [86, 107, 157], which render the differential equation system easier to handle analytically, but do not describe the reaction rate properly at very low or very high substrate concentrations.

3 Network Analysis

3.1 Conservation Relations

From physics, it is known that many systems exhibit so-called conservation quantities, such as energy, momentum and angular momentum. Conservation quantities occur also in many metabolic systems. For example, in Eq. (9) describing the elementary reactions of a monomolecular enzyme reaction, it can be seen that the sum of the concentrations of E and ES is constant in time because this is the total enzyme, which is neither consumed nor produced by the overall catalytic reaction. Of course, in the living cell, the total amount of an enzyme does change, due to gene expression and protein degradation. However, these processes are separate from, and much slower than, the catalytic steps given above and can, therefore, often be neglected. Mathematically, we can describe reaction (9) by the stoichiometry matrix:

$$\mathbf{N} = \begin{pmatrix} -1 & 1 \\ -1 & 0 \\ 1 & -1 \\ 0 & 1 \end{pmatrix} \tag{10}$$

with the rows corresponding to E, S, ES and P (in this order). The sum of the first and third rows (corresponding to E and ES) is the null vector (and so is the sum of the second, third and fourth rows). This implies $\mathrm{d}E/\mathrm{d}t = -\mathrm{d}ES/\mathrm{d}t$, which means that $\mathrm{d}(E + ES)/\mathrm{d}t = 0$, showing that the reaction scheme can never change the total enzyme concentration.

Hence, more generally, conservation relations can be derived from the stoichiometry matrix by analyzing the linear dependencies among its rows. Let **G** denote a matrix the rows of which express these linear dependencies. That is, **G** satisfies the matrix equation:

$$\mathbf{G}\,\mathbf{N} = \mathbf{0}. \tag{11}$$

In mathematical terms, the rows of **G** span the left-hand side nullspace of **N** (i.e. the nullspace of the transpose of **N**). The nullspace of a matrix is the space of all vectors that give the null vector when multiplied by that matrix. Standard methods exist [72] and are usually included in computer mathematics packages, for computing the nullspace of a matrix such as **N**. Multiplying Eq. (4) by **G** from the left yields:

$$\mathbf{G}\frac{\mathrm{d}\mathbf{S}}{\mathrm{d}t} = \mathbf{0}. \tag{12}$$

Integration over time gives:

$$\mathbf{G}\,\mathbf{S}(t) = \mathbf{G}\,\mathbf{S}(0). \tag{13}$$

$\mathbf{S}(0)$ is the concentration vector at time zero and, thus, a vector of constants.

For the enzyme reaction (9), matrix **G** can be chosen to be:

$$\mathbf{G} = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 \end{pmatrix}, \tag{14}$$

which, given that the columns of **G** correspond to the rows of **N**, yields the conservation relations $E + ES = \text{const.}$ and $S + ES + P = \text{const.}$ The second relationship expresses the fact that the system is modeled as closed, i.e. both S and P are considered to be internal, and there is no mass flow into or out of the system via external metabolites.

The search for conservation relations is an example of a structural analysis, which does not require the knowledge of kinetic parameters such as Michaelis–Menten constants. It is helpful because, if the system involves conservation quantities, it allows one to reduce the dimension of the system equation (4). In fact, only a set of linearly independent differential equations needs to be considered since any dependent concentrations can be calculated from Eq. (13). Each conservation relationship allows for the removal of one dependent variable, though whether it is *E* or *ES* that is considered to be dependent in the above example is a matter of choice. [In principle it should not make any difference which is chosen, but there may be problems of numerical accuracy if the solution of Eq. (13) involves small differences between large concentrations.] Knowledge of conservation relations is also of importance in stability analysis [51] and for the quasi-equilibrium approximation (see Section 4.1).

Most conservation relations reflect the conservation of chemical entities such as the phosphate group and can thus be chosen to involve non-negative coefficients only. A method for calculating the coefficients in this case was given [117]. However, conservation relations may occur due to other reasons. These may not have this non-negativity property [117] or may even be nonlinear [110]. Biological implications of conservation relations have been discussed in Ref. [29].

3.2 Stationary States and Stability Analysis

Many synthesis or degradation processes in metabolism subsist (approximately) at a stationary state. This is not to be confused with a thermodynamic equilibrium state, in which all net reaction rates are zero and no entropy is produced. Cellular metabolism is an open system, so that there is a permanent throughput of mass. Very often, the input and output are balanced in such a way that the concentrations of metabolites do not change. This is in fact due to stability properties because a steady state can only be observed when it is stable, i.e. when small fluctuations are damped. Examples of stable steady states from everyday life are provided by a calmly flowing river and a light bulb converting electricity into light. Examples of unstable steady states are provided by a vibrating violin string and waves induced by the wind blowing over the ocean.

Examples of stable steady states in metabolism are glycolysis (degradation of glucose to give pyruvate or lactate and concomitant ATP production, see Figure 1) in many cells, amino acid synthesis and, at a lower level, the turnover of the enzyme–substrate complex in almost any enzymatic reaction.

At steady state, Eq. (4) simplifies to the algebraic equation system:

$$\mathbf{N}\,\mathbf{v} = \mathbf{0}. \tag{15}$$

For example, for the glucose phosphorylation system (1) in Section 2.2 with the stoichiometry matrix (5), this reads $v_1 - v_2 = 0$, which correctly describes the steady state for this system if only glucose-6-phosphate is considered to be an internal metabolite.

A large part of the theory underlying the modeling of metabolic networks is based on the steady-state equation (15). This equation is very attractive due to its simplicity. Moreover, it has a rather wide range of applicability because so many biochemical systems subsist in steady state. In the case of small fluctuations, it can still be used as an approximation; even when the system behaves in an oscillatory manner with constant amplitude, the averaged fluxes obey that equation because the internal metabolites must not accumulate nor run down in the long term. The difference between the terms *reaction rate* and *flux* is worth mentioning. The former term is used for reaction velocities at any state, e.g. at any time point of an oscillation, whereas the latter term is normally used for a reaction rate at a steady state.

To check whether a steady state is stable, stability analysis can be applied. This analysis is, strictly speaking, beyond structural (network) analysis because it requires some knowledge of kinetic parameters. Nevertheless, we treat it in this section because it is closely related to the study of steady states. A stability analysis is called local if the idealized situation of infinitesimally small fluctuations is considered.

To explain the basic idea of local stability analysis, we consider the simple case of two sequential monomolecular reactions, A → S → B, with S being considered to be an internal metabolite. Thus, we deal with a system that is one-dimensional (1-D) in terms of concentrations. Let the first reaction have a constant rate, v_{in} (input), while the second reaction follows the Michaelis–Menten kinetics given in Eq. (6). The steady-state equation $v_1 - v_2 = 0$ then reads:

$$v_{\mathrm{in}} = \frac{V_{\mathrm{max}} S}{K_{\mathrm{m}} + S} = 0\,, \tag{16}$$

Solving this for S gives:

$$S = \frac{v_{\mathrm{in}} K_{\mathrm{m}}}{V_{\mathrm{max}} - v_{\mathrm{in}}}\,. \tag{17}$$

This term is positive if $V_{\mathrm{max}} > v_{\mathrm{in}}$. In the opposite case, the limiting rate of the second enzyme is not sufficient to convert S with the same rate as it is fed into the system. Checking stability in this system can be done in a graphical manner, by plotting $\mathrm{d}S/\mathrm{d}t$ ($\dot{S}$ for short) versus S (Figure 3). The intersection of this curve with the S-axis gives the steady state. Assume there is a small fluctuation of the concentration, S, decreasing it. This leads to a positive value of $\dot{S}$, such that S increases. In contrast, a positive deviation leads to a negative

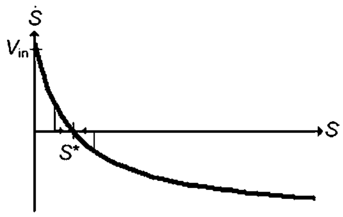

Figure 3 Plot illustrating the stability analysis of a simple system consisting of two sequential monomolecular reactions. S^* denotes the steady-state concentration. A negative deviation leads to a positive value of $\dot{S}$, such that S increases, while a positive deviation leads to the opposite effect. In either case, the system is running back to the steady state, so that this state is stable.

value of $\dot{S}$, such that S decreases. In either case, the system is running back to the steady state and, hence, this state is stable. For any 1-D system, a steady state is stable if the curve $\dot{S}$ versus S intercepts the S-axis with a negative slope.

In systems of dimension greater than one, stability analysis is more complicated. It is usually performed by using the so-called Jacobian matrix. As this is beyond the scope of this chapter, the reader is referred to Refs. [51,70].

3.3 Constraints on Steady-state Fluxes

If the fluxes in the steady-state equation (15) are regarded as variables rather than functions, then the equation is usually underdetermined, meaning that there is no unique solution for them. However, the steady-state requirement places constraints on their values, e.g. in a simple linear pathway of single-substrate, single-product reactions, the steady state would require that the fluxes were all identical, without specifying what their value would be. Just as the conservation relations between metabolites correspond to the left-hand side nullspace of matrix $\mathbf{N}$, it turns out that the relationships between fluxes are given by the right-hand side nullspace. This can be represented by the column vectors of a matrix $\mathbf{K}$ with maximum rank fulfilling an equation similar to Eq. (15) (e.g. Ref. [72]):

$$\mathbf{N}\,\mathbf{K} = \mathbf{0}\,. \tag{18}$$

Thus, the nullspace to the stoichiometry matrix is the region of all flux vectors that are, in principle, possible at steady state.

For identifying metabolic pathways, it is of interest to find very simple flux distributions. As an example, consider the simple network in Figure 4(A) consisting of a short linear pathway with a substrate cycle (e.g. Ref. [31]). The cycle would have to be driven by, for example, ATP hydrolysis, but ATP and ADP are not shown because they are being considered external metabolites in this case. Eq. (15) for this system is:

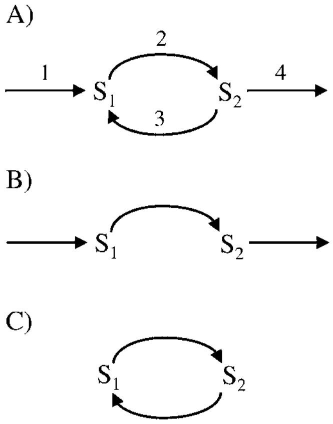

Figure 4 (A) Simple reaction scheme involving a substrate cycle. External metabolites are not shown. Pathways corresponding to the nullspace vectors (1 1 0 1)^T and (0 1 1 0)^T are depicted in (B) and (C), respectively.

$$\begin{pmatrix} 1 & -1 & 1 & 0 \\ 0 & 1 & -1 & -1 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{19}$$

A possible basis for the nullspace of the stoichiometry matrix is:

$$\mathbf{K} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \\ 1 & 0 \end{pmatrix}, \tag{20}$$

where the two vectors correspond to two component pathways shown in Figure 4(B and C). The vectors do not contain the actual fluxes, but any observable flux vector can be expressed as a scaled combination of these two vectors, i.e.:

$$\begin{pmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix} = \begin{pmatrix} \lambda_1 \\ \lambda_1 + \lambda_2 \\ \lambda_2 \\ \lambda_1 \end{pmatrix}, \tag{21}$$

where λ_1 and λ_2 are scaling factors. Apart from substrate cycles [31], biochemical pathways of amino acid synthesis, for example, have been analyzed using the nullspace approach [131, 136].

For many biochemical reactions, it is known whether they are reversible or irreversible. As mentioned in Section 2.4, in metabolic network analysis, irreversibility is not meant to exclude that the reaction involves a reverse step; rather, the reverse step is supposed to always have a lower rate than (or at most the same rate as) the forward step. Thus, the net flux is always non-negative for irreversible reactions. For example, most phosphatases (EC numbers 3.1.3.x) are irreversible, while all isomerase reactions (EC 5.x.y.z) are reversible. Information on the directionality of reactions is available much more often than kinetic data. It can be obtained from the original biochemical literature, textbooks and databases such as the authoritative NIST database of thermodynamics of enzyme-catalyzed reactions (http://xpdb.nist.gov/enzyme_thermodynamics/enzyme_thermodynamics_data.html) or somewhat indirectly and not always correctly from KEGG (http://www.genome.ad.jp/kegg) and BRENDA (http://brenda.uni-koeln.de). For example, the hexokinase reaction mentioned in Section 2.2 has such a high equilibrium constant that it is usually written as an irreversible reaction:

glucose + ATP → glucose-6-phosphate + ADP.

Without loss of generality, the sign definition of reaction rates can be chosen in such a way that the subvector in **v** corresponding to the irreversible reactions satisfies the inequality:

$$\mathbf{v}^{\mathrm{irr}} \geq \mathbf{0}\,. \tag{22}$$

The admissible region determined by relations (15) and (22) in flux space is a convex polyhedral cone (Figure 5). For instance, $[-1\ -1\ 0\ -1]^{\mathrm{T}}$ is a mathematically valid nullspace vector for our example substrate cycle (Figure 4), but uses the three reactions in the "wrong" direction and so is physically invalid. Of course, in this case the problem can be easily fixed by multiplying the vector by -1, thus reversing all the reactions. However, $[1\ 0\ -1\ 1]^{\mathrm{T}}$

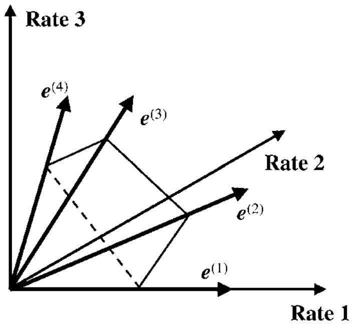

Figure 5 Schematic representation of a flux cone. The coordinates are the reaction rates of enzymes. The flux cone shown here is 3-D. Usually, the dimension of the space of rates (in which the cone is embedded) is then higher than three; only three axes are shown. Each generating vector (edge), $\boldsymbol{e}^{(i)}$, of the cone represents an elementary mode. Note that here the number of generating vectors is larger than the cone's dimension. The thin lines indicate a normalization by Eq. (27) and help to visualize the shape of the cone.

is also a valid nullspace vector, but this cannot be simply resolved, since reversing it merely changes which reactions are being used in the wrong direction. Moreover, a full set of linearly independent basis vectors often does not involve all biochemically meaningful pathways.

3.4 Defining Component Pathways of a Network

Based on early attempts in chemistry [17], methods for defining biochemical pathways in a formal way were developed [79, 116, 129]. Note that it is unnecessary to split the reversible reactions into forward and reverse steps, although this is sometimes done. Relations (15) and (22) constitute a linear equation/inequality system where, as in the example above, the solutions $\mathbf{v}$ of this system are indeterminate with respect to scaling. Thus, it is sensible to consider relative flux distributions, called flux modes.

A *flux mode*, $\boldsymbol{M}$, is defined as the set:

$$\boldsymbol{M} = \{\mathbf{v} \in R^r | \mathbf{v} = \lambda \mathbf{v}^*, \lambda > 0\} \,, \tag{23}$$

where r and λ are the number of reactions and an arbitrary real positive number, respectively, R^r denotes the r-dimensional Euclidean space, and $\mathbf{v}^*$ stands for a vector (different from the null vector) fulfilling the following two conditions:

(C1) Steady-state condition: $\mathbf{v}^*$ fulfills Eq. (15).

(C2) Sign restriction for irreversible reactions: if the system involves irreversible reactions, then the corresponding subvector $\mathbf{v}^{\text{irr}}$ of $\mathbf{v}^*$ satisfies inequality (22).

According to this definition, a flux mode can be characterized by one representative vector. A transformation route in metabolism can be formalized as a simple flux vector satisfying Eq. (15) and inequality (22) because along such a route, all intermediates must be balanced with respect to production and consumption and the irreversible enzymes must operate in the appropriate direction. The rationale for looking for a *simple* flux distribution rather than an arbitrary distribution fulfilling relations (15) and (22) arises from the general scientific paradigm of decomposing a system under study into its simplest components. Examples of this paradigm are Fourier analysis or the decomposition of gene expression patterns into principal components [1]. Decomposition under the side constraint of non-negativity plays a role also in pattern recognition, where the method of non-negative matrix factorization is used [73]. Dealing with simple routes (i.e. enzyme sets involving only a few enzymes) is particularly interesting in functional genomics, because the set of identified metabolic genes is often incomplete, so that it is meaningful to test whether at least one functional route can be realized by this set [20].

The crux of a proper pathway definition is to define what we mean by simplicity of the flux vector. An appropriate definition is the following: a flux mode, $\mathbf{v}^*$, is called elementary if there is no other flux distribution involving only a subset of the enzymes involved in $\mathbf{v}^*$. More exactly, this can be written in the following way [121]: a flux mode $\boldsymbol{M}$ with a representative $\mathbf{v}^*$ is called an *elementary flux mode* if, and only if, $\mathbf{v}^*$ fulfils the condition:

(C3) Simplicity (nondecomposability). There is no vector $\mathbf{v}'$ (different from the null vector) with the following properties: (i) $\mathbf{v}'$ obeys restrictions (C1) and (C2), and (ii) $\mathbf{v}'$ contains zero components wherever $\mathbf{v}^*$ does and includes at least one additional zero component.

Note that, upon testing whether a vector $\mathbf{v}^*$ is elementary, the test vector $\mathbf{v}'$ need not have the same values of the nonzero components as $\mathbf{v}^*$. Elementary modes can be visualized as follows. It can be shown that if all reactions are irreversible, each elementary mode corresponds to one edge of the cone (see Figure 5) determined by relations (15) and (22) and *vice versa* [116]. If some reactions in the system are reversible, there may be additional elementary modes in the interior of the cone [97].

In the case where all reactions are irreversible, the elementary modes can be computed by enumerating the edges of the cone. This enumeration can be performed by tableau methods starting from the stoichiometry matrix augmented with the identity matrix [88] or from the nullspace matrix [149]. These algorithms have been adapted to the case where some elementary modes lie inside the cone [120, 121, 144]. The extended algorithms have been implemented in METATOOL (http://pinguin.biologie.uni-jena.de/bioinformatik/networks) [97, 146] and several of the simulation packages mentioned in Section 4.1.

Whereas the choice of nullspace vectors to form a basis, as previously described in Section 2, was not unique, the elementary modes are uniquely determined (up to multiplication by a non-negative factor). Moreover, each flux mode possible in the living cell can be written alternatively as a linear combination of basis vectors or of elementary flux modes. If the combination in terms of elementary modes is used, all coefficients, α_k, must be non-negative [121]:

$$\mathbf{v} = \sum_k \alpha_k \mathbf{e}^{(k)} \,, \quad \alpha_k \geq 0 \,, \tag{24}$$

where $\mathbf{e}^{(k)}$ denotes vectors representing elementary modes. This non-negativity condition needs to be included because the sign restriction for irreversible reactions must be satisfied. Importantly, enzyme deficiencies and gene knockouts can properly be described by elementary-mode analysis, but not with the nullspace approach. Upon deletion of an enzyme, all elementary modes not involving this enzyme remain unchanged, while the basis vectors of the nullspace need to be recalculated in some cases. Consider, for example, the system depicted in Figure 4. Deletion of enzyme 2 in that system would imply that both nullspace vectors given in Eq. (20) drop out, although the remaining system still has a 1-D nullspace [represented by the vector $(1\ 0\ -1\ 1)^{\mathrm{T}}$, which may be relevant if reaction 3 is reversible].

One inconvenience of the larger number of elementary modes than nullspace vectors is that there may be multiple solutions for the values of the α_k in equation (24) that relate the elementary modes to an observed flux vector [152]. However, a least-squares solution (which minimizes the norm of the α vector) is uniquely defined and has advantages as a practical solution that facilitates the interpretation of changes in the utilization of different elementary modes by an organism as environmental conditions change [102].

3.5 Examples of Elementary-modes Analysis

The elementary modes of a list of reactions of carbohydrate metabolism include familiar metabolic pathways such as glycolysis, and various functionalities of the oxidative and nonoxidative pentose phosphate pathways (Figure 1), as well as other pathways catabolizing glucose that are not generally named [120]. It is worth noting that, although the term "pentose phosphate pathway" is firmly established in biochemistry, there is not just one pathway deserving this name. Rather, it occurs in several functionalities [138], as confirmed by elementary-modes analysis [120]. This demonstrates that elementary modes have every right to be regarded as biochemical pathways. In this section, we will show the "added value" of elementary modes in avoiding incorrect interpretations and in deducing novel interpretations of metabolism.

Several authors have used graph-theoretical concepts to define metabolic pathways [60,76,128]. However, paths traced on graphs may not be competent metabolic pathways. An illustration of this point recapitulates a controversy from the history of biochemistry. Figure 6 shows the pathways of the tricarboxylic acid (TCA) cycle and gluconeogenesis to glucose. It has long been considered that, given an input of acetyl-CoA from the breakdown of fatty acids or ketogenic amino acids, it is not possible for animals to achieve net synthesis of glucose from this precursor. However, it is evidently possible to trace a route from acetyl-CoA, around the TCA cycle to oxaloacetate, from oxaloacetate to phosphoenol pyruvate (PEP) and from there to glucose (Figure 6A). Indeed, with the introduction of ^{14}C isotopic labeling in the 1950s, it was established that isotope could pass along this apparent pathway. Nevertheless, animals cannot make glucose from two-carbon precursors in a sustained steady state. All organisms that can (e.g. green plants and many bacteria) contain the glyoxylate cycle, yielding the metabolic network illustrated in Figure 6(B). The potential flows of carbon in this network can be investigated by regarding all cosubstrates (ATP, NAD, etc.) as external and computing the elementary modes (e.g. by METATOOL). This results in two modes that completely oxidize acetyl-CoA to CO_2 and the only mode that generates glucose from acetyl-CoA does so via the glyoxylate cycle enzymes. The reason is that the TCA cycle alone cannot cause a net synthesis of oxaloacetate; for every acetyl-CoA that enters the cycle, two carbons are lost as CO_2, so none is available to form glucose.

This example illustrates that if only the connectedness of the graph is considered and the stoichiometric constraints are neglected, then it is likely that nonfunctional pathways will be postulated. Moreover, this is not an isolated case: significant problems about our understanding of plant plastid metabolism have been revealed by elementary-modes analysis [100, 101].

Figure 6(C) indicates how elementary modes can identify previously unrecognized pathways. The elementary modes computed for the network include two different modes for complete oxidation of glucose to CO_2. One of the modes corresponds to oxidation via the TCA cycle as normally described in textbooks. The alternative pathway uses the glyoxylate cycle in catabolic mode; the oxaloacetate produced by the glyoxylate cycle is converted to PEP, with loss of one CO_2, and then to pyruvate before decarboxylation to acetyl-CoA with loss of a second CO_2. The oxaloacetate produced by malate dehydrogenase is used in equal proportions by the enzymes leading to citrate and PEP. The ATP yield of this pathway per mole of glucose is smaller than that of the usual TCA cycle (1 instead of 2). We originally noted this pathway [119], which is part of a larger pathway predicted for *Escherichia coli* earlier [74]. This theoretical prediction has been confirmed experimentally, as the occurrence of this pathway in *E. coli* growing slowly at low glucose concentrations has recently been shown by Fischer and Sauer [34] (preliminary observations have been presented in Ref. [153]). Since the enzymes involved in the pathway are present in many microorganisms, it can be supposed that it operates also in other microbes.

An example of how elementary-modes analysis can shed new light on plant metabolism is provided by a special form of photosynthesis. Crassulacean acid metabolism (CAM) is a variant of photosynthesis employed by a range of plants (e.g. cacti) as an adaptation to arid conditions [22, 141]. In order to reduce water loss, the stomata are closed during the daylight hours, so CO_2 cannot be obtained directly from the atmosphere. Instead, the plants fix CO_2 during the night by breaking down stored carbohydrate to give PEP, which is then carboxylated to oxaloacetate and reduced to malate, which is stored in the vacuoles. In the daytime, malate is released from the vacuoles and decarboxylated in the cytoplasm; the CO_2 released then diffuses into the chloroplast where it is fixed by ribulose bisphosphate carboxylase (rubisco) and the rest of the Calvin cycle. CAM plants vary with respect to the enzyme

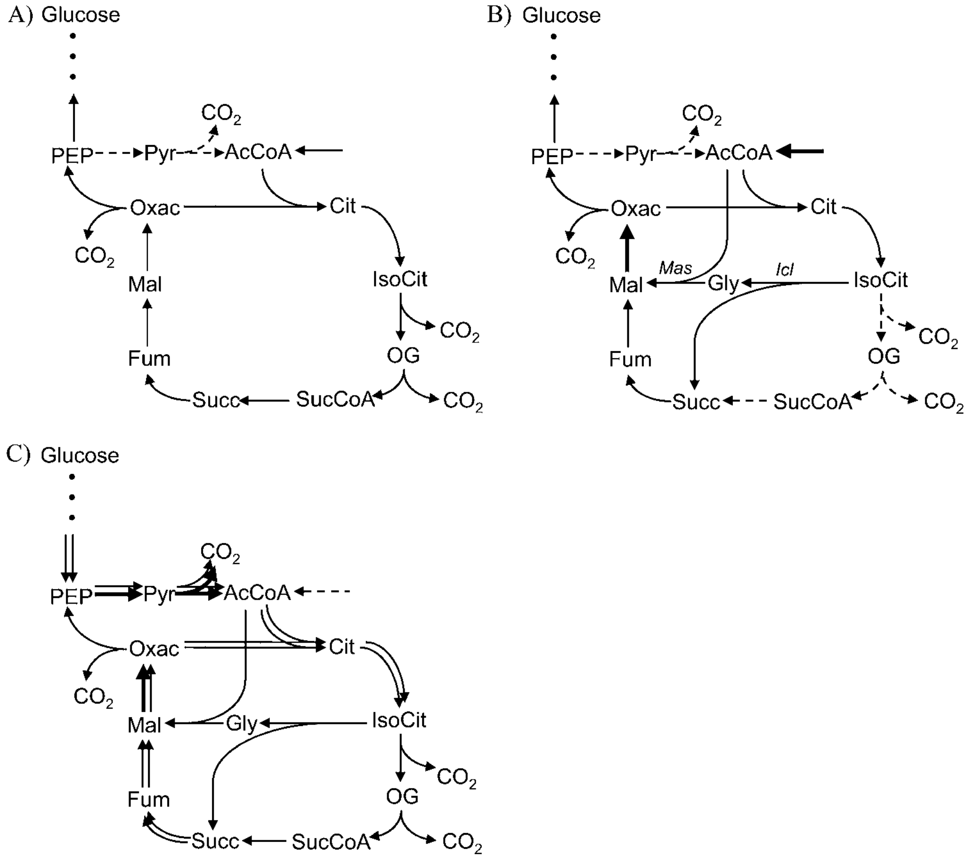

Figure 6 Scheme of the TCA cycle and gluconeogenesis. Thick arrows represent fluxes that are double as high as through the other reactions. Dashed arrows represent unused enzymes. Abbreviations of metabolites: AcCoA, acetyl-coenzyme A; Cit, citrate; Fum, fumarate; Gly, glyoxylate; IsoCit, isocitrate; OG, oxoglutarate; Oxac, oxaloacetate; PEP, phosphoenolpyruvate; Mal, malate; Pyr, pyruvate; Succ, succinate; SucCoA, succinyl coenzyme A. (A) Situation in mammals. A pathway from acetyl-CoA to glucose seems to exist (solid arrows). However, Oxac is not stoichiometrically balanced at steady state. (B) Situation in plants and many bacteria, where the TCA cycle involves the glyoxylate shunt, consisting of isocitrate lyase (*Icl*) and malate synthase (*Mas*). This allows conversion of acetyl-CoA into glucose at steady state (pathway in blue). (C) Classical TCA cycle (red); pathway of glucose catabolism alternative to the classical TCA cycle (green).

used to break down the malate, which is either PEP carboxykinase (PEPCK) or malic enzyme [23]. They also vary in whether the primary product of photosynthesis is chloroplastic starch or cytosolic hexoses. On this basis, Christopher and Holtum [16] proposed there were potentially four distinct groups of CAM plants described by these two criteria, and they classified a range of plants to show that each of the four categories had members.

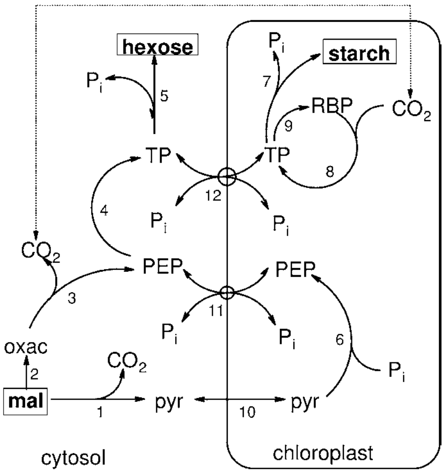

Figure 7 Reaction scheme of CO_2 fixation in CAM plants. Reactions: 1, malic enzyme; 2, malate dehydrogenase; 3, PEPCK; 4, enolase and phosphoglyceromutase; 5, gluconeogenesis; 6, pyruvate, phosphate dikinase; 7, starch synthesis; 8, rubisco; 9, Calvin cycle; 10, pyruvate translocater; 11, PEP translocator; 12, phosphate/triose phosphate translocator.

This is an interesting problem to examine with elementary modes, since we already knew that the metabolic exchanges between chloroplast and cytosol allowed (or not) by the chloroplast membrane metabolite transporters were a significant constraint on feasible plant metabolism [100]. A scheme of the metabolism under study is shown in Figure 7 and the stoichiometries of the reactions are given in Table 1. The model has been drawn up to represent carbon and phosphate balancing in the reactions, but redox balance is not represented. Figure 8 shows the six elementary modes of this scheme that convert malate to hexose and/or starch. There are three modes each using malic enzyme and PEPCK, respectively, to release CO_2 from malate. For each of the modes leading to one product only, Christopher and Holtum [16] gave examples (Figure 8). For example, in pineapple (*Ananus comosus*), sugar is produced via PEPCK. The reason that, in addition to the modes producing hexose only and starch only, there is a third mode coproducing hexose and starch is that the latter involves no net flux through the triose phosphate translocator and is, hence, no superposition of the former two. In the coproduction modes, the carbon in the hexose comes from the triose, whereas the starch comes from the CO_2 derived from malate breakdown; the hexose to starch stoichiometry is 3:1.

The question then arises whether coproduction of starch and hexose defines a subset of CAM plants. In fact, Christopher and Holtum [16] noted that the PEPCK-containing plant *Aloe vera* produced both hexoses and starch during the day, in the ratio of about 2:1 from their figures, although they

Table 1 Reactions of the CAM plant metabolism model

No.	Step	Reaction
1	ME	mal + NAD → pyr_cyt + NADH + CO_2
2	MDH	mal + NAD → oxac + NADH
3	PEPCK	oxac + ATP_cyt → PEP_cyt + ADP_cyt + CO_2
4	glc1	PEP_cyt ↔ tp_cyt
5	glc2	2tp_cyt → hex_cyt + 2Pi_cyt
6	PPDK	pyr_chl + P_i_chl + ATP_chl → PEP_chl + PPi + AMP_chl
7	StSyn	2tp_chl → starch + 2P_i_chl
8	RbCo	RBP + CO_2 → 2tp_chl
9	CC	5tp_chl + P_i_chl → 3RBP
10	PyrTr	pyr_cyt ↔ pyr_chl
11	PEPT	P_i_cyt + PEP_chl ↔ P_i_chl + PEP_cyt
12	TPT	tp_cyt + P_i_chl ↔ tp_chl + P_i_cyt
13	OP	ADP_cyt + P_i_cyt → ATP_cyt
14	AK	AMP_chl + ATP_chl ↔ 2ADP_chl
15	LR	ADP_chl + P_i_chl → ATP_chl
16	PPase	PP_i → 2P_i_chl

The full names for steps 1–12 are given in the legend to Figure 7. Malic enzyme is shown as the NAD version, but since nicotinamide nucleotides (NADP, etc.) are treated as external in the model (and are not shown in the grouped reactions), the NADP-linked enzyme is implied as well. The reactions 13–16 not shown in Figure 7 are added to represent recycling of adenine nucleotides and pyrophosphate in the appropriate compartments: OP, oxidative phosphorylation; AK, chloroplast adenylate kinase; LR, light reactions, i.e. photophosphorylation; PPase chloroplast pyrophosphatase. Irreversible reactions are designated by "→" and reversible ones by "↔". Except for CO_2, metabolites occurring both in cytosol and chloroplast are represented twice with designations "cyt" and "chl", respectively, and are treated as separate entities for modeling purposes. Other abbreviations are: mal, malate; pyr, pyruvate; oxac, oxaloacetate; tp, triose phosphate; RBP, ribulose 1, 5-bisphosphate; hex, hexose sugars; PP_i, pyrophosphate.

classed it as a hexose producer. This leaves hexose and starch-producing malic enzyme plants as the category to be filled. Christopher and Holtum characterized CAM-induced *Mesembryanthemum crystallinum* as a starch-producing malic enzyme plant. However, it seems that it can produce both hexose and starch [6]. Furthermore, even when starch is a major product, study of diurnal variation in the transporter transcripts and activities [49] shows that the triosephosphate transporter activity does not increase in the day, whereas the glucose-6-phosphate transporter does, suggesting that cytosolic hexose rather than triose phosphate is used as a substrate for starch synthesis. This is more like the pattern in Figure 8(C) than Figure 8(B). A better example of a malic enzyme plant producing both starch and hexose, however, is *Clusia minor* [7]. The experiments reported a ratio of formation of hexose to glucans and starch of 2:1; although this is lower than the hexose to starch ratio of the elementary mode, the glucan component is likely to be cytosolic. In all, there is an arguable case that there are six modes of operation of CAM, as revealed by elementary modes, with plants that predominantly use each of

them. Whereas, in general, metabolic flux distributions are a superposition of several elementary modes, the considered part of the metabolism in CAM plants is a case where virtually "pure" elementary modes occur. Another such case is glycolysis in mature yeast cells.

3.6 Extreme Pathways

In many applications, e.g. in the analysis of robustness [91, 103] (see Section 3.8), the concept of extreme pathways [108] is used. This differs only slightly from that of elementary modes. One of the goals is a reduction in the number of pathways to cope with the problem of combinatorial explosion of the number of pathways in large networks. As mentioned above, the admissible flux region determined by relations (15) and (22) is a convex cone (Figure 5), and there may be some elementary modes lying in the interior of the cone. It has been argued that for a minimal description of the system, the edges of the cone (sometimes called the *convex basis*) are sufficient; each admissible flux distribution can be written as a non-negative linear combination of the convex basis vectors [89, 97]. However, the elementary modes in the interior of the cone often represent biochemically meaningful pathways, such that it is not really justified to drop them.

Schilling and coworkers [108] have tackled this issue in the following way. They make a distinction between exchange reactions and internal reactions. The former connect to external metabolites, while the latter do not. Then, all reversible internal reactions are decomposed into forward and reverse steps. The convex basis vectors of the resulting flux cone are defined to be the set of extreme pathways. They have the advantage of a one-to-one correspondence to the edges of the flux cone. Note, however, that the respective flux cone is of higher dimension than the original one because the decomposition of reversible internal reactions adds dimensions to the flux space. In effect, many of the internal elementary modes are brought to the surface of the flux cone.

As shown in Ref. [67], elementary modes and extreme pathways are equivalent if all exchange reactions are irreversible. This is the case in several simulations [91, 103]. If there are reversible exchange reactions, the number of extreme pathways may be considerably smaller than the number of elementary modes [92], which is favorable in view of the problem of combinatorial explosion. However, care must be taken that no external metabolite takes part in more than one reversible exchange reaction. Otherwise, there would be a reversible extreme pathway, because that metabolite can be produced by one reaction and consumed by the other, and the opposite process is possible as well. This would be in contradiction to the desired property that extreme pathways are edges of a pointed cone. Therefore, for this case, Schilling and coworkers [108] suggested making the external metabolites connecting to these exchange reactions internal and extending the system by adding formal exchange fluxes connecting to these metabolites. They called this, together with the decomposition of reversible internal reactions, the reconfiguration of the system. This, however, generates an extended system in which extreme pathways and elementary modes are again equivalent [115]. For a comparison of the two concepts, see also Refs. [67, 92].

3.7 Optimization of Molar Yields and Flux Balance Analysis (FBA)

In biotechnology, one is often interested in increasing the molar yield of a given biotransformation, i.e. the molar ratio indicating how many molecules of product are formed per mole of substrate. Some product of interest may be synthesized on several routes with different yields, as in lysine synthesis [21] or tryptophan synthesis [119]. Thus, one may try to overexpress the enzymes along the route allowing maximum yield and possibly suppress other enzymes. A flux mode using only the optimal route is certainly not feasible alone since other products (e.g. other amino acids) must also be synthesized. Nevertheless, it is of interest to calculate upper bounds on the molar yield, to learn what can at best be expected, especially as many products of interest are formed in the stationary phase where there is little biosynthetic activity, and the cell's remaining requirements are largely for "maintenance energy".

The molar yield of a biochemical transformation can be expressed as:

$$\eta = \frac{\text{rate of product synthesis}}{\text{rate of substrate consumption}} . \tag{25}$$

Let S and P stand for the substrate and product of interest, respectively. [Note that we here allow for a larger number of reactions between S and P than in Eq. (9).] We denote their stoichiometric coefficients by m_{Sk} and m_{Pk}, respectively, with k being the reaction index. Then the optimization criterion can be written as:

$$\text{maximize } \eta = -\frac{\sum_k m_{Pk} v_k}{\sum_k m_{Sk} v_k} , \tag{26}$$

where the minus sign enters because the coefficients m_{Sk} are negative. Note that the objective function is nonlinear, with the variables being the fluxes v_k. As Eq. (26) is invariant to a scaling of the v_k by a common factor, and the side constraints (15) and (22) are linear and homogeneous, the solution to the maximization problem is indeterminate with respect to scaling. Thus, usually the substrate consumption rate is written in a normalized form:

$$-\sum_k m_{Sk} v_k = 1 \, . \tag{27}$$

Substituting this into Eq. (26) yields a linear objective function. Sometimes, Eq. (27) is phrased as an inequality imposing an upper bound on the input flux. Yet, in most cases, maximization of the numerator in Eq. (26) implies that the upper bound is attained by the system, such that an inequality side constraint is equivalent to Eq. (27).

Since any flux mode is a superposition of elementary modes with nonnegative coefficients (see Eq. 24), the molar yield of a flux distribution is a weighted average of the yields of the elementary modes involved:

$$\eta = \frac{\sum_k \alpha_k \eta_k}{\sum_k \alpha_k} \, , \tag{28}$$

where the α_k are the weighting coefficients as appearing in Eq. (24). Therefore, η cannot exceed the maximum value of all η_k. Consequently, the optimal flux distribution with respect to maximizing the molar yield always coincides with an elementary mode. When two or more elementary modes realize the same, maximum yield, any linear combination of these implies that maximum yield.

Elementary-modes analysis was successfully applied in Ref. [74] for predicting maximum yields in the synthesis of precursors for aromatic amino acids in *E. coli*. Carlson and coworkers [13] studied a metabolic pathway model of a *Saccharomyces cerevisiae* strain that had been engineered genetically to produce poly-β-hydroxybutyrate (PHB). Adding the natively absent ATP citrate-lyase to the network, the maximum theoretical PHB-to-carbon yield was increased from 0.67 to 0.83. Recently, Schwender and coworkers [123] conducted a combined experimental and theoretical study (using elementary modes) on oilseed rape, and found a previously undescribed metabolic route with high carbon efficiency.

As the objective function of maximizing molar yields and the side constraints [relations (15) and (22)] are linear, the maximization problem can alternatively be solved by linear programming [26, 27, 33, 93, 145, 150]. That method finds the pathway with the highest yield. In the event that there are multiple solutions giving the same yield, care has to be taken that all of them are detected [78] since linear programming returns a single solution by default. In contrast, elementary-modes analysis provides a set of candidate solutions, from which the best for a given substrate–product pair, and consecutively for different substrate–product pairs, can be selected easily. This allows for detecting not only (possibly multiple) optimal solutions, but also suboptimal, equally simple situations. These might be realized more readily (at least approximately) in biotechnological setups than the optimal situation. Accordingly, this analysis gives more output information than linear programming.

One method in the framework of stoichiometric network analysis is *FBA*. While *metabolic pathway analysis* is about computing the simplest flux distributions (elementary modes or extreme pathways), which need not necessarily occur in living cells in pure form, FBA is about computing optimal flux distributions, with a stronger focus on predicting real situations in living cells. The main idea is that the molar yield of some important product has been maximized during evolution. This is a principle of economy – cells that use the resource as efficiently as possible are assumed to have a selective advantage. This approach can be traced back to the linear programming approaches mentioned above [33, 93, 150]. Later, the method was refined, extended and applied to various systems of increasing complexity, and the term FBA was coined [24–27, 57, 145]. In most cases, biomass has been taken as the product of interest. The method is attractive because it allows the computation of flux distributions in living cells based on very little data: the reaction stoichiometries, information about irreversibility and the weighting coefficients m_{Pk} in the objective function (Eq. 26). However, the question arises whether maximization of output yield is really an outcome of evolution for all cells under all circumstances. If this were so, why does baker's yeast (*S. cerevisiae*) use the respiro-fermentation pathway (leading mainly to ethanol and implying an ATP per glucose yield of slightly more than 2) even under aerobic conditions if sufficient glucose is available? In order to maximize the ATP per glucose ratio it should use pure respiration, which allows a yield of more than 30. An answer was given from the viewpoint of evolution [98]. Fermentation allows a very high ATP production rate, although yield is low. Due to the high rate, yeast can grow fast and outcompete other species, withdrawing their nutrients. However, other yeast genera such as *Kluyveromyces* do use respiration [44]. It is hard to explain this diversity in sugar degradation among yeast species by a single optimization principle.

Maximization of yield and maximization of rate are not necessarily equivalent principles [2, 98, 147]. For instance, the bacterium *Holophaga foetida* growing on methoxylated aromatic compounds switches from a high-rate regime to a high-yield regime when the substrate level becomes very low [64]. The pathway active in hungry *E. coli* mentioned in Section 3.5, however, has a lower ATP yield than the usual TCA cycle. Other examples are provided by dimorphic fungi, i.e. fungi that switch between unicellular and multicellular stages. *Mucor racemosus*, for example, mainly relies on fermentation in the unicellular stage and on respiration in the multicellular stage [58]. Interestingly, it is the other way round in *Candida albicans* [71]. In any case, the main hypothesis underlying FBA cannot apply to both forms of dimorphic fungi. Recent experimental data on *Bacillus subtilis* [35], and theoretical and computational results [54] cast doubt on the principle of maximizing yield as well. Thus, it may be questioned whether maximization of (biomass, ATP or any other) yield is an over-riding goal in biology. Nevertheless, FBA is a helpful tool in many situations, such as adaptive evolution of *E. coli* after a change in substrate [57] or after a knockout [36].

3.8 Analyzing the Robustness of Metabolism

A striking feature of living cells is their homoeostasis, i.e. they are robust to external and internal perturbations within some range. For example, many knockout mutants of microorganisms are able to grow, some showing almost the same growth rate as the wild-type. This has been demonstrated by a systematic study on single-knockout mutants of virtually all genes in *S. cerevisiae* [42, 155]. Although an analogous systematic study on double mutants is not yet feasible due to the large number of combinations, first attempts in this direction have been made [130, 143]. As mentioned in Section 3.7, many cells harbor parallel and, thus, redundant metabolic pathways. For example, the pentose phosphate pathway circumvents the upper part of glycolysis (Figure 1). However, this bypass implies a loss in ATP production. Often, redundancy in metabolism cannot be seen as easily as in this example. Theoretical tools are needed [66, 83, 135, 154] to understand robustness in complex systems such as metabolic networks.

Elementary-modes analysis (see Section 3.4) is well suited for analyzing the structural robustness of metabolic networks because each elementary mode is nonredundant, with redundancy meaning that an enzyme could be deleted without interrupting the transformation of a substrate into a product. Therefore, redundancy can be quantified by the number of such modes [135]. The concept of extreme pathways has also been used for analyzing redundancy [91, 103]. Simulations for amino acid metabolism of *Haemophilus influenzae* showed that there was an average of about 40 extreme pathways corresponding to the same input/output regime (the exact number depending on conditions), when its metabolic network was used to produce a single amino acid [91]. Similar calculations for *Helicobacter pylori* gave the result that the synthesis of amino acids and ribonucleotides in this bacterium is less redundant than in *H. influenzae*, with only about two extreme pathways per input/output regime [103]. In these studies, the number of extreme pathways with the same overall stoichiometry (in terms of initial substrates and final products) is used as a measure of redundancy.

A somewhat different approach was suggested in Ref. [12]. The importance of each enzyme was assessed by the number of elementary modes in which it is involved, i.e. by the number of modes disrupted when the enzyme in question is deficient. Along these lines, it has been argued that robustness is not perfectly identical to redundancy [154]. In defining structural robustness, the intact system should be compared with a mutated system. To characterize the structural robustness against the knockout (deficiency) of one enzyme, E_i, the ratio between the number of elementary modes remaining after knockout, $z^{(i)}$, and the number in the wild-type network, z, can be used. This gives a normalized value between zero and unity. The extreme values are reached when no elementary mode is left and when all elementary modes remain. To quantify the global robustness of the network, the arithmetic mean of all these numbers can be taken:

$$R_1 = \frac{\sum_{i=1}^{r} z^{(i)}}{r \cdot z} \, . \tag{29}$$

Apart from this general measure of robustness, we defined measures for the robustness of the synthesis of specific products [154]. For a model of the metabolism of human erythrocytes proposed in Ref. [151], the quantity R_1 was computed to be 0.3834, while for various subsystems of the amino acid metabolism in *E. coli* (e.g. Ref. [135]) this measure was computed to be in the range 0.5112–0.5479. This is in agreement with the well-known fact that erythrocyte metabolism is very susceptible to enzyme deficiencies while the metabolism of *E. coli* is rather robust.

4 Dynamic Simulation

4.1 How is a Dynamic Model Constructed?

Before constructing a dynamic model, one should decide what type of model is needed. There is a basic distinction between deterministic and stochastic models. The latter is needed if the molecule numbers are so low that fluctuations play an essential role. Indeed the concentrations of many intermediates are rather low, often much lower than the resolution of nuclear magnetic resonance measurements, which is of the order of 10 μM *in vitro* and 100 μM *in vivo*. For example, in the analysis of calcium oscillations, stochastic simulation is sometimes used due to the low cytosolic concentration of calcium [28]. Another distinction is made between spatially homogeneous and heterogeneous models. Spatial gradients inside living cells may play a role due to the highly organized structure of cell organelles, the cytoskeleton and multienzyme complexes. Still another distinction can be made between models that are discrete or continuous in concentrations (with most stochastic models being discrete).

Most metabolic models, however, are deterministic, spatially homogeneous and continuous [5, 14, 15, 39, 51, 59, 61, 70, 84, 124, 156]. This is because, in that way, they are much simpler and because the numerical computational techniques are better developed, so simulation using them is more rapid and accurate.

The basis for deterministic, spatially homogeneous and continuous models is Eq. (4) together with the rate laws $\mathbf{v} = \mathbf{v}(\mathbf{S})$. This gives a system of n ordinary differential equations in the variables S_i. The differential equations are generally nonlinear because some, if not most or all of, the rate laws are nonlinear in concentrations. Therefore, solving the system equation (4) in time is not normally feasible by analytical methods, so that numerical methods are employed.

Many general purpose computer mathematics packages will solve sets of nonlinear differential equations given that the user has prepared a set of equations in the required format [corresponding to the system equation (4)]. However, this is a tedious and error-prone task that needs to be repeated whenever the model is altered, since changing a rate function means finding all its occurrences in the differential equations (one for each substrate and product involved in the reaction concerned) and changing them. Therefore many authors have devised computer software that generates and solves the appropriate differential equations from a set of reaction definitions and rate equations, using either a set of predefined rate equations or others defined by the user or both. Such software also usually checks for linear dependencies and conservation equations (as explained in Section 3.1) and reduces the set of equations to be solved appropriately. Two different types of solution to the differential equations can be computed: integration of the equations to produce time courses of metabolite concentrations and fluxes, and solution of the equations for the substrate concentrations (and hence fluxes) giving a steady state [when all derivatives in system equation (4) equal zero]. Techniques for the former are much more dependable than those for the latter, which usually work by successive approximation from an initial estimate of the solution and are prone to failure if the initial estimates are not good enough. One way of generating appropriate initial estimates to improve the success rate is to simulate a time course as far as a close approach to a steady state and then to pass the substrate concentrations to the steady-state solver. It is unreliable to compute a time-course to an apparent steady state alone, since even when the differential equations are all near-zero, it is impossible to tell how far away the steady state is if there are slow processes in the system being studied.

In developing special software packages for both simulation and steady-state solution of metabolic systems, two different approaches have been adopted (e.g. Ref. [94]). GEPASI (http://www.gepasi.org) [80, 81] and DB-Solve [46] are examples of packages that are operated through a graphical user interface. The other approach is the command-line driven program, originally operating on pre-written scripts, but more recently working interactively. Examples include SCAMP [105], Jarnac [106], ScrumPy [100,102] and PySCeS [90] (see Table 2). The distinction is breaking down as more of the packages can inter-operate through the Systems Biology Workbench (SBW; http://sbw.kgi.edu) [106] and by model exchange through a common model definition language, Systems Biology Markup Language (SBML) [56]. They not only serve for numerical integration of differential equation systems, but also for computing steady states and checking their stability, and computing elementary modes, control coefficients (e.g. Refs. [32, 51, 70]) and other quantities. Table 2 gives an overview of widely used software packages for simulating metabolic networks. Many more packages have been developed, such as PLAS (http://www.dqb.fc.ul.pt/docentes/aferreira/plas), DBSolve [46] and the JJJ web simulator (http://jjj.biochem.sun.ac.za).

Table 2 Software for simulating metabolic networks

Software package	Analyses performed	Reference	URL

CSS, calculation of steady states; DS, dynamic simulation; LSA, local stability analysis; MCA, metabolic control analysis; MFA, metabolic flux analysis; MPA, metabolic pathway analysis; PE, parameter estimation.

When choosing the appropriate method for numerical integration, one should keep in mind that most biological systems show the phenomenon of timescale separation (time hierarchy). They involve slow and fast processes. Metabolic systems, for instance, are characterized by the presence of slow and fast enzymes. Isomerases, for example, are usually present in high concentrations so that they catalyze the corresponding reactions very fast. Time hierarchy makes biological systems simpler with respect to their dynamics. Nonlinear systems with more than two dimensions can potentially exhibit behaviors more complex than steady states or regular oscillations. For example, they may allow deterministic chaotic behavior, in which the system never returns to the initial state exactly and in which small deviations in the initial conditions lead to large deviations later [137]. However, most biological systems at the cellular level do not exhibit chaos. This is probably due to a reduction in the effective dimension by time hierarchy [50]. In mathematical terms, the differential equations describing systems showing time hierarchy are called *stiff*. Special numerical integration routines have been developed for dealing with stiff systems, such as the Gear procedure [41], but the development that brought metabolic modeling easily within the scope of the desktop computer was the routine LSODA [95], which was incorporated into GEPASI, SCAMP and ScrumPy amongst others. This is an adaptive routine that only switches into the more computationally demanding Gear-like algorithm when the solution is judged to be stiff. More recently, a successor to LSODA, CVODE [18], is being exploited in, for example, Jarnac.

The time hierarchy in biochemical systems can be usefully exploited in modeling. Any modeling is done for a certain timescale of interest. All processes slower than this timescale can be considered to be constant. As for the processes faster than this timescale, a simplifying method can be applied that is based on the reasoning that these processes have relaxed to a quasi-steady state after a very short transient time. There are two main types of simplification: the quasi-steady-state and quasi-equilibrium approximations (e.g. Refs. [19, 51, 70]). These two types are sometimes confused in the literature. In the former method, the assumption is made that some metabolite concentrations reach a quasi-steady state while others do not. That is, only some component equations within the equation system (4) are set equal to zero, in the sense of Eq. (15):

$$\sum_{i \in I} n_{ij} v_j(\mathbf{S}_{\text{slow}}, \mathbf{S}_{\text{fast}}) = 0\,, \tag{30}$$

where I is the set of fast variables, and $\mathbf{S}_{\text{slow}}$ and $\mathbf{S}_{\text{fast}}$ are the subvectors of the concentration vector that involve the slow and fast variables, respectively. This has to be interpreted correctly. It does not mean that the quasi-steady state variables are constant in time; they do change slowly, following the slow

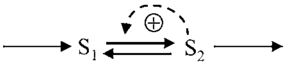

Figure 9 Simple reaction system with two internal metabolites and a positive feedback of S_2 on reaction 2. Reactions 1 and 3 are irreversible, while reaction 2 is reversible. The dashed arrow represents the activating regulatory interaction.

variables. They are linked with the slow variables by Eq. (30). Therefore the word "quasi" is used.

Equation (4) with part of it fulfilling Eq. (30) is called an algebro-differential equation system. There are various options for solving such equations systems numerically. If Eq. (30) can be transformed analytically so that $\mathbf{S}_{\text{fast}}$ can be written as a function of $\mathbf{S}_{\text{slow}}$, then this can be inserted into Eq. (4), so that this can be written as a differential equation system for $\mathbf{S}_{\text{slow}}$ and be integrated by any solver. Another option is to integrate the equations for the slow variables using the current values of the fast variables, then recompute the fast variables by solving Eq. (30). This needs to be either implemented individually or a hybrid algebraic-differential equation solver (such as DASSL by L. R. Petzold, e.g. Ref. [10]) can be used. A simulation package for cellular systems that is able to cope with algebro-differential equation systems is ProMoT/Diva [43].

The quasi-equilibrium approximation, in contrast, starts from the assumption that the fast enzyme reactions reach, after a short transient, a near-equilibrium state. That is, the mass-action ratio involving the concentrations of the metabolites participating in the fast reactions are approximately equal to the equilibrium constant:

$$\prod_{i=1}^{n} S_i^{n_{ij}} = q_j \,. \tag{31}$$

For numerical solution, similar methods as in the case of the quasi-steady-state approximation can be used.

Consider, for example, the simple reaction system in Figure 9, in which the second reaction is activated by its product. Such a positive feedback occurs in several biochemical reactions. For example, phosphofructokinase (see Figure 1) in yeast is activated by ADP [4], in many species also by AMP. (However, the mechanism underlying oscillations in glycolysis appears to be more complicated, see Section 4.4.) Let us assume that the reactions in the system in Figure 9 obey the rate laws:

$$v_1 = \text{const.} \tag{32a}$$

$$v_2 = (k_2 S_1 - k_2 S_2/q_2)\left(1 + \frac{S_2^2}{K_A}\right) \tag{32b}$$

$$v_3 = k_3 S_2 \,, \tag{32c}$$

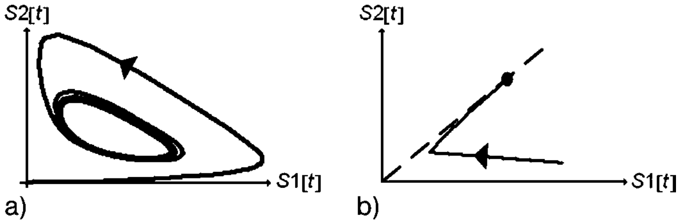

Figure 10 Dynamics of the reaction system shown in Figure 9 plotted in the phase plane of the two concentration variables. a) Case of oscillation; the trajectory tends to a stable limit cycle. b) Case of stable steady state (filled circle). Parameter values: $v_1 = 1$; $q_2 = 100$, $K_A = 0.1$; $k_3 = 1$ (A and B), $k_2 = 0.065$ (A), $k_2 = 100$ (B).

where k_2 and q_2 denote the rate constant and equilibrium constant, respectively, of reaction 2. K_A is called activation constant. The rate law for v_2 involves two factors. The first factor is an approximation of the reversible Michaelis–Menten rate law (7) (with $S = S_1$, $P = S_2$) for low concentrations. The second term describes the positive feedback. A term of the form (1 + concentration/parameter) is typical for enzyme kinetic rate laws describing activation (then this term is in the numerator) or inhibition (then it is in the denominator). Note that, when the concentration of the activator or inhibitor is zero, the original, unaffected rate law results. An oscillating system with a simpler version of the rate law for reaction 2, notably $v_2 = k_2 S_1 S_2^2$ has been proposed by Higgins [52] and Selkov [125] and is, therefore, nowadays called Higgins–Selkov oscillator. However, this rate law is less realistic then Eq. (32b) because it implies $v_2 = 0$ when $S_2 = 0$.

For a certain range of parameters, the system under study shows self-sustained oscillations (Figure 10A, see also Section 4.4). For other parameter values, the system runs to a stable steady state (Figure 10B). To show the usefulness of the quasi-equilibrium approximation, consider the case where the rate constant k_2 is large. The dynamics of relaxation to the steady state then shows two relatively distinct regions (Figure 10B). First, the curve (usually called the trajectory) representing the system dynamics in the space of variables goes from the initial conditions towards a straight line given by Eq. (31), which here reads:

$$\frac{S_2}{S_1} = q_2 \,. \tag{33}$$

In the second phase, the trajectory moves very close to this straight line. This can be explained as follows. When k_2 is large enough, i.e. when reaction 2 is fast enough, this reaction is, after a short transient, nearly at equilibrium even if it carries a nonzero flux. Accordingly, the concentration ratio approximately fulfils Eq. (33). When the quasi-equilibrium approximation is applied, it is often suitable to define combined ("pool") variables, such as $S_1 + S_2$ in our example [51]. Interestingly, they are the conservation quantities of the fast subsystem (see Section 3.1).

By the quasi-equilibrium and quasi-steady-state approximations, the dimension of the differential equation system is reduced. One might argue that with modern computers available, the size of equation systems is not an issue for numerical computation. However, these approximations also reduce the number of kinetic parameters. Since these parameters are often imperfectly known, this is a major advantage.

An intuitive way of implicitly using the quasi-steady-state or quasi-equilibrium approximations is the formulation of so-called skeleton models [50,126]. In writing down such models, one only considers the most essential variables, where the decision on what is essential is left to intuition or empirical knowledge. For example, Selkov [126] established a model of glycolysis with only two independent concentration variables (ATP and pool of trioses), while the skeleton model of [156] for the same system involves five variables.

4.2 Metabolic Databases

One of the major achievements of bioinformatics is the availability of large online databases. The fast access to genome-scale biological data of various types is of invaluable help in the modeling and simulation of processes in living cells, as stressed repeatedly in this book. As for the modeling of metabolic processes, especially enzyme and metabolic databases are used. Prominent examples are:

- ExPASy Enzyme (http://www.expasy.org/enzyme) [40]. This is a repository of various data on enzymes organized according to the EC (enzyme catalogue). Entries can be searched online, in a variety of ways, such as entering the EC number, official or alternative names, names of chemical compounds, or by browsing through the enzyme catalogue. The stored data comprise the reaction equation, protein sequence, alternative substrates, bibliographic links, etc., of the enzyme. Links to other databases and to biochemical pathway charts are included. The intention of the enzyme catalogue was to give a unique reference, and recommended name, to a distinct enzyme activity. Unfortunately, it does not use a controlled vocabulary for metabolite names, so that the name for the product of one reaction may not be the same as that used as the name for the substrate of the reaction that consumes it in the cell [55]. However, the data is curated, and there are mechanisms for submitting new entries and reporting errors.
- KEGG (http://www.genome.jp/kegg) [63]. Its full name being Kyoto Encyclopedia of Genes and Genomes, this database includes gene sequence information. It is, moreover, one of the most widely used metabolic databases

because it also includes a plethora of enzyme and metabolic pathway data. Interactive pathway charts allow the user to highlight all enzymes found so far in a specific species and click on specific enzymes to get information on these (such as reaction equations). KEGG also contains ample formation on diseases caused by enzyme deficiencies. Enzymes are distinguished by their EC number, where available, and metabolites participating in enzyme reactions. The reactions themselves are given supposedly unique identifiers and their own database entries. However, the metabolite identifiers have not avoided the problem of synonyms [55], and the incidence of other errors means that metabolic networks generated automatically from the databases are not fully connected and require manual correction. It is unclear whether there is an effective error-reporting procedure. Metabolic pathway information is also stored in the EMP database (http://www.empproject.com) [127].

- BRENDA (http://www.brenda.uni-koeln.de) [111]. This database can be compared to ExPASy Enzyme, but differs in one main aspect. It includes information on kinetic properties of enzymes, such as Michaelis–Menten constants, optima and intervals of pH and temperature, inhibitors, reaction mechanisms (e.g. ordered versus random mechanism), and subcellular localization. Therefore, it is particularly helpful as a basis for dynamic modeling.
- BioCyc (http://www.biocyc.org) [65]. This collection of databases has originated from an *E. coli* specific database, EcoCyc (which is still a part on its own within BioCyc) and is now devoted to many organisms. It involves both enzyme and pathway information, similar to KEGG, and its datamodel deals with the many-to-many relationships of genes, enzymes and reactions. Another part of that collection, MetaCyc, includes pathway information about more than 300 different organisms. EcoCyc is manually curated by experts in microbial metabolism; other organism specific data varies from being partially curated, to not significantly curated after automatic generation. There is a mechanism for reporting database errors.
- Reactome (http://www.reactome.org) [62] is a knowledgebase of core pathways and reactions in humans. In addition to curated entries about human biology, inferred orthologous events in 15 nonhuman species such as mouse, fly, yeast and *E. coli* are also available. In addition to metabolic pathways, signal transduction pathways such as those occurring in apoptosis, are included.

Several databases (e.g. KEGG and BioCyc) allow one to download data by ftp or other means. Thus, one might assume that an automated compilation of metabolic models on the basis of databases is feasible. This goal has not, however, been completely reached so far. First, the information is often error-prone, insecure and incomplete [8, 55]. To build a reliable model still requires checking the data in the original literature. At present, a genome-scale reconstruction of a metabolic network specifically assembled for one species is a nonautomated and iterative decision-making process requiring at least one researcher-year (e.g. Refs. [8, 37]). Second, ontological issues arise, as indicated above. In enzyme databases (as well as in the literature), substances are given at different levels of specificity. For example, in some databases, the term "branched-chain amino acids" is used in the context of aminotransferases, while in others the specific amino acids are mentioned separately. Another example is provided by alcohol dehydrogenase. The substrate of that enzyme is given as ethanol or primary alcohol. Thus, the additional information is needed that ethanol is a special case of primary alcohol. Nevertheless, online databases are extremely helpful for modeling because they provide an easy-to-get, comprehensive overview, which can be detailed and cross-checked later in the modeling process.

4.3 Example: Red Blood Cell Metabolism

The "guinea pig" of metabolic modeling is the red blood cell (*erythrocyte*) for various reasons. Mature erythrocytes in mammals are very simple cells. They do not contain any cell organelles such as mitochondria, not even a cell nucleus. The biological reason for this is that almost the entire cell volume is packed with hemoglobin, which serves for oxygen transport. The metabolism of these cells involves glycolysis (the most important pathway in these cells), the pentose phosphate pathway and part of purine metabolism. Figure 1 shows the main biochemical reactions involved in typical models of erythrocyte metabolism, notably glycolysis and the pentose phosphate pathway. Some models also include purine metabolism and the oxidation/reduction cycle of glutathione, which is driven by NADP/NADPH. Erythrocyte metabolism is even simpler than that of unicellular parasites such as *Mycoplasma*. Paradoxically, erythrocytes transport oxygen (as well as purine nucleotides), but are not "allowed" to use it for respiration. Another reason why erythrocytes are so intensively studied theoretically is that they have been thoroughly investigated experimentally due to easy accessibility. Moreover, they are of great medical importance.

The dominance of glycolysis in erythrocytes allows one to study a metabolic pathway of moderate size without much interference with other pathways. Depending on whether pyruvate or lactate are considered as end-products and whether the 2,3-bisphosphoglycerate bypass is included, glycolysis involves 10–13 reactions and about 15 concentration variables (Figure 1). In glycolysis, as in most other pathways, a timescale separation can be observed due to the presence of both slow and fast enzymes. This fact can be employed

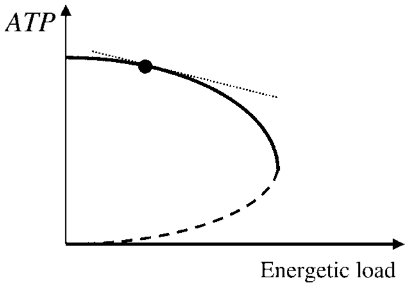

Figure 11 Schematic representation of the dependence of the stationary ATP concentration on the rate constant of ATP consumption (energetic load) in models of erythrocyte metabolism. Thick solid and dashed curves indicate stable and unstable steady states, respectively. The tangent (dotted line) to the branch of positive steady states characterizes the robustness of the system. Filled circle, *in vivo* point.

by applying the quasi-equilibrium approximation to about half of the reactions [113].

The most comprehensive kinetic models of erythrocyte metabolism so far have been developed in Refs. [61, 86]. These models include all the three parts of metabolism mentioned above. Subsequent models and simulations of erythrocyte metabolism [59,84] have focused on special aspects rather than extended the earlier models.

From a detailed kinetic model, many conclusions can be drawn. In the case of erythrocyte models, medically relevant conclusions concern, for example, the robustness of the ATP and NADH levels against changes in the energetic and oxidative loads. Energetic load means the consumption of ATP by diverse processes such as ion pumps, while oxidative load refers to the consumption of reduced redox equivalents such as NADH, NADPH, and glutathione by oxidizing reactions involving, for example, free radicals. Figure 11 shows a schematic picture of the dependence of the stationary ATP concentration on the rate constant of ATP consumption. Similar figures based on numerical simulations can be found, for example, in Ref. [51]. Note that for physiological values of the energetic load, there are two stable steady states – the trivial state with $ATP = 0$ and the *in vivo* state with positive ATP concentration. The reason for the existence of the trivial state is that glycolysis starts with a reaction consuming ATP (hexokinase, Figure 1). If no ATP is available, glycolysis is not "ignited" and cannot produce ATP.

Consider now the branch involving the *in vivo* state. If the energetic load becomes too high, the positive steady state disappears and the system "breaks down". The slope of the branch at the *in vivo* state can be interpreted as the robustness of the ATP producing system. Such figures (based on computational results) have also been presented for the dependence of redox equivalents on the energetic and oxidative loads [113, 114].

An important medical application of models of erythrocyte metabolism is the description and analysis of enzyme deficiencies. Many inherited diseases are based on complete or partial deficiencies of some enzymes, as mentioned in Section 2.1. An example relevant to red blood cells is provided by the sometimes occurring insufficient production of the enzyme hexokinase, which may lead to the disruption of these cells (hemolytic anemia). The impact of various enzyme deficiencies was assessed by simulations [112,114]. If (nearly) complete enzyme deficiencies are studied, network-based models can be used to make qualitative assertions [12,118].

4.4 Oscillations

Analysis of stationary states is the main paradigm in biochemical modeling. However, it is obvious that not all biological processes are stationary. The heartbeat, circadian clocks, cell division cycles, labor pain in childbirth and many other examples show oscillatory dynamics. There are, however, relatively few examples of oscillating metabolic processes (e.g. Ref. [45]). In most cases, the cause of oscillation is at a level other than the metabolic level, notably the genetic and hormonal levels, and electrophysiological effects (such as in the case of the heartbeat) can also play a role. A metabolic system relatively intensively studied in view of oscillations is the glycolytic pathway in yeast [5,77,104,125,126,156]. In these oscillations, the concentrations of all glycolytic intermediates move with the same frequency, yet partly in different phases.

However, glycolytic oscillations seem not to be very relevant under physiological conditions. Rather, they occur under special experimental conditions, e.g. after addition of cyanide during the diauxic shift from glucose consumption to ethanol consumption. In general, biochemical oscillations appear to be the exception rather than the rule. Most biochemical systems subsist in stable steady states, due to the stabilizing effect of usual chemical kinetics and probably because metabolic oscillations are rarely physiologically favorable. Nevertheless, glycolytic oscillations are of high academic interest because they can be used as an appropriate example to which the toolbox of theoretical methods can be applied. For example, the parameter values at which the Higgins–Selkov system (see Section 4.1) starts oscillating can be calculated analytically (e.g. Refs. [51,70]).

A physiologically very important oscillating system where biochemical processes are involved is the so-called mitotic oscillator, that is the system underlying the cell division cycle (for a model, see Ref. [87]). Another intensely studied case is cAMP oscillations in *Dictyostelium discoideum* (for a model, see Ref. [48]). However, that system rather belongs to signal transduction because cAMP oscillations serve for communication among these amoebae before formation of the fruiting body. A phenomenon studied even more intensely than glycolytic oscillations is that of intracellular calcium oscillations [28, 45, 122, 134]. These play an important role in signaling as well because calcium is a second messenger (see Chapter 22).

Different types of oscillations need to be distinguished depending on their stability. The biologically most relevant type is that of asymptotically stable oscillations; after a small fluctuation, the system returns to the same time course (though perhaps with another phase of oscillation). This type is usually called stable limit cycle (see Figure 10B). A second type is that of marginally stable oscillations. Here, a small fluctuation leads to a permanent shift in the maximum and minimum values of the oscillatory variables. A prominent example is the predator–prey system in population dynamics first analyzed by Lotka and Volterra (e.g. Ref. [85]). In linear differential equation systems, limit cycles cannot occur while marginally stable oscillations can. This is because the solutions of such equations are exponential functions. The real part of the exponents is either positive (which leads to a permanent increase in amplitude until infinity), zero (which leads to a marginally stable amplitude) or negative (which leads to damped oscillations). Thus, limit cycles can occur only in nonlinear systems. In fact, the nonlinearity must usually be rather strong. The essential nonlinearity in Eq. (32b) is $S_1S_2^2$. It can be shown by analyzing the Jacobian matrix that the term S_1S_2 would not suffice to produce oscillations. In the model of calcium oscillations developed by Somogyi and Stucki [134], for example, it is a Hill kinetics of the fourth degree. One oscillatory mechanism is positive feedback (e.g. due to autocatalysis or product activation). Most models of calcium oscillations are based on the positive feedback of cytosolic calcium on its release from the endoplasmic reticulum. For a long time, positive feedback by product activation of the glycolytic enzyme phosphofructokinase (see Figure 1) has also been discussed as an oscillatory mechanism (see Section 4.1). Apart from this, a positive feedback due to stoichiometric effects, notably the consumption of ATP at the upper end of glycolysis and production of ATP at the lower end, was also considered [125, 126]. However, the mechanism underlying glycolytic oscillations appears to be more complicated than either of these hypotheses [77].

In continuous modeling, autonomous oscillations cannot occur in a 1-D system. If for a 1-D equation, $\mathrm{d}x/\mathrm{d}t = f(x)$, the curve $x(t)$ were to have a monotonic increasing part and a monotonic decreasing part, it would need to pass a point where the time derivative $\mathrm{d}x/\mathrm{d}t$ equals zero. At this point, however, $f(x)$ is zero, so that x remains constant and cannot, hence, decrease – a contradiction (see also Ref. [137]). Accordingly, all continuous models of the above-mentioned types of biological oscillations are at least 2-D.

4.5 Whole-cell Modeling

A current trend in metabolic modeling is to aim at simulating the metabolism of entire cells (e.g. Ref. [142]). This is motivated by the breathtaking achievements in sequencing whole genomes. Thus, many groups are making attempts to perform modeling on a genome scale. This is done either by scaling up models on the basis of existing software tools or by creating new software tools specially designed for large systems. Projects in the latter direction are Electronic cell [139], Virtual Cell [132] and Silicon Cell [133]. Virtual Cell has the special feature that it allows spatial modeling. It provides a formal framework for simulating biochemical, electrophysiological and transport processes, while considering the subcellular localization of the various substances. However, most systems simulated by packages for "whole-cell modeling" so far have a size that can be treated with other simulation packages (such as GEPASI) as well.

There has been much controversy in the literature about the pros and cons of whole-cell modeling. While this issue is largely beyond the scope of a textbook, we wish to discuss at least some points. Any model is a simplified representation of some aspect of reality and usually serves a practical purpose. For example, a model can be established to answer the question what mechanism allows for calcium oscillations in the cell. A 2-D differential equation system is sufficient to provide the answer to this specific question: the positive feedback exerted by calcium-induced calcium release provides such a mechanism (e.g. Refs. [28, 45, 122]). The idea of whole-cell modeling is based on a different "philosophy" – rather than dealing with a specific question and restricting the analysis to some part or aspect from the outset, a comprehensive picture of the cell in its entirety is aimed at, from which specific answers are to be derived later. Such a model would integrate the available knowledge of the structure of the metabolic network and the parameters of the system (such as enzyme kinetic parameters), and could establish whether it is sufficient to account for the observed metabolic characteristics and responses of the cell. Whether this would amount to an explanation is open to question, since it would still be necessary to analyze the model further to determine which structural features and kinetic parameters are particularly influential for specific behaviors. The predictive power of such a detailed and comprehensive model could potentially be greater, since the consequences of any intervention at the molecular level (such as mutation or enzyme inhibition by a drug) could be followed through the whole system.

It has been questioned whether such a comprehensive, perfect picture can be established. Major problems arise from three sources:

(i) For the vast majority of enzymes, the kinetic parameters such as maximal velocities (which are proportional to *in vivo* enzyme concentrations) are unknown. Therefore, approximation methods such as the quasi-steady-state approximation are often used, and most models are restricted to small parts of metabolism. In fact, each enzyme-kinetic rate law is based on an approximation (see Section 2.4).

(ii) Computational problems. While modern computer technology allows one to solve thousands of differential equations simultaneously and deal with large linear programming problems, there are some questions in metabolic modeling that are computationally hard. This concerns, in particular, problems related to combinatorial explosion, such as in the computation of extreme pathways or elementary modes.

(iii) Sometimes, the objection against whole-cell models is raised that even if all data were known and the respective computer simulations were feasible, the huge amount of output data are hard to understand and interpret. This is to do with constraints in the human mind. However, analyzing the output data of computations can often be facilitated by automated extraction methods. Computer routines can help extract the features of interest (e.g. all elementary modes producing a given substance).

The problems in establishing dynamic models of the metabolism of whole cells can be illustrated by the huge amount of work that has been spent over about 40 years on the modeling and simulation of a very simple cell – the human erythrocyte [50,51,59,61,84,86,113]. In spite of these enormous efforts, we are far from being able to simulate all aspects of erythrocyte metabolism. Thus, simulating the entire metabolism of more complex cells is unlikely to be attained in the near future.

On the other hand, laboratory automation of the type that accelerated genome sequencing and that is applied in the pharmaceutical industry for high-throughput screening could be used to acquire enzyme kinetic parameters much more rapidly than in the past. Of course, it is of great academic and practical interest to scale up metabolic models. For example, testing the effect of a drug *in silico* at the whole-cell level can be extremely useful. The academic quest for whole-cell or even whole-organism models can be compared to the striving of mankind to achieve nuclear fusion or flying to Mars. Indeed, the development of computable models of organisms has been nominated as one of the current grand challenges in computing (http://www.ukcrc.org.uk/grand_challenges/index.cfm).

An approach that is, in a sense, in between small (or even minimal) models and whole-cell models is to simulate only special aspects of whole cells, such as their network properties, rather than all their dynamic properties. However, even this aim is difficult to achieve because of combinatorial complexity. For example, computing the elementary modes for the whole of metabolism is impossible at present due to combinatorial explosion, even for microorganisms as simple as *Mycoplasma pneumoniae*. Currently available software tools for network analysis are able to cope with systems of about 200 reactions. Stelling and coworkers [135] computed the elementary modes for a model containing 110 reactions, covering a considerable part of central metabolism of *E. coli*. When four different substrates are allowed simultaneously, this gives rise to about half a million modes. The current version, METATOOL 5.0 (http://pinguin.biologie.uni-jena.de/bioinformatik/networks/index.html) is able to cope with a system extended to 112 reactions, computing 2 450 787 modes [146]. The number of elementary modes depends very much on the special properties of the network. In particular, adding reactions connecting to external metabolites (exchange reactions) usually increases the number of modes much more than adding internal reactions.

The above-mentioned *E. coli* system [135] was used to predict the viability of single mutants, with 90% of the predictions being consistent with experimental data. An even larger system of *E. coli* metabolism with 720 reactions was analyzed in Ref. [25]. The viability of single mutants was predicted by FBA rather than by elementary-modes analysis, with 86% of the predictions being correct. In fact, FBA is sufficient to predict viability because, if the flux distribution with the best biomass-over-substrate yield is not able to sustain growth, then no flux distribution is. FBA (which is based on linear programming) can cope with larger systems than elementary-modes analysis because not all possible extreme flux situations need be enumerated. On the other hand, it gives a less comprehensive picture of the system's capabilities. The extreme-pathway analyses in Refs. [91, 103] (see Section 3.6) have been called "genome-wide" by their authors. However, combinatorial explosion was avoided by considering one product (amino acid in that case) at a time and macromolecule synthesis was excluded.

One of the largest metabolic networks so far reconstructed from genome data was presented in [37]. It comprises 1175 enzymatic reactions and 584 metabolites in *S. cerevisiae*. Carrying out a linear programming analysis (FBA) is feasible for that network. Applying FBA to the reconstructed network, Förster and coworkers [37] predicted the metabolic capabilities of *S. cerevisiae* when glucose is the sole carbon source and compared them with *E. coli*. It turned out that *S. cerevisiae* can synthesize the 12 most important precursor metabolites and the 20 proteinogenic amino acids more efficiently than *E. coli.*

The *S. cerevisiae* network reconstructed in Ref. [37], the *E. coli* network compiled in Ref. [25] and a network of *Helicobacter pylori* metabolism comprising 389 reactions [109] were used for a flux-coupling analysis [11]. Flux coupling analysis is part of network analysis and means that the coupling between directionalities or values of fluxes in steady states is computed. For example, in an unbranched reaction chain, in which at least one reaction is irreversible, all fluxes must be equal and their directionality is determined by the irreversible reaction. Flux-coupling analysis allows, in particular, the detection of infeasible fluxes (called blocked reactions in Ref. [11]). These are fluxes that are always zero at steady state. It was determined that 10, 14 and 29% of the reactions in the three above-mentioned networks, respectively, are blocked reactions. This may, however, be due to incompleteness of the reconstructed networks.

5 Conclusions

In this chapter, an outline of the modeling and simulation of metabolic systems has been given. Of course, the field of metabolic modeling is much broader than could be sketched here. We should at least mention metabolic control analysis [5, 19, 32, 50, 51], in which the control by particular enzymes over systemic properties such as steady-state fluxes is analyzed.

In addition to models of erythrocyte metabolism, many models of parts of metabolism in other cell types have been established. For example, a model and computer simulations of the threonine-synthesis pathway in *E. coli* were presented by Chassagnole and coworkers [14, 15]. As pointed out above, glycolysis in yeast has been studied intensely in view of oscillations. Nevertheless, simulations of this pathway in the physiologically more relevant regime of steady state have been presented as well [39, 140]. A number of them can be examined, and run, at a web repository curated by J. L. Snoep (http://jjj.biochem.sun.ac.za).

An important current trend is network modeling (constraint-based modeling), as outlined in Section 3. As shown by the CAM plant and TCA cycle examples in Section 3.5, relevant conclusions can be drawn by this analysis without the need for kinetic data. The algorithms and mathematical theory in this field are permanently refined [38,66,144], and applied to biotechnological [13,101,115,119,120,123,136] and medical problems [12,118,151] as well as to functional genomics [20, 30]. A large body of literature on FBA has emerged (some papers are cited in Section 3.7). Moreover, there are a number of approaches to explaining the properties of metabolic networks by optimality principles other than maximum yield, e.g. maximum pathway flux [2, 51, 147] and also flux minimization [54]. A modern line of research is based on game-theoretical approaches to studying the evolution of metabolic pathways [3, 47, 96, 99].

Mathematical modeling and simulation in all fields of science have several objectives. One goal is the explanation and better understanding of experimental observations. This goal has been reached many times in metabolic modeling. For example, modeling has allowed us to find the mechanistic bases of glycolytic and calcium oscillations (see Section 4.4). Another example is provided by the elementary modes of the CAM plant metabolism, which allowed a systematic classification of experimental data (see Section 3.5). A more ambitious goal is to predict some novel phenomenon, which has not been observed before. Theoretical physics has often achieved this (e.g. the prediction of the positron). Theoretical biology is less predictive so far. Nevertheless, some success stories exist. For example, the theoretically predicted optimal time course of gene expression in an unbranched metabolic pathway [69] could be confirmed experimentally [158]. The predictions of FBA for *E. coli* could be verified in adaptive evolution experiments [36, 57]. Another example is the catabolic pathway in hungry *E. coli* mentioned in Section 3.3. In conclusion, it can be said that theoretical biology and bioinformatics will shift more and more towards predictive sciences.

Acknowledgments

D. F. thanks Alyson Tobin and Anne Borland for their suggestions for starch and hexose-producing CAM plants. His research on elementary-modes analysis has been supported by the BBSRC and Oxford Brookes University. Moreover, the authors wish to thank Beate Knoke for technical support with the figures, and Chris Lauber, Herbert Sauro and Ernst Günter Schukat-Talamazzini for helpful discussions.

21 Inferring Gene Regulatory Networks

Michael Q. Zhang

1 Introduction

Gene expression (normally referring to the cellular processes that lead to protein production) is responsive to environmental signals, and is controlled and regulated at multiple levels [108]. In addition to protein-coding genes, there are also non (protein)-coding RNA (ncRNA) genes, such as tRNAs, rRNAs, small nucleolar RNAs (snoRNAs), small interfering RNAs (siRNAs)/micro RNAs (miRNAs), antisense RNAs and many others [74]. A molecular network is often represented by a graph of *nodes* (representing molecules) and *links* (representing interactive relations between pairs of molecules). Such interactions can be either symmetric, indicated by an undirected link, or asymmetric, indicated by a directed link. There are many definitions (or incarnations) of gene regulatory networks (GRNs) depending on the nature of the nodes (i.e. DNAs, RNAs, proteins or a mixture) and the links (i.e. regulatory relations). For example, signaling networks (one type or one part of GRNs that is discussed in more detail in Chapter 22) are protein networks that describe post-translational modification, degradation, subcellular localization or physical interaction of proteins. In this chapter, the discussion is mainly focused on protein–DNA and protein–RNA interactions, as such so-called *trans*-factor and *cis*-element interactions are the key for understanding how eventually genes are turned on or off. Therefore, knowledge of these interactions is a prerequisite for building any gene regulation pathway or more extended networks. The central question is how various input signals are integrated at each step of gene expression to produce differential output of the gene products in order to respond to different physiological conditions in different types of cells at different developmental stages.

2 Gene Regulation at the Transcriptional Level

Transcription is the first and the major step in gene expression during which genetic information is transcribed from DNA to RNA transcript. Molecularly, there are several substeps (e.g. initiation of the transcription, promoter escape, whereby the polymerase overcomes the pausing at nucleosomes, elongation of the transcript and termination of transcription) each of which can be subject to regulation. Transcription factors (TFs) binding to specific promoter DNA (*cis*-elements) is the most basic requirement for recruiting the transcription machinery (polymerase and associated factors) to form the preinitiation complex (PIC) at the transcriptional start site (TSS), and for switching on and off RNA transcript synthesis. Co(transcription) factors (CTFs) that do not directly bind to DNA, but to other molecules of the PIC, are also crucial as they can help activating or deactivating TFs or transcription machinery and can modify histones or chromatin structures (see Chapters 6 and 45, and reviews, e.g. Ref. [132]).

Although many mathematical models have been developed for modeling single-cell dynamics of highly simplified systems ranging from lactose metabolism in bacteria [118] to cell cycle control in yeast [26, 97], they are largely based on known factors, pathways and network topologies. Given the complexity of the GRNs and very limited dynamical measurements with current experimental technologies, it may be still too early to build comprehensive and accurate dynamical models for truly realistic GRNs. (It is a fascinating problem why a biological system is robust against fluctuating environments, for recent review on the stochasticity problem in realistic dynamic modeling, see Ref. [81].) The majority of the new computational methods for detecting *cis*–*trans* relationships are based on modern statistical or machine learning approaches; these methods are quite effective in the discovery of *cis*-regulatory elements (single motifs) or *cis*-regulatory modules (CRMs, also called motif combinations or composite motifs) and the inference of GRN modules. A GRN module is a triple of TFs/CTFs, *cis*-element and target genes).

In the study of transcriptional regulation, there are two related problems: one is to identify regulatory regions, i.e. promoters or TSSs (they may also include introns and 3′ flanking regions in vertebrates); another is to detect *cis*-element motifs [most of them are TF-binding sites (TFBSs)]. In Chapter 6, Werner has given an excellent description of *de novo* promoter prediction methods, and the interplay between promoter recognition and *cis*-element analysis. (One can also find related reviews, e.g. in Refs. [165–167]). In this chapter, I focus on finding *cis*-element motifs or network modules using large-scale functional genomics microarray data.

2.1 Finding TFBSs and Motifs

The traditional approach for finding *cis*-elements is to collect a set of (target gene) promoter sequences believed to be enriched by some common TFBS motifs. They may either be collected from the literature or from systematic experiments [such as SELEX (selection-amplification), etc.]. There are many *de novo* TFBS motif-finding algorithms that may be used. For recent reviews on computational TFBS finding methods, see, e.g. Refs. [19, 120, 126, 156, 166], and see Ref. [153] for a recent benchmark of some popular motif finders. In addition to the three classical alignment-based motif-finding algorithms, i.e. CONSENSUS [64], MEME [3] and Gibbs motif sampler [115], most modern approaches have tried to extend either to discover motif combinations or CRMs (e.g. Refs. [52, 53, 57]), or to use evolutionary conservation or comparative genomic information. The latter approach is also called phylogenetic foot printing, e.g. Refs. [106, 113, 138, 155, 162]. There are also combinations of both approaches, e.g. Refs. [122, 151, 161]. One can also increase specificity by incorporating structural information [84, 107], e.g. if the protein binds as a homodimer, one could restrict the search to palindromic motifs.

More powerful and flexible motif finders can take advantage of a separate sequence set called the *background set*, serving as a negative control. The goal is to search only for motifs that are most discriminating, i.e. only those enriched in the foreground set relative to the background set. Such motif finders are called *discriminant motif finders*. Examples are ANN-Spec [159], PSSM [6], DMOTIFS [137], DWE [146] and DME [141].

2.2 Identifying Target Genes

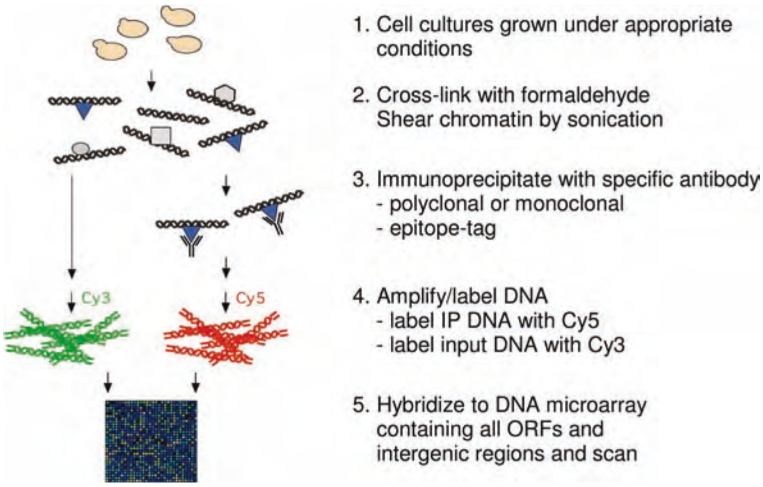
For known TFs, one needs either to get or to construct their nucleotide weight matrices (NWMs). (For a definition and discussion of NWMs, see Chapter 6.) Currently there are at least two new types of microarrays for measuring *in vitro* protein–DNA binding –protein binding microarrays (PBMs [114]) and DIP-chip (DNA immunoprecipitation with microarray detection [103]). PBM uses purified and tagged proteins binding to an array of double-stranded DNA oligos. In DIP-chip, protein–DNA complexes are immunoprecipitated from an *in vitro* mixture of purified protein and naked genomic DNA fragments and the sequences of the bound DNA fragments are determined by hybridization to a genomic DNA array. Both methods are very useful for systematically studying TF-binding specificity and hence defining motif-scoring matrices, because most motifs in the existing transcription factor databases, such as SCPD (yeast promoter database [171]), TRANSFAC (general commercial transcription factor database [63]), JASPAR (derived database from TRANFAC [133]) and TRED (cancer-related transcriptional regulation element database [169]), may still be very limited and therefore biased. It would only be possible to use known motif matrices to search for target genes computationally when the expectation of finding such a motif is much smaller than in a random promoter region. This means (i) the motif should be long and/or highly conserved, (ii) multiple motifs form clusters (homotypic or heterotypic modules) or (iii) the search space could be further restricted (to conserved regions, to nonrepeat regions, to be close to TSS, etc.) so that the total information content is well above the background noises.

2.3 Discovering Novel Motifs and Target Genes

Often, neither the motif nor target genes are known. Then motif finding and target identification have to be done simultaneously and/or iteratively. Comparative sequence analysis by itself may give some reasonable results for simple organisms [125]; however, in general, microarray data are required for any comprehensive studies. Currently, two major types of microarray data have provided large-scale input for transcriptional GRN studies. One is mRNA expression microarray data (see Chapter 24) and the other is localization data obtained by the ChIP-chip method (also called ChIP-on-chip, see Refs. [70, 127] and Chapter 45). ChIP-chip differs from DIP-chip by formaldehyde cross-linking proteins to chromatin DNA *in vivo*. Instead of using hybridization with genomic DNA arrays as in the ChIP-chip method, the SACO (serial analysis of chromatin occupancy [76]) method employs SAGE-tag sequencing after chromatin immunoprecipitation.

There are many approaches based on expression microarrays. The expression data is the direct readout of mRNA responses for a given condition; it becomes much more powerful when data is collected under multiple conditions or at multiple time points. The biggest problem in practice is that it is difficult to identify the direct targets after a treatment or perturbation to the cells. The best data for motif/target identification can be obtained when a perturbation is done directly on DNA-binding TFs (such as by TF knockout, mutation or knockdown, see, e.g. Ref. [25]). Things become more difficult when perturbation is more upstream, which often causes the activation of many pathways, as in heat shock or other stress responses, or when the top of a signal transduction pathway is perturbed, as it happens in drug treatment at the receptor level. As multiple TFs are likely to be involved in such general perturbations, responsive target genes would consist of a mixture of direct targets for different TFs. Another complication arises if the sample is heterogeneous, either due to technical difficulties of pure sample extraction or due to intrinsic mixtures such as embryonic stem cell differentiation. Classical approaches were based on clustering analysis in order to identify correlated gene expression patterns from which one could try to identify coregulated genes and common *cis*-elements enriched in their promoters (e.g. Ref. [72, 142]). When microarray data from a large number of conditions are combined, more sophisticated two-dimensional or biclustering methods must be used to identify significant expression patterns involving only some subset of genes and subset of conditions [21, 28, 47]. For more information on clustering of expression microarrays, see also Chapters 24, 26 and 27, and Ref. [56]. Since coexpressed genes may not all be coregulated, and genes expressed at different conditions and times may be regulated by the same TF, other information has also been used for filtering for functionally coregulated genes, such as, using Gene Ontology (GO) annotations, protein–protein interactions, metabolic networks or localization/binding data, etc., or combining potential target genes at different time-points by using TF expression profiles (e.g. Refs. [14, 172]. Since clustering can help in motif identification and good motifs can help refining clusters, MDscan [104] tries to iterate the process in order to sample the "good" genes and to weed out the "bad" ones. Models using joint likelihoods for sequence and expression have also been developed [7, 68].

Finding discriminating motifs that can best classify the foreground promoters of the responsive genes from the background promoters of the nonresponsive genes may be used for motif discovery with expression microarray data. The most powerful generalization of this idea would be to turn motif finding into a feature selection problem in regression analysis by asking what is the set of features X (some functions of the motifs or CRMs) that can best explain the expression data Y (e.g. as scored via the log-ratio of the expression data under a given condition). This is very similar to the general problem in genetics: Y represents the phenotype (mRNA expression) and X represents the genotype (measures of the DNA elements). One would like to learn a model (function f) so that $f(X)$ can best predict Y. When "best" is measured by the average squared error based on the distribution $Pr(X,Y)$, the solution is the conditional expectation (also known as the regression function, see, e.g. Ref. [61]: $f(X) = E(Y \mid X = x)$. REDUCE is the first successful motif-selection algorithm based on linear regression [20]. It has been generalized later to include cross-interaction terms [85], to use NWMs discovered by MDscan (Motif_Regressor [31]), to apply logistic regression [86] and MARS (multivariate adaptive regression splines [43]) – a nonlinear model based on regression trees (MARS_Motif [33]). Using a simple Bayesian network to learn the AND, OR and NOT logic with constraints on motif strength, orientation and relative position from a training set of yeast cycle cell genes and their expression patterns (coded as binary on–off variables), Beer and Tavazoie [11] demonstrated that the inferred regulatory rules can correctly predict expression patterns for about 70% of other cell cycle genes (not used for training the model) in the same arrays.



1. Cell cultures grown under appropriate conditions
2. Cross-link with formaldehyde
   Shear chromatin by sonication
3. Immunoprecipitate with specific antibody
   - polyclonal or monoclonal
   - epitope-tag
4. Amplify/label DNA
   - label IP DNA with Cy5
   - label input DNA with Cy3
5. Hybridize to DNA microarray containing all ORFs and intergenic regions and scan

Figure 1 ChIP-chip example: genome-wide localization analysis in yeast [128].

Almost all the tools developed for analyzing expression microarray data can also be easily applied to the analysis of localization data, e.g. of protein-binding sites in the genome, such as ChIP-chip data. Although ChIP-chip is a global measurement for *in vivo* binding of proteins to chromatin DNA and, hence, is potentially capable of revealing direct target genes – most targets identified in expression arrays are not direct targets – due to the current resolution and to non-specific or non-functional cross-links, not all putative targets are functional or possess functional *cis*-elements. ChIP-chip data have also been used to further refine motifs found by expression data (e.g. using boosting approach [69]). The most comprehensive ChIP-chip analysis done to date is the study of 203 TFs in yeast (Figure 1); since experimental resolution can only narrow down the binding sites to 200- to 1000-kb regions, further computational analysis is required for functional motif discovery. Using genome alignment information of four related yeast species and six *de novo* motif finders, a transcriptional regulatory code for the yeast genome has been inferred [58].

2.4 Inferring GRN Modules and Integrating Diverse Types of Data

Fully probabilistic graphical models, Bayesian networks in particular, have become very popular in GRN module inference. They are flexible with respect to the integration of diverse data sets (see also Chapter 35; for a recent review, see Friedman [44]). Bayesian networks have frequently been used to infer regulatory relationships between a regulator and its (often indirect) target given the expression data, ChIP-chip data were initially used as an informative prior to bias the Bayesian network model (posterior probability) towards potential direct regulator–target pairs [13,60] or as a noisy sensor [135]. If a parent gene in the hierarchical Bayesian network is a TF, its children may share its binding side motif in their promoter DNA. This idea may be used to refine Bayesian networks iteratively [149].

To reconstruct robust GRNs, network modules of genes that are coregulated under a set of experimental conditions have been proposed [75, 136] in which all the genes within a single module are controlled by a common regulatory program (shared set of TFs/*cis*-elements). When ChIP-chip data is also incorporated, physical links between TFs and their targets allow for building more robust GRNs (GRAM [5]). Inferring modules simultaneously using all three data types, i.e. Motif, ChIP-chip and expression microarray, have only been tried with the yeast cell cycle data. Here, a two-step process was used. The seed construction step predicts the putative modules consisting of TFs, their binding motifs and the common expression profile; the validation step filters false positives, and determines the module size and function [36]. Similar results have also been obtained previously by an iterative procedure for reconstruction of the yeast cell cycle regulation network [83] (see Banerjee and Zhang [4] for a specific review on yeast cell cycle regulatory networks).

Expression microarray data can also been regarded as quantitative phenotypes for so-called genetic genomics analysis. In such an approach, the genetic mechanisms of segregation and recombination are used to reshuffle the genomes of two or more donor parents, to produce a population of segregating offspring with many combinations of gene variants, both *cis*-linked or *trans*-linked quantitative trait loci (QTL) may be mapped by comparing differential expression (the method is also called eQTL) in the segregating population [16,29]. The power has been further demonstrated recently with novel application in epistasis analysis for determining the order of function of genes in pathways [154]. Although differential mRNA expression levels are used, the regulatory relation inferred by eQTL analysis can be at any level: from the genomic (*cis*–*trans*) level to the protein (interaction) level.

3 Gene Regulation at the Level of RNA Processing

The next level of gene regulation is at the level of RNA processing, which includes capping, splicing, polyadenylation, editing, degradation (including nonsense mediated decay) and transport; many of these (in particular, the first three) steps are co-transcriptional and hence directly coupled to transcription [108]. Hence, the steady state of the transcript level measured in an expression microarray is the result of a combined (or net) effect (see Grigull [51] for a microarray RNA stability study after a general transcriptional shutoff). In this section, we will only focus on RNA splicing, especially alternative splicing that is responsible for generating diverse protein isoforms from a single gene locus. Alternative splicing plays many critical roles in regulatory pathways in metazoans, including those controlling cell growth, cell death, differentiation and development, and its misregulation has been implicated in a large number of human diseases [143]. Genomic technologies for RNA-splicing regulation studies are much less developed, largely due to the difficulty of handling RNAs and to much more complex structure and dynamics of the spliceosome, which incorporates more than 300 protein/RNA components and thus has significantly more parts then the transcriptional (e.g. the PIC) or translational (ribosome) apparatus. Computational prediction of alternative exons is still in its infancy – almost all the exon–intron annotations are primarily based on cDNAs and expressed sequence tags (ESTs) [93,166].

3.1 Identification of Splicing Enhancers and Silencers

Like the TFs in transcription, splicing factors (SFs) play important roles in regulating RNA splicing. Most well-characterized SFs belong to one of two classes: heterogeneous nuclear ribonucleoproteins (hnRNPs) and arginine/serine-rich (SR) proteins, besides some TFs and elongation factors (see reviews, e.g. Refs. [15, 170]). There have been only a few large-scale discovery and characterization projects of splicing enhancers – mostly bound by SR proteins in exons – using SELEX through either a binding assay [148] or a functional assay [32, 101, 102]. Even less data is available on intron elements, many of which are silencers often bound by hnRNPs [18,73] (see review by Ladd and Cooper [90]). Hence there are limited entries in SF-binding site databases [144, 145, 150]. Several computational approaches have also been developed for finding putative *cis*-elements genome-wide *in silico* [22,41,42,124,139,168].

3.2 Splicing Microarrays

The feasibility of using microarrays to study RNA splicing regulation was first demonstrated in yeast [30]. Since 40–60% of mammalian genes have introns (a typical gene has about eight introns, see also Chapter 45), compared to 3.8% intron-containing genes in yeast, detecting alternative splicing in a mammalian system with microarrays has only become possible recently [79, 82,98,119,163]. Often, genes have many complex alternative-splicing isoforms that cannot be tracked unambiguously by the limited number of exon or junction probes – the biggest challenge of all splicing array experiments is data analysis and biological interpretation (see review, e.g. Ref. [92]). As transcription and splicing are intrinsically coupled, it may not be possible to separate their individual contributions to the steady-state levels of the transcripts despite some initial attempts [91, 97, 164]. It is interesting that transcription and alternative splicing appear to act independently on different sets of genes in order to define tissue-specific expression profiles [119].

4 Gene Regulation at the Translational Level

Regulated translation controls a wide range of cellular processes in eukaryotes. Like regulation at the other gene expression levels, global (cell-wide) regulation can be exercised through modification of the basic translation machinery via events such as phosphorylation. Otherwise, control is more selective with sequence-specific RNA-binding proteins recognizing target transcripts, thereby regulating translation. While the number of such factors is growing rapidly, the molecular details of how they regulate translation are not well understood for most of them. The binding sites for many of these regulatory proteins are located in 5′- or 3′-untranslated regions (UTRs) of the target transcript [37, 67, 123, 130, 158]. The databases UTRdb and UTRsite maintain a collection of sequence and regulatory motifs in the UTRs of eukaryotic mRNAs [112]. Computational studies of sequence elements in UTRs have been used mainly for UTR classification [35] or prediction of start or polyadenylation sites [49, 54, 94, 147]. Comparative genomics has also been applied to detect conserved mammalian *cis*-regulatory elements in 3′-UTRs [162]. One of the best studied *cis*-regulatory motifs in the 5′-UTR is the internal ribosome entry site (IRES) [88] and the one in the 3′-UTR is the PUF/pumilo binding site [46, 157]. SELEX has also been applied to studying UTR motifs [71]. The PUF family of RNA-binding proteins is highly conserved and plays important roles in regulating mRNA transcript satiability. The first human PUF homolog – PUM2 target: P2P-R – has also been identified by a microarray study using WebQTL (similar to the eQTL mentioned above [134]). Another famous example of translational regulators is the nuclear–cytoplasmic shuttling protein HuR. It has the dual functions of regulating RNA stability through the AU-rich element in its 3′-UTR and differentially repressing cap-dependent and IRES-mediated translational initiation via 5′-UTR binding, and its targets and binding sites have also proved to be amenable to genome-wide studies [111]. In addition to expression microarrays, high-throughput genomic arrays are currently being developed and tested for large-scale identification of *cis*-regulatory elements related to RNA binding proteins. This technology is similar to ChIP-chip for detecting DNA-binding targets and is termed ribonomics [46, 121]. Genome-wide translational regulatory network studies are clearly on the horizon. A comprehensive review on UTR elements and post-transcriptional regulation in cancer may be found in [1].

5 Gene Regulation by Small ncRNAs

RNA transcripts that are not mRNA, tRNA or rRNA are often referred to as ncRNAs. They include small nuclear RNA (snRNA), snoRNA, small temporal RNA (stRNA), Xist (X inactive specific transcripts)-like RNA, antisense RNA, processed pseudogenes, short RNAs (miRNA), siRNA, trophoblast ncRNA (tncRNA), small modulatory RNA (smRNA) [17] and other RNA transcripts of unknown function (TUFs) [27]). Here, we only focus on miRNA (some results are also applied to other short RNAs, such as siRNA) discovered recently that can add "micromanagement" fine-tuning layers in complex GRNs [8, 9]. Processed by the RNA interference machinery, these short (around 22 bp) RNAs can lead to sequence-specific inhibition of gene expression either at the transcriptional level – through chromatin modification and epigenetic silencing – in the nucleus or at the post-transcriptional level – through target message cleavage or degradation, or alternatively through translational repression – in the cytoplasm [62, 110, 152]. Recently, microarrays have been used for profiling tissue-specific expression of miRNAs [2, 100] as well as for identifying target genes [99]. It has been found that miRNAs clustered within 50 kb tend to be cistronic (transcribed together as a single transcript) and those in introns tend to transcribe together with the host mRNA [10].

Based on training samples in databases, such as the microRNA Registry (which contains 227 human miRNAs in release 6.0) and in Rfam [50], there has been a tremendous flood of computational programs and predictions for miRNAs (based on conservation, secondary structure, etc.) as well as their target genes (based on complementarity, conservation, etc.), mostly in the 3′-UTR (see the recent reviews of Bengert and Dandekar [12] and Brown and Sanseau [17]). In animals, imperfect complementarity with miRNAs makes computational prediction of their targets very difficult. Although it has been computationally predicted that there may be about 2000 [78], 5000 [162] or more than 5300 [96] human miRNA targets, given that we do not yet know even a single authentic training sample (an experimentally characterized human endogenous target gene *in vivo*), we must be very cautious about those computational predicted targets. In a zebrafish maternal-zygotic Dicer null, where all miRNAs are globally removed, many of the early developmental pathways computationally predicted to be targeted by miRNAs remain intact [48]. This experimental result implies that either the predicted targets are wrong or they have no functional consequences. The miRNA target gene regulatory code mostly in 3′-UTRs appears to be very similar to the transcriptional *cis*-regulatory code in promoters. Specificity mainly comes from combinatorial binding of multiple regulators, as each individual miRNA can target multiple genes [66]. With tissue-specific microarray data and motif-finding algorithms, identification of functional target genes and *cis*-regulatory sites may be more reliable [99]. Incorporation of known secondary structure information can further improve the target prediction accuracy [131]. Using a conservation filter (which require target recognition sites must be conserved among ortholog genes) of eight vertebrate species, a new algorithm PicTar [89] is able to predict tissue-specific mammalian target genes for a combination of miRNAs. This method was used to estimate about 200 targets per miRNA in the mammals. After all, miRNAs and TFs form an integrated regulation network – natural feedback loops: pre-miRNAs are regulated by TFs and many of the miRNA target themselves are TFs. It is a computational challenge to be able to treat them simultaneously. It has been demonstrated experimentally that such fascinating networks can regulate left and right symmetry in nematode chemosensory neuron localizations, and the two miRNAs that repress the die-1 zinc-finger TF were totally missed by previous computational predictions [24]. Another endogenous feedback loop was recently uncovered in the mammalian cell cycle regulation system where two miRNAs regulated by c-Myc modulate another c-Myc activated target E2F1 [116].

6 GRNs in Development and Evolution

The best context in which to study GRNs is metazoan organ development (see the special section in *Proceedings of the National Academy of Sciences USA* 2005, vol. 102, no. 14). Unlike the dynamics at the single-cell level, tissue lineage differentiation and organogenesis involve much slower dynamics of creation and evolution of cellular populations. In the terminally differentiated tissues, the regulatory program is often relatively simple, *cis*-regulatory regions in promoters tend to be closer to TSS and many TFBS are less conserved among distant species. In fact, it has been shown recently that proximal promoters can predict tissue-specific gene expression [140]. In contrast, the regulatory programs that control early development tend to be much more complex, almost always involving distal enhancers and/or complicated locus control regions (LCRs). However, lineage developmental master TFs and their binding sites (hence the core networks) are often more conserved during evolution. Using conservation and structural properties of TF modules (inter-distance and orientation), large-scale computational identification of distal enhancers has become possible [55]. Developmental GRNs refer to “logic maps of the control functions that direct development, and they relate these maps directly to the genomic regulatory sequence” [117]. They are typically large scale, multilayered, and organized in a nested, modular hierarchy of regulatory network kernels, function-specific building blocks and structural gene batteries. They are also inherently multicellular and involve changing topological relationships among a growing number of cells [105]. The two best-studied early developmental systems are the specification of the endomesoderm in sea urchin embryos and the dorsal–ventral patterning in the *Drosophila* embryo [95]. The central problem for GRN reconstruction is to identify CRMs and to figure out what kind of logic function, i.e. mapping from regulatory signal input to protein production output, each DNA module is programmed to compute and how different modules are integrated in the circuit [77].

Since the regulation of gene expression is ultimately the result of the evolutionary response to the challenge of surviving in a changing environment in the past history [23], we need to understand what is the core (conserved) subnetwork and what are the species-specific innovations. Different species may use different pathways to accomplish the same task or may invent unique pathways for their survival in a particular niche or environment. Evolutionary comparison of GRNs of related species is essential [38,160] (also Ref. [34] for a discussion on evolution-development convergence). Studies on conservation and evolution of *cis*-regulatory architectures [45], of global expression profiles [39, 80, 109] or of GRNs [40, 65] have yielded valuable insight on history, diversity and function of various genetic regulatory systems.

The obvious future task is to develop high-throughput experimental technologies to measure dynamic gene regulation at many different levels simultaneously and to develop large-scale computational tools to integrate diverse data (DNA, RNA, protein, metabolites, etc.) in order to obtain a coherent picture at the systems biology level [59,105]. The current emphasis should not be on graphs or "regulatory linkage, but the *nature of biological systems that allows gene products to be linked together* in many nonlethal and even useful combinations" [87]. Such a comprehensive study is important for inferring regulatory programs not only in normal biological systems, but also in pathological systems, such as in cancer [129].

The central dogma of molecular biology, stating that the flow of genetic information from DNA to RNA to protein is hardly an archaic myth. Yet, the subsequent discoveries that RNA can be transcribed back to DNA ("reverse transcription"), that it can cause gene silencing ("epigenetic control" or imprinting) as well as degradation of mRNA transcripts or repress translation ("RNA interference") and that it can also function enzymatically like a protein (ribozymes, cleave messages) have forced people to rethink: what is a gene and in how many ways can it be regulated? The fact that information may flow in more than one direction compels us to wonder if RNA may be the truly central player with both the informational capacity of DNA and the functional capacity of protein? With the dual role of information carrier and processor, RNA cannot only store information into DNA for more stable preservation of information (genetic structure), but also translate information into protein for more flexible and efficient processing of information (biochemical function).

Modeling Cell Signaling Networks

Anthony Hasseldine, Azi Lipshtat, Ravi Iyengar and Avi Ma'ayan

1 Introduction

A cell's signaling network is in many ways analogous to an animal's nervous system, connecting and directing the activities of its constituent parts, and processing information from the outside world; and, as in neurobiology, despite extensive study, there is still a lot to learn about cell signaling. The reason for the intricacy of signaling networks is evident if one considers that they are responsible for the control of cellular functions and information processing, and that such control systems are often more complex than the core functions they regulate. To borrow a classical example from Kuipers [33] and Lauffenburger [36], consider a simple system in which water delivery is required from a tank with in- and outflow pipes. This is a primitive core function indeed, but to prevent accidental overflow or depletion, it still requires a control system comprised of valves, flow meters, transducers and regulators, used in combination according to an appropriate computational algorithm, i.e. a relatively complex control system. Cells, which are considerably more sophisticated than water tanks, have vastly more complex control systems (signaling networks), presenting a considerable challenge in developing detailed predictive models. Different problems call for different approaches. Hence, in this chapter we outline a few complementary modeling strategies and the circumstances in which they may be useful.

1.1 Components and Cascades

The signal transduction field was born with the discovery of adenosine 3′,5′-cyclic monophosphate (cAMP) by Earl Sutherland and coworkers in the 1950s [58]. They called this molecule a "second messenger" in order to differentiate it from extracellular "first messengers" (hormones and neurotransmitters), which were the only real signaling molecules known at that time. Subsequently, other components of the cAMP signaling pathway were identified. In particular, the discovery that hormones, such as epinephrine and glucagon,

Bioinformatics – From Genomes to Therapies Vol. 2. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

do not act by binding directly to adenylylcyclases. It was later discovered that receptors and GTP-binding proteins (G-proteins) are required to mediate such response. This finding led to the formulation of the "signal transduction" concept, inspired partly by the burgeoning field of cybernetics [52].

In addition to cAMP, several other small molecules also play important roles in signal transduction. From other work in the 1950s, it was noted that membrane phospholipid metabolism was altered in response to acetylcholine treatment of cells [23]. This response involves inositol phospholipids and consequently the products of their hydrolysis, i.e. phosphoinositols (e.g. IP_3, IP_4) and diacylglycerol (DAG), are among the best characterized lipid-derived signaling molecules. Arachidonic acid, another lipid metabolite, is also highly important in a variety of signaling events, both intra- and intercellularly.

Some small molecules signal via the production or release of other small molecules. For example, adenylylcyclase, an enzyme that catalyzes the production of the small messenger cAMP, causes an indirect activation of protein kinase A (PKA). cAMP binds to the regulatory subunit of PKA and this binding reaction causes the release of the catalytic subunit from the regulatory subunit. The catalytic subunit of PKA is then free to diffuse, and can now catalyze the phosphorylation, potentiation and activation of ion Ca^{2+} channels. Ca^{2+}, via its binding protein, calmodulin (CaM), can also activate, for example, certain isoforms of phosphodiesterases and the phosphatase, calcineurin. However, the most common effect of small-molecule release or synthesis is the regulation of protein kinase activity. The best known of these are cAMP-dependent protein kinase (PKA), cGMP-dependent protein kinase (PKG), the DAG-sensitive kinases PKC and PKD, the inositol phospholipid-sensitive PKB/Akt, and the calcium-CaM-dependent kinases (CaMK I–IV).

Protein phosphorylation is a very common regulatory modification in cell signaling. Most protein kinases listed above are themselves regulated by phosphorylation, while protein kinases of another important family, the mitogen-activated protein kinases (MAPKs), are activated by phosphorylation alone, in the classic MAPKKK–MAPKK–MAPK cascade.

In addition to small-molecule sensitivity and phosphorylation, there are also many regulatory protein–protein binding interactions in cell signaling. Many of these involve another important category of molecule: G-proteins. G-proteins fall into two categories: heterotrimeric G-proteins (e.g. G_q, G_s, G_i and G_z), which are activated by cell surface receptors of the seven-transmembrane (7TM) receptor superfamily, and monomeric G-proteins ("small G-proteins", e.g. Ras, Rho, Rab), which are activated by specific guanine nucleotide exchange factors (GEFs). In both cases, the GTP-bound form is the active state and G-protein activation is terminated by its hydrolysis to GDP. For small G-proteins, this is usually catalyzed by a GTPase-activating-protein (GAP), while the intrinsic GTPase rates of heterotrimeric G-proteins may be boosted

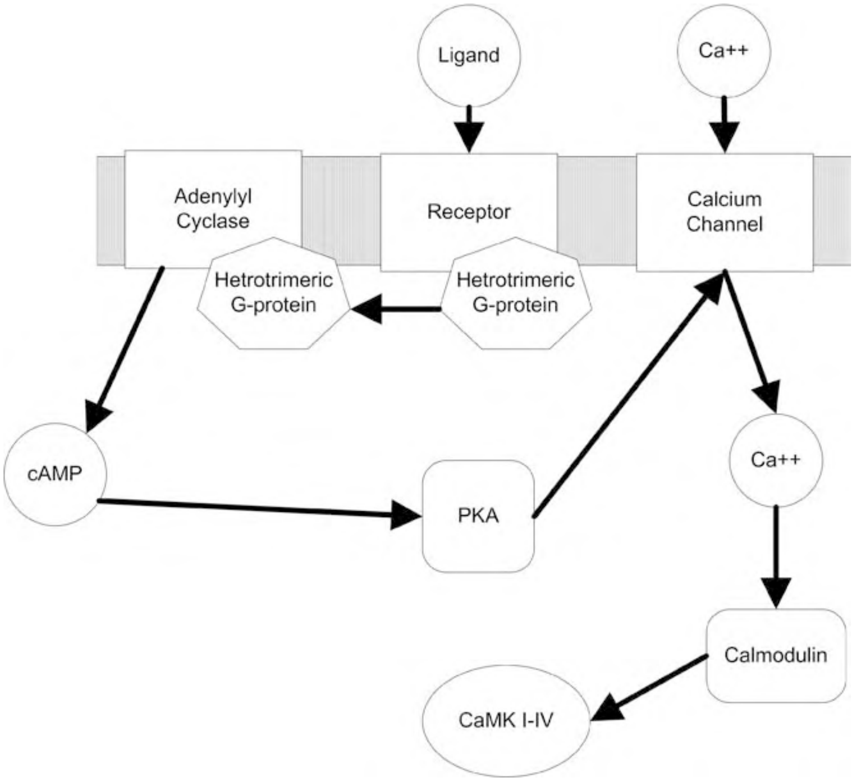

Figure 1 Canonical signaling pathway to illustrate how increase in production of one small-molecule second messenger (cAMP) can lead to an increase in intracellular concentration of another second messenger (Ca^{2+}). Here, an example from heart cells is shown. The signal starts by the binding of some extracellular ligand to a transmembrane cell surface GPCR. The binding of the ligand induces a conformational change in the receptor structure, which results in the activation of a heterotrimeric G-protein. The heterotrimeric G-protein activates the membrane-bound enzyme adenylylcyclase. This enzyme catalyzes the formation of the second messenger cAMP, which in turn diffuses through the cytoplasm to bind the regulatory subunit of protein kinase PKA. This binding of cAMP to the regulatory subunit of PKA results in the release of the catalytic subunit, which now is able to diffuse and phosphorylate Ca^{2+} channels, and potentiate their open state to induce intracellular Ca^{2+} entry. Intracellular Ca^{2+} can bind to a calcium sensor protein named CaM which can bind to and activate CaMK-type family of CaM-activated kinases.

by the GAP activity of RGS proteins (regulators of G-protein signaling). See Figure 1 for a canonical cascade of signaling interactions using some of the components and interactions described.

The conformational change that results from a binding interaction often causes a change in the target’s catalytic activity. 7TM receptor activation by an agonist, permitting the receptor to catalyze G-protein activation, is an example of this. Alternatively, the conformational change may result in the concealment or exposure of other binding sites on the target, thus regulating protein complex formation, for example. Autoinhibitory domains and subunits are common; PKA, for instance, is activated by the binding of cAMP to its regulatory subunits, causing them to dissociate from the catalytic subunits, which may then phosphorylate its targets.

Most of the protein kinases described above target serine or threonine residues for phosphorylation, but tyrosine kinases are also very important in the signal transduction systems of higher organisms, particularly in the regulation of growth [44]. They come in two classes: receptor tyrosine kinases, which are transmembrane proteins sensitive to growth factors, neurotrophins and/or insulin, and nonreceptor tyrosine kinases, such as Src, Jak and FAK.

Counterbalancing the effects of protein kinases are protein phosphatases. Serine/threonine phosphatases are far fewer in number than serine/threonine kinases and appear to be regulated less extensively. Nonetheless, some, such as the calcium-CaM-dependent calcineurin, do regulate the activity of phosphorylated substrates in a signal-dependent manner. Tyrosine phosphatases are well known to be important regulators of cell signaling – many, such as the T cell marker CD45, are in fact cell surface receptors.

There are also some protein kinases and phosphatases that are known as "dual specificity", because they catalyze the addition or removal of phosphate groups from both serine/threonine and tyrosine residues.

The molecules detailed above comprise the basic building blocks of the canonical signal transduction network: several types of small molecule (e.g. cAMP, Ca^{2+} and the phosphoinositol IP_3), G-protein-coupled receptors (GPCRs/7TM receptors), heterotrimeric G-proteins, receptor tyrosine kinases, nonreceptor serine/threonine and tyrosine kinases, dual-specificity kinases, serine/threonine, tyrosine and dual-specificity phosphatases, lipid kinases (although not mentioned explicitly, these produce phospholipids), phospholipases (which hydrolyze phospholipids), small G-proteins, GEFs, GAPs, and nucleotide cyclases. More generally, the kinetic building blocks of cell signaling are small-molecule–protein and protein–protein binding interactions, and enzymatic reactions.

1.2 From Pathways to Networks

1.2.1 Interactions between Signaling Pathways

With the discovery of each of the signaling components described above, much effort was focused on discovering a corresponding functional role. This process was, to a large extent, informed by the original view of signal transduction as a linear cascade for information transfer and signal amplification. However, even from the earliest biochemical and cell biological research,

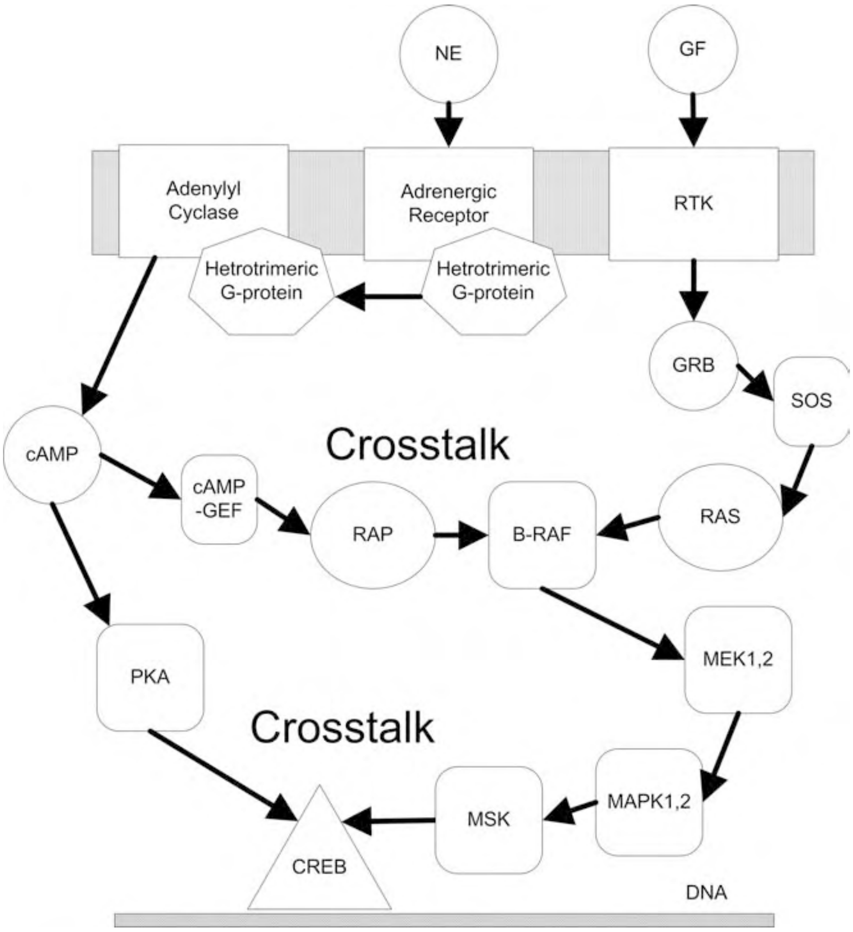

Figure 2 Illustration of "cross-talk" between two canonical signaling pathways: the cAMP–PKA pathway and the MAPK pathway. Here, an example from neurons is shown. Norepinephrine (NE) is a ligand that can bind to adrenergic GPCR receptor types. This induces the cAMP cascade (see for Figure 1). cAMP is also known to activate an exchange factor (cAMP-GEF) that can influence the MAPK cascade through the activation of the small G-protein Rap. The MAPK cascade is typically induced by the binding of growth factors (GF) to cell surface family of receptors named receptor tyrosine kinases (RTK). Once ligand bound, these receptors dimerize, autophosphorylate each other, and can bind and phosphorylate intracellular proteins such as GRB. GRB once bound to the receptor can bind to SOS which binds and activates the small G-protein RAS. RAS in turn activates MAPKKK (B-RAF) which is in turn phosphorylates and activates MAPKK (MEK1,2) which phosphorylates and activates MAPK1,2. Both MAPK activated kinase MSK and PKA can phosphorylate and activate the transcription factor CREB. CREB forms homodimers or heterodimers (with other CREB family members) when it is in its phosphorylated form. Active CREB translocates into the nucleus, binds to DNA and affects gene transcriptional regulation.

it was clear that pathways did not really operate independently, and the interactions between them were termed "cross-talk".

Examples of interactions between signaling pathways can be found at many levels, from receptors to effectors. For example, the two endogenous adrenergic agonists, epinephrine and norepinephrine, activate one or several (depending on the cell type) of 10 different α- and β-adrenergic receptors, which differ in their regulation and also, by class (α_1, α_2, β), in their G-protein/effector coupling. Other hormone and neurotransmitter receptors may affect adrenergic receptor sensitivity (e.g. by heterologous desensitization), and also share some of the same effector pathways, which in turn are further connected at multiple levels downstream. See Figure 2 for two examples of "cross-talk" between two canonical signaling pathways – the cAMP–PKA pathway and MAPK pathway.

Interactions between pathways result in regulatory signaling computation, which is limited in "linear" signal cascades. Much as signaling pathways themselves connect and control core cellular functions, these interactions between pathways, while not central to the task of getting information through the cell, are no doubt critical for sophisticated control of cellular behavior. Note, however, that this distinction between pathways and their interactions is contextual, because many signaling components are multifunctional. This point is further expanded below.

1.2.2 Implications of Network Topology

The growth in understanding signaling pathways and interconnections, and the advent of high-throughput techniques for studying large-scale protein interactions and protein post-translational modifications (i.e. phosphorylation) have led to the mapping of intracellular interactions on a breadth never considered before. One striking characteristic of the networks that have emerged from assembling many interactions to form *in silico* networks data sets is the so-called "small-world" topology; this type of organization means that on average there are a small number of connection "steps" between any two components (nodes), as well as high clustering (the proportion of a node's interacting partners that interact with one another) compared with the same statistics computed for random or shuffled networks [64]. This has interesting biological implications. Short paths across the signaling network would presumably be advantageous for rapid signal transfer, while high clustering implies the existence of network motifs, which can confer the ability to process information as it is being transferred.

The second striking topological property that emerges in complex cell signaling networks is their nodal connectivity degree distribution which is referred to as being "scale-free". The distribution of nodes with the same number of neighbors (number of direct biochemical interacting partners) commonly follows a power law [4]. That is, there are many nodes with very few connections and fewer, but substantial, numbers of nodes with many connections (the distribution has a long heavy tail). In terms of the components and cascades described above, it is easy to see that there are several candidate proteins for "hubs", i.e. highly connected nodes such as CaM, PKA and PKC. Graph theory tells us that, while the eradication of most nodes is tolerated easily, hubs are very important for maintaining network structure. This conclusion might appear trivial in light of the examples above – one does not need graph theory to conclude that PKA or PKC are important signaling molecules since they are known to be involved in almost all cell signaling processes and have many phosphorylation targets. Many other hubs are not so well characterized, however, and understanding network vulnerability has clear implications for understanding and identifying drug targets and treating disease. The appearance of power law-distributed networks in many complex systems abstracted to networks, including biology, has been proposed to have come about by "highly optimized tolerance" [10]. This term was coined for a design or evolutionary process that confers robustness to a wide variety of anticipated or experienced conditions. The trade-off is that these networks are very vulnerable to unforeseen or novel perturbations or attacks; again, the pathophysiological implications of this may be far reaching for drug discovery.

Network/graph theory is in itself a way of modeling cell signaling pathways [9], but it is a technique that is still in its infancy and one that can yield only a qualitative picture. It should also be noted that questions have been raised about the data used to draw some of the above conclusions, in particular, the validity of the interactions from yeast-two-hybrid and proteomics studies [30, 63] (see also Chapters 28 and 31). However, similar network characteristics have also been observed in data sets painstakingly collected from older studies in the scientific literature that used less error-prone techniques [40]. Of course, manually collected data also have their limitations, being the product of research driven by human interest and hypotheses, but the similarity in topological properties that emerges from the two approaches is encouraging.

1.2.3 Network Motifs

A group of connections or direct interactions between few components in the cell signaling network that has the potential to perform an information-processing function may be described as a regulatory network motif. Probably the best known is the negative feedback loop (NFBL), which occurs often in metabolic pathways and in desensitization, as in the case of G_s-coupled receptor phosphorylation by PKA and GRK (G-protein-coupled receptor kinase) (Figure 3). The former forms a five-node NFBL which permits the

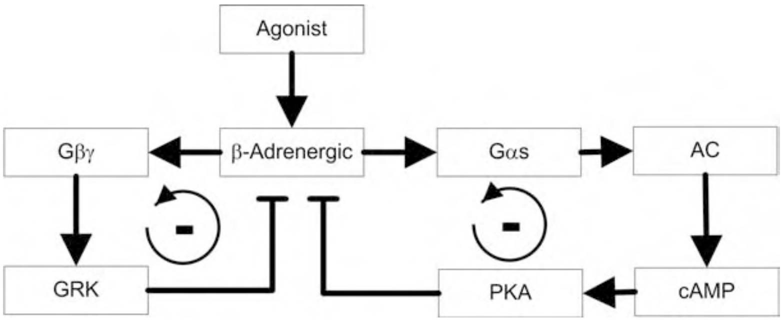

Figure 3 The NFBLs that regulate the sensitivity of a G_s-coupled receptor. Stimulatory connections are symbolized by arrows and inhibitory connections by plungers. Agonist/ligand binds to the receptor which activates G_s, causing it to dissociate to $G\alpha_s$ and Gβγ subunits. GRK is recruited to the plasma membrane by Gβγ subunits, where it phosphorylates and uncouples the active receptor. PKA, which is activated by increased cAMP concentrations, also phosphorylates the receptor. This may be caused by activation of this or another G_s-coupled receptor, or by other stimuli that activate adenylylcyclase (AC).

cell to adjust its sensitivity to the extracellular environment according to the concentration of a second messenger (cAMP) that is downstream of the receptor. This allows for modulation of receptor sensitivity by other detector systems that are coupled to cAMP. GRK, by contrast, is recruited directly by the heterotrimeric G-protein Gβγ and regulates receptor sensitivity in direct proportion to receptor activation. Hence, these two mechanisms, in concert, confer the ability to tightly regulate receptor sensitivity according to the cell's experience. In general terms, negative feedback is a mechanism for setting cellular expectations and preventing signaling hyperactivity.

In contrast to NFBLs, positive feedback loops (PFBLs) can produce *bistability* (or *switching*). Bistability, as the name suggests, is the ability of a system to stably occupy one of two steady states, with very little chance of coming to rest at an intermediate activity level. This can occur if there is an even number of inhibitory interactions, producing "double-negative" regulation or no negative interactions (all the links in the feedback loop are positive). There are several examples of human engineered systems which this motif has been engineered [16].

Switching behavior and multistability are often associated with hysteresis [37]. PFBLs are known to be involved in amplification of small stimuli and the triggering of cellular state changes. A similar biochemical switch has also been proposed: "ultrasensitivity" emerges readily from a signaling cascade, such as the sequential phosphorylation of kinases leading to MAPK activation [7, 8]. Like the bistability PFBL motifs described above, this is a threshold mechanism, but in the case of an ultrasensitive cascade, the switching need only be in one direction such that the PFBL is internal to one enzyme. Of course, ultrasensitive cascades can exist in combination with other motifs, which may confer bidirectional switching overall.

The network motifs described above have long been known, at least in terms of regulatory negative feedback inhibition, and amplification by ultrasensitivity and positive feedback created by a group of coupled biochemical reactions, but the concept of switching is relatively new in cell signaling. Experimental methods such as immunoblotting to observe state changes often do not produce evidence for this behavior, because switching occurs at the single-cell level which is below the resolution of most experimental techniques, i.e. bistability in cell populations, be they in a tissue or a culture dish, will be hidden by averaging. The result of a stimulus is an apparently gradual change in behavior, reflecting a cumulative distribution of single-cell threshold responses.

One important contribution of cellular switches is that they comprise a means of producing cellular state by consolidating many inputs into a single output response. This might be compared with decision making, classification and information processing. Hence, the ubiquitous MAPK cascade (Figure 2), which controls a broad range of cellular outcomes, e.g. by regulating the machinery required for differentiation or proliferation, is not only ultrasensitive, but displays bistability because of a PFBL between MAPK activation and arachidonic acid-mediated PKC activation [7,8].

An additional implication of bistability and ultrasensitivity is a reduction in the number of possible steady states. The signaling network is constrained to a given range of presumably dynamical stable steady-state configurations, improving response reproducibility and network stability to perturbations. This analog-to-digital conversion is obviously not desirable in all regions of the cellular regulatory network, but may be particularly advantageous in the regulation of key effector systems. The term "attractor" is used by mathematicians to describe one of these small volumes in "state space" that biochemical regulatory networks tend to occupy [25].

In addition to the well-studied PFBL and NFBL network motifs outlined above, two other motifs, feedforward loops (FFLs) and *bifans*, have recently been found to be statistically enriched in cell signaling regulatory networks compared with network motifs identified in randomized or shuffled networks. These additional two motifs are potentially important for information processing capabilities in biological networks (these motifs are diagrammed in Figure 4). The FFL has been studied most intensively in gene regulatory networks (GRNs), where it has been proposed to perform several biologically interesting functions that can be extrapolated to cell signaling. FFLs have been categorized into two subdivisions: *coherent* and *incoherent* [41]. The former refers to FFLs in which regulation is consistent across the two arms of the motif, i.e. the node furthest downstream (output node) receives the same

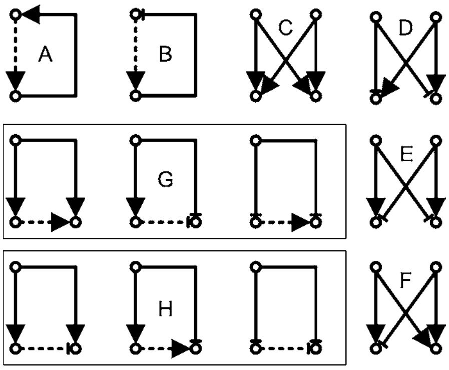

Figure 4 Network motifs. Nodes are symbolized by circles, stimulatory connections by arrows and inhibitory connections by plungers. A dashed line indicates that the connection is not necessarily direct. (A) PFBL. (B) NFBL. (C) "All-positive" bifan. (D) Bifan with "accelerator" and "brake" arrangement. (E) "Competitive" bi-fan. (F) A "biased" bifan (three negative and one positive is another possible configuration). (G) Examples of coherent FFLs (i.e. consistent influence on the output across both arms). (H) Examples of incoherent FFLs (in which conflicting signals are sent across the two arms).

type of signal from both its input arms (Figure 4). In contrast, incoherent FFLs are those in which the two arms have antagonistic effects on the activity of the downstream node. A FFL can modulate the duration of signaling, conferring either signal-onset delay or signal-decay acceleration, depending on its configuration. Detail analysis of different FFL configurations and their potential dynamical behavior was developed by Alon and coworkers [14, 41–43].

The bifan motif, like the FFL, plays a potentially important role in signal integration, although it has not yet been studied extensively. In principle, there are several functions it could perform (see Figure 4 for diagrams). "All-positive links" or "all-negative links" bifans would be expected to act as coincidence detectors and branching points, to produce consistent cellular responses from multiple inputs. The all-negative and all-positive bifan configuration is highly abundant in cell signaling networks most likely because cellular components (proteins) arise in these networks through duplication–divergence evolutionary processes. Regulation in tandem may also be achieved when upstream nodes are connected as follows: positive–positive ("accelerator" input) and negative–negative ("brake" input), with each output receiving one of each. This configuration is probably the most common, biologically, due to the tendency for kinases and phosphatases, as well as GEFs and GAPs, to share substrates. Alternatively, if the inputs each have one positive and one negative connection to the output nodes, the motif would be expected to function as two competing cascades. This could occur under circumstances in which phosphorylation stimulated one pathway and inhibited the other. There is also the "biased" bifan, with just one connection differing in sign from the other three; this is expected to produce coincidence detection at one output and competition at the other. The information-processing function of each of these motifs will further depend on the nature of the inputs' interactions, be they competitive, conditional or synergistic. In Boolean algebra or in electrical engineering parlance, it depends whether the inputs form OR or AND gates.

Other motifs, and more analysis of their functions, have been reported, particularly by Arkin and coworkers. These include signaling configurations that act as oscillators, various frequency filters and amplitude filters [3, 56, 65]. With further research, it will become clearer which of these are utilized in nature. Such analyses may provide some interesting insights into evolution's engineering principles of biological systems.

2 Types of Models and the Information they can Yield

2.1 Boolean Networks and Bayesian Networks Modeling Approaches

The broadest analysis that can be applied to a signaling network is the top-down approach employed by graph (network) theory. This approach yields a description of the entire network in terms of its topology, as well as measures such as average number of connections per component and maximum distance across the signaling network (see Section 1.2.2). This is a rapidly growing new field, from which many novel applications and techniques are exponentially emerging. For example, the analysis of "dynamic networks" may deliver biologically relevant insights into the way in which signaling and GRNs are rewired in response to external cues and the cell cycle [5, 39]. Furthermore, techniques from the field of machine learning have recently been employed in an attempt to derive the evolutionary foundation of biological networks by analyzing the frequency of the motifs they contain [47]. None of these techniques, however, yet offer a dynamic simulation system for predicting and investigating the function of cell signaling network interactions.

Boolean networks modeling is the simplest dynamical depiction of a signaling system, representing states of components as "1" and "0" [31]. The activation state of a node is governed by that of its input neighbors using Boolean logic (Boolean function). Activation and inhibition in a linear cascade can be represented by activation links and inhibition links, while there are eight possible Boolean functions to decode two Boolean inputs, OR and AND suffice to be used to simulate the effects of two converging inputs in signaling networks. For diagrams, formulas and an explanation of these, see Figure 5.

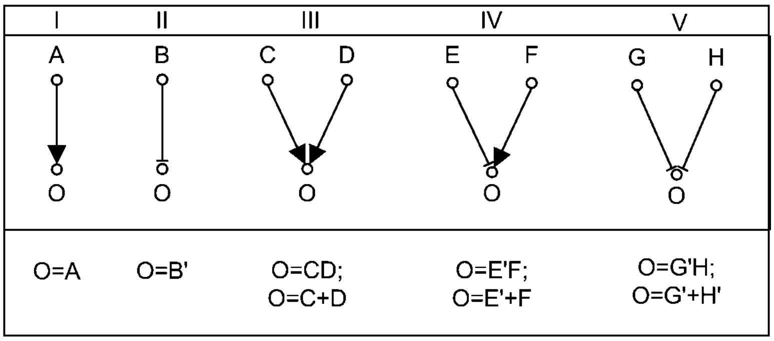

Figure 5 Boolean representations of signaling interactions. Components (nodes) are represented by circles, each labeled with a letter: A–H are inputs and O is the output. Stimulatory connections are symbolized by arrowheads and inhibitory connections by plungers. The two unary functions (single input), I and II, are IF (O = A) and NOT (O = B′), respectively; in Boolean notation, the prime symbol represents the *complement* (it "flips" a value between "0" and "1"). The other three functions are two-input Boolean functions. In III, two stimulatory inputs converge on an output; this interaction may be represented by an AND function (O = CD) if both inputs are required to activate the output and by an OR function (O = C + D) if only one input is required to propagate the signal. In IV, dual regulation (positive and negative) of a node is shown. The AND function (O = E′F) describes this interaction if the inhibitor is off and the activator is on. Whereas the OR function (O = E′ + F) describes activation either when the inhibitor is off OR the activator is on. V shows a binary interaction in which two inhibitors converge on the output. Again, AND (O = G′H′) and OR (O = G′ + H′) functions can be used to represent the interaction; in the former case, both inputs need to be inactive, for the output to be turned on. In the latter case, both inputs need to be activated to inhibit the output.

The Boolean approach is useful for handling very large models, as it is computationally cheap compared with other dynamical modeling approaches such as ordinary differential equations (ODEs) and partial differential equations (PDEs) representations. It is particularly useful when the relationships between nodes have not been characterized quantitatively, i.e. in systems with unknown kinetics of binding and catalysis. Pseudodynamics modeling can also be used to create dynamic "maps" of signaling network topology, which reveal the presence of information-processing motifs specific to particular pathways or regions of signaling space [40]. While quick and easy, relative to other modeling strategies, Boolean and pseudodynamics representations of cell signaling do have limitations. Imposition of binary descriptions can at times be somewhat arbitrary, as many complex, conditional activation events exist in cell signaling. Some of these issues are being addressed by ongoing work in the field. The introduction of more complex functions, customized for every node based on careful experimental observation [11], may go some way towards ameliorating these problems.

Cell signaling networks could also be modeled by classifier systems [24]. Statistical classification machine learning-based models are called Bayesian networks. Bayesian networks are most commonly used to build GRNs from microarray time series or single knockout data sets [18, 53, 66]. Bayesian networks are acyclic graphs where nodes represent variables and links are probabilistic influences of variables on each other. Bayesian networks can be useful in interpreting multidimensional signalome type experimental data such as phospho-proteomics. For example, a Bayesian network was built to understand mouse embryonic stem cells cellular choices under different stimulations protocols [51, 65]. These cells can be driven to self-renewal or to differentiation in culture based on extracellular media provided. A similar approach was used to study the relationships between proteins and phospholipids, and the directionality of their links, after T cell activation of naive T cells [54]. Using data from single-cell measurements using flow cytometry to measure the phosphorylation levels of key signaling components [26] it is possible to determine the hierarchical ordering of signaling components by applying experimental perturbations, such as knocking out genes and proteins, by either pharmacological agents or RNA interference. Another relatively simple qualitative related statistical method was used to study cell signaling axes of apoptosis [28].

2.2 Quantitative Dynamics Modeling

In order to understand intracellular behavior on a quantitative detailed level, quantitative system dynamics need to be captured. Although certain behaviors are fairly robust with respect to kinetic parameters, there are also frequent examples of systems-level behaviors that emerge from quantitative dynamics rather than simply connection maps. An example of this is a system alluded to earlier, in which bistability results from a PFBL formed by the MAPK cascade in conjunction with arachidonic acid production and PKC activation (see Figure 6). This switch is in turn regulated by a PFBL between MAPK and MAPK phosphatase (MKP): active MAPK phosphorylates MKP, protecting it from degradation, while MKP activity inhibits MAPK. Once enough MKP has accumulated, its inhibitory influence attenuates the activity of the PFBL and the MAPK response becomes proportional to the input stimulus, rather than sustained or switch-like (Figure 6).

Kinetics-dependent behavior is also evidenced in the activation of immediate early genes by MAPK – an example of a coherent FFL. MAPK can stimulate transcription and translation of c-Fos, and it can also phosphorylate the c-Fos protein, which protects it from degradation by the ubiquitin–proteasome system. However, the duration of MAPK activation is critical for the function of the motif. If it is brief, then protection and synthesis are asynchronous,

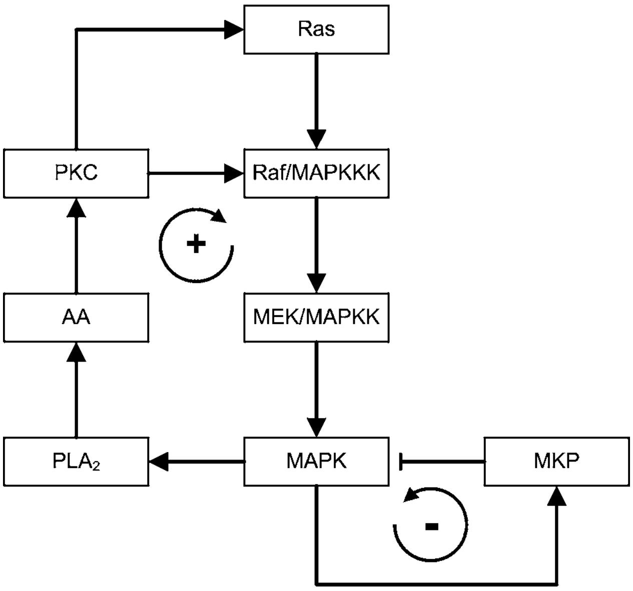

Figure 6 MAPK regulatory modules include both PFBLs and NFBLs. The former includes the small G-protein, Ras, which activates the MAPKKK, Raf, which in turn activates the MAPKK, MEK1,2, which activates MAPK1,2. MAPK1,2 stimulates phospholipase A_2 (PLA_2), which synthesizes arachidonic acid (AA), activating PKC, which in turn can promote both Ras and Raf activation. This PFBL confers bistability of the system in the absence of high levels of MKP. The NFBL involves increased synthesis of MKP and its protection from degradation, both of which are stimulated by MAPK. Dephosphorylation inhibits MAPK, so high levels of MKP, which can come about either through persistent activation of MAPK as outlined above, or via other regulators, prevent the sustained activation of MAPK despite the positive feedback loop, thus eliminating the system's bistability.

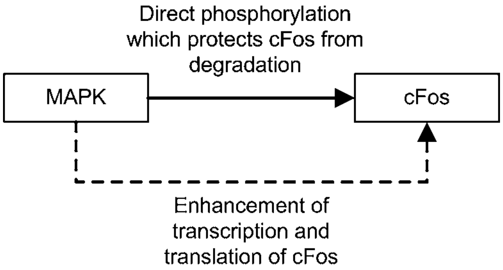
meaning that the FFL is ineffective, i.e. if MAPK activity has returned to a low level in the time required for transcription and translation, the new c-Fos is not phosphorylated and is consequently degraded. By contrast, when MAPK activation is sustained, the FFL is functional, causing an increase in c-Fos activity (Figure 7) [15, 50].

Signal processing can also be affected simply by an activation cascade that works across divergent time scales. For example, the dynamics of calcium concentration changes (due to channel fluxes and diffusion) is faster than that of calcium detection systems (small-molecule–protein binding interactions), which in turn operate faster than the downstream protein–protein interactions and enzymatic processes that rely upon calcium detection. This change in dynamics can act as a frequency filter, typically low pass, which removes noise from the external input signal. Dynamic quantitative models can capture these traits, whereas Boolean representations probably cannot.



Direct phosphorylation which protects cFos from degradation
MAPK
cFos
Enhancement of transcription and translation of cFos

Figure 7 Example of a PFFL where MAPK directly phosphorylates c-Fos and protects it from degradation, while at the same time it can enhance c-Fos transcription and translation through indirect pathways. Sustained activation of MAPK is required to achieve enhanced c-Fos activity.

2.2.1 **Deterministic Models**

Signaling reactions are discrete events, involving binding and/or chemical transformation of individual molecules, sometimes catalyzed by other individual molecules. Predicting the exact details at a molecular level requires calculations of individual probability trajectories, and is currently not feasible for systems with more than just a few molecules. However, if there are many reacting molecules, their average behavior can be described by some relatively simple mathematics, in which concentrations are treated as continuous variables.

The reactions in a signaling network can be broken into two categories: binding and/or catalyzed transformation; in most cases, the latter process is irreversible or may be considered irreversible for the purposes of modeling. In cases where some details are not known, approximations can suffice. The most commonly used such approximation is the Michaelis–Menten formulation [46], that assumes that the mass-action is significantly faster than the catalyzed transformation, and so the forward and reverse reaction rate constants, k_f and k_r, collapse into one term, K_M; enzyme activity is also described by the constants V_max, which is the product of total enzyme concentration and k_cat. The use of V_max in the Michaelis–Menten equation can be particularly advantageous to the modeler, as this parameter is more easily measured and is found often in the biochemistry and molecular biology literature compared with enzyme concentrations and k_cat. See Box 1 for details of these reactions and the expression of their kinetics. Other customized kinetic formalisms are also possible, so long as the reaction can be expressed by an ODE. Chapter 20 also discusses the kinetics of biochemical reactions.

Box 1 Basic reactions and the deterministic expression of their kinetics

$$A + E \leftrightarrow AE \tag{1}$$

$$AE \rightarrow B + E \tag{2}$$

The rate equations (ODEs) that describe these reactions deterministically are, respectively:

$$\frac{\mathrm{d}[AE]}{\mathrm{d}t} = [A][E]k_{\mathrm{f}} - [AE]k_{\mathrm{r}} - [AE]k_{\mathrm{cat}} \tag{3}$$

$$\frac{\mathrm{d}[B]}{\mathrm{d}t} = [AE]k_{\mathrm{cat}} \ , \tag{4}$$

where k_{f} and k_{r} are the forward and reverse rate constants, respectively, having units of concentration^{-1} time^{-1} and time^{-1}, respectively (herein, following convention, we use µM and s); k_{cat} is the first order rate constant of catalysis (s^{-1}); thus all reaction rates are expressed in units of µM s^{-1}.

Combining Eqs. (3) and (4), and making the assumption that the concentration of enzyme–substrate complex is initially constant (i.e. the steady-state assumption) yields the Michaelis–Menten approximation:

$$V = k_{\mathrm{cat}}[E]_{\mathrm{total}}\frac{[A]}{[A] + K_{\mathrm{M}}} \tag{5}$$

where V is the initial rate of the reaction, before appreciable changes occur in components' concentrations (equivalent to the initial rates of change in Eqs. (3) and (4); $[E]_{\mathrm{total}}$ is the total amount of E present in the system, i.e. $[E]_{\mathrm{total}}$ = $[E]$ + $[AE]$; and K_{M} = $(k_{\mathrm{r}} + k_{\mathrm{cat}})/k_{\mathrm{f}}$. The maximum reaction rate ($V_{\max}$ = $k_{\mathrm{cat}}[E]_{\mathrm{total}}$) is the rate under the extreme condition $[AE]$ = $[E]_{\mathrm{total}}$ and when $[A] \gg K_{\mathrm{M}}$.

The formulations above are all based on the well-stirred assumption, implying that there is a homogeneous distribution of molecules in space. If this is not reasonable, compartments may be introduced (e.g. intracellular/extracellular). Compartmentalization can be implemented by duplication of the relevant equations for the spatially segregated species, with a flux term where necessary, such as:

$$[A]_{\mathrm{ic}} \overset{C}{\longleftrightarrow} [A]_{\mathrm{ec}} \tag{6}$$

$$\frac{\mathrm{d}[A]_{\mathrm{ec}}}{\mathrm{d}t} = [C]\left(k_{\mathrm{f}}[A]_{\mathrm{ic}} - k_{\mathrm{r}}[A]_{\mathrm{ec}}\right) = -\frac{\mathrm{d}[A]_{\mathrm{ic}}}{\mathrm{d}t} \ , \tag{7}$$

where $[A]_{\mathrm{ic}}$ and $[A]_{\mathrm{ec}}$ are the concentrations of A in the intracellular and extracellular compartments, respectively, and C is a channel. Note that the rate constants here are in units of µM^{-1} s^{-1} and the reaction rate is again in μM s^{-1}. The equations are more complex, but well established [1], if membrane potential is involved.

If compartments are insufficient to describe the spatial distribution of the reactions, e.g. if one wishes to study the development of concentration gradients within a single compartment, then PDEs must be used in place of ODEs. In the resulting reaction–diffusion equation, rate of change of concentration varies with respect to several parameters (normally, two- or three-dimensional space and time) rather than one (time). For example, the equation describing reaction 2 would be:

$$\frac{\partial[B]}{\partial t} = D\nabla^2[B] + [AE]k_{\text{cat}} \,, \tag{8}$$

where the first term represents change due to diffusion, and the second term represents change due to reaction (*cf.* Eq. 4). D is the diffusion coefficient of B; $\nabla^2[B]$ is the three-dimensional Laplacian that describes the change in distribution of B in space, being the sum of the second derivatives of $[B]$ with respect to each spatial dimension. The equation's second term is simply the function that describes the reaction-driven rate of change of $[B]$ with respect to time [34].

As was alluded to above, one key assumption in the use of any deterministic model is that there are large numbers of molecules in the reactions. If this is not the case, then reality can deviate significantly from the predicted average behavior. Furthermore, ODE models also assume that the reactions take place in a "well-mixed" environment, i.e. concentrations are the same everywhere, as there is no representation of space. If this assumption is unreasonable, then the simplest solution, computationally, is to introduce compartments. For example, if a molecular species is capable of existing on either side of a membrane, it and its reactions must be represented twice – once for each compartment. If transit across the membrane is possible, then a flux term can be added (see Box 1).

Sometimes, independent compartments do not offer an appropriate solution for the representation of concentration differences in space, e.g. when studying chemical gradients across a single cellular compartment. In this case, PDEs can be used instead of ODEs. PDE models explicitly include spatial dimensions, in addition to time. The reaction–diffusion equation they utilize is detailed in Box 1; although its complete derivation is beyond the scope of this chapter, an excellent introduction to its physical meaning and application may be found in Ref. [6].

Deterministic modeling, with either ODEs or PDEs, requires the numerical solution of differential equations, using a solver. There are many algorithms available, whose precise workings are beyond the scope of this chapter. The modeler does not normally need to know the mechanistic details of a solver's function, although some understanding of its strengths and weaknesses can be useful. Numerical problems can lead to spurious simulation results and a modeler should be aware of what to look out for. Numerical problems are usually obvious, and inspection of the reaction rates and component concentrations over the time course of the simulation will reveal rapidly changing (spiking) or unreasonable or logically irrelevant values (unreasonable values may also be caused by errors in the model). In many cases, a simple operation such as reduction in the size of the time step will solve the problem. At other times, a change of algorithm is required; higher-order, variable time-step algorithms are usually recommended. Systems that have heterogeneous kinetics wherein some reactions are much faster than others are described as being *stiff*. The exact definition of stiffness has been investigated in considerable depth since the term was first proposed by Curtiss and Hirschfelder in 1952 [13]. Pragmatically, it refers to problems that can be solved better using implicit methods than explicit methods. These require an appropriate solver, which is included in many simulation packages, e.g. LSODA (http://www.llnl.gov/CASC/odepack) and Rosenbrock algorithms [12]. One drawback of a stiff solver is that, when solving nonstiff systems, it is slightly slower because of the extra calculations it carries out.

Depending on the size of the model and the time of the simulation, deterministic models can be fairly quick and easy to run, using, for example, MATLAB (http://www.mathworks.com) on a desktop PC. PDE models and large ODE models usually require many hours of processor time, however. One convenient option in these cases is the program Virtual Cell [57], which runs in a web browser and does all of its calculations on a centralized server of very powerful processors. This is not only faster than performing the calculations on the local machine, but allows the user to shut down their computer or run other software while the simulation progresses. Virtual Cell also has the benefit of an intuitively simple graphical user interface. Other alternatives to MATLAB and Virtual Cell include E-Cell [59], Gepasi/Copasi [45], Genesis/Kinetikit [62] and Berkeley Madonna.

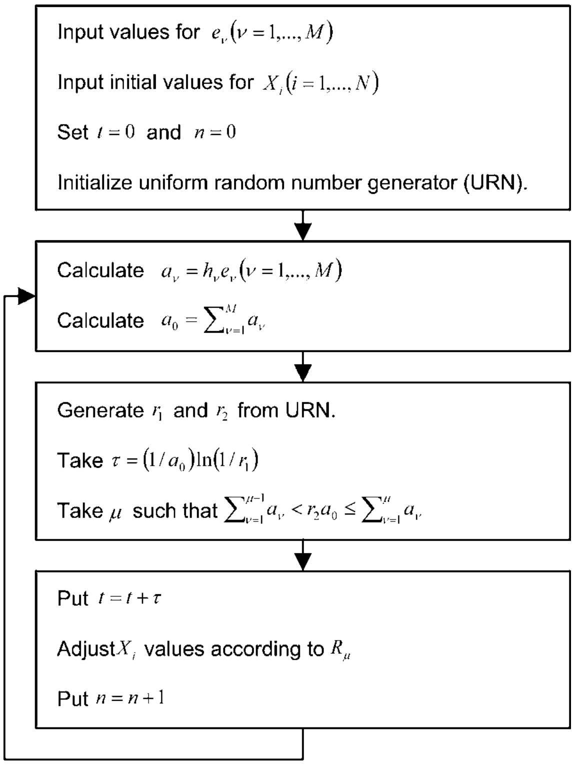
Deterministic models have been used successfully to derive a number of insights about signaling systems. However, they are not always adequate or appropriate. They do not capture behavior that emerges from fluctuations, such as stochastic resonance, and they are only accurate when there are many molecules of each species involved in reactions.

2.2.2 Stochastic Models

Stochastic models deal with discrete molecules or reactions, rather than treating concentration as a continuous variable, and are probabilistic in nature. Stochastic models are frequently used in systems that are so physically small that concentration is no longer a meaningful parameter. For example, the distal part of a neuronal dendrite can be as little as 0.2 μm across; thus a 2-μm stretch of approximately cylindrical dendrite has a volume of just 6×10^{-17} L. If the concentration of a signaling molecule in that part of the neuron is, say, 100 nM, then there will be on average fewer than four molecules in the section of interest and deterministic modeling breaks down. Stochastic modeling may also be advantageous in physically larger systems when addressing the problem of very low concentration. A common example of this is the regulation of transcription. There are usually two copies of a gene in a eukaryotic cell, each having adjacent to it one or few binding sites for promoter sequences recognized by transcription factors. Again, concentration as a continuous variable lacks meaning in this situation. Thirdly, stochastic models are useful in situations where random fluctuations can determine system behavior. Recent work has shown, for example, that certain types of switching are stochastic in nature [48, 56] and there is a phenomenon known as stochastic resonance that produces oscillatory behavior based on the amplification of a low-level signal by random fluctuations. Stochastic resonance is a well-studied phenomenon and may be important in a range of biological processes, such as neuronal excitability. Its dynamical origins have been elucidated mathematically [2], so it can now be modeled deterministically, although it must be included specifically in the model design to do so.

The best-known stochastic algorithm for the simulation of biochemical kinetics comes from the work of Gillespie [21]. He developed a set of rules for calculating the probability of a given reaction occurring in a simulation time step, i.e. a *reaction probability density function*, based on kinetic rate parameters that can be measured physically. He showed that his Monte Carlo method relates directly to the chemical master equation, which describes the change over time of reactants' and products' existence-probability. The Gillespie algorithm is illustrated as a flow diagram in Figure 8. It is based on two assumptions – that the molecules are distributed evenly in space ("well mixed", as in a deterministic ODE model) and that the system is at thermodynamic (though not necessarily chemical) equilibrium. Since it was originally described, the Gillespie algorithm has been modified, improved and updated. In particular, Gibson developed the *next-reaction method*, which is a more efficient version of Gillespie's *direct method*, as well as techniques for conducting sensitivity analysis within a stochastic framework [19].

The Gillespie algorithm deals with reaction probabilities and so treats all molecules of a given species as identical. The alternative to this approach is an object-oriented algorithm, such as that developed by Morton-Firth and implemented in the program StochSim [49]. This algorithm tracks the number of molecules and complexes (i.e. objects) themselves, instead of reactions. When the absolute number of molecules is relatively small, but there are many



Input values for $e_\nu(\nu = 1,...,M)$
Input initial values for $X_i(i = 1,...,N)$
Set $t = 0$ and $n = 0$
Initialize uniform random number generator (URN).
Calculate $a_\nu = h_\nu e_\nu(\nu = 1,...,M)$
Calculate $a_0 = \sum_{\nu=1}^{M} a_\nu$
Generate r_1 and r_2 from URN.
Take $\tau = (1/a_0)\ln(1/r_1)$
Take μ such that $\sum_{\nu=1}^{\mu-1} a_\nu < r_2 a_0 \le \sum_{\nu=1}^{\mu} a_\nu$
Put $t = t + \tau$
AdjustX_i values according to R_μ
Put $n = n + 1$

Figure 8 Flow diagram for the Gillespie algorithm [21], where t is time and n is the number of steps taken; e_v and X_i are the reaction constants and concentrations, respectively, for the M reactions and N species in the simulation; e_v is a combinatorial factor describing the number of potential occurrences of a reaction in the current system state, usually calculated as product of the reactants concentrations; τ is the time to the next reaction (note that it is inversely proportional to the total reaction rate) derived from the reaction probability density function; and μs an index number that references a point on the probability density function, determining which reaction will take place. R_μ represents the reaction channel, i.e. the reaction that has just taken place, which determines the change in species concentration values, X_i. The algorithm is followed until some predetermined value of n or t is reached [21].

possible reactions and/or states for each molecule (the so-called *combinatorial explosion*), this technique can be significantly more efficient than the Gillespie algorithm. The latest releases of StochSim also have the advantage of being able to represent spatial heterogeneity.

Stochastic modeling, while more accurate in some circumstances than a deterministic approximation, requires a great deal of computer processor time. This is because stochastic simulations require an entire cycle of the algorithm to run for every single molecular-level reaction event. By comparison, each cycle of a deterministic solver's algorithm gives a reaction rate value, which typically would involve a large number of reacting molecules. For example, a 0.01-s simulation time step of the first-order reaction from Box 1, $AE \rightarrow B + E$, taking place in a cell of volume 1 pL, having a rate constant of 1 s^{-1} and an initial AE concentration of 100 nM, would proceed at an initial rate of 10^8 molecular reaction events per time step. Thus, if deterministic modeling is a valid option, it is usually by far the more efficient strategy. Nonetheless, with the increasing availability of affordable computing power and continuing improvements to stochastic calculation strategies, including multistep approximations [20] and even hardware solutions [55], stochastic simulation is fast becoming a practical approach to a wide range of problems.

As the Gillespie algorithm is based on an underlying master equation, it was proposed recently to solve the master equation by direct integration [38]. In this method, a set of deterministic ODEs is solved, where the dynamic variables of the equations are the probabilities of the system to be in the various states. This method is advantageous in several aspects: it provides temporal evolution of the concentrations which cannot be calculated by the Gillespie algorithm, and it is computationally efficient since no averaging is required and the master equation can be easily coupled to other deterministic rate equations in case a hybrid model is used.

2.2.3 **Hybrid Models**

As described above, deterministic and stochastic approaches to biochemical kinetic modeling have their own advantages and disadvantages. In order to exploit the benefits of both, it is possible to combine the two approaches in a so-called hybrid model. Parts of the system are represented deterministically and parts stochastically. In this way, one may take advantage of a deterministic model's computational efficiency (for those reactions where the necessary assumptions hold) and the stochastic model's accuracy (in representing low-concentration and low-volume effects, and fluctuations). For example, in our laboratory, we model the isotropic phase of fibroblast cell spreading. This process is driven by actin polymerization and thus a stochastic model is appropriate. However, the regulation of polymerization is by biochemical signaling reactions that can be modeled deterministically. In this case, custom C++ code has been written, which was necessary because of the particularly complex and dynamic geometry of the problem. For most modeling problems, however, programs are available that can perform hybrid modeling via a reasonably user-friendly interface. The most recent versions of Kinetikit (an add-on for the popular simulator, Genesis) have the capacity for hybrid modeling [61], as does the Biochemical Network Stochastic Simulator (BioNetS), which utilizes Gibson's enhancement of the Gillespie algorithm [1].

3 Identifying Parameters/Data Sets for Modeling

3.1 Functionally Relevant Connections

The cellular signaling network in eukaryotic cells is both vast and highly connected. Modeling the entire intracellular network is not currently feasible. The type of information sought, the size of the network being studied and the physical context in which the model operates determine the model type. This, in turn, limits the size of the network that can be modeled with the computational power available and determines the level of detail required to describe an interaction.

Modularity is a term that is commonly used to describe the structure of signaling functional modules. In engineering parlance, a module is a set of components that act together to perform a function, e.g. the navigation system in an airplane or an organ in an animal. When modeling signaling networks, in which many components are reused to a multitude of different ends, modules are defined relatively flexibly. Because of their context-dependence, it is often useful to think of functional modules. For example, PKA is involved in a large number of interactions and is therefore included in many mathematical models of signaling. However, the majority of interactions involving PKA are excluded from most models, because the inclusion of dozens of functionally unrelated actions can quickly make a system intractable. Thus, the boundaries of a module in a signaling network are defined by function. The decision about whether to include or exclude given interactions must be made on a case-by-case basis; clearly, the better informed one is about the functional importance of reactions, the better the decision. However, often there is inadequate information, and hence the need for modeling through trial and error must be employed, followed by careful validation.

A major repercussion of function-based component and connection selection is that models are invariably incomplete. It is therefore necessary to test a model against experimentally derived data in order to ensure that the omissions have not compromised realistic function and to examine which parameters warrant the greatest accuracy.

3.2 Qualitative Relationships

For graph theory analysis of networks and Boolean modeling, qualitative relationships are all the information that is needed. One must, however, be careful to include only data of acceptable quality. High-throughput techniques have produced a lot of data recently. The accuracy of the information content in these data sets is uncertain [29]. The yeast two-hybrid screen, for example, is a technique that involves the activation of a promoter by a split activator – one half of which is fused to the *prey* protein and the other to the *bait*. The fusion proteins are transfected into yeast, where, if they interact, the two halves of the activator come together and the reporter gene is transcribed [17]. Protein interaction networks for yeast and *Drosophila* have been constructed using this technology, but there was worryingly little overlap between some of the findings of different groups [27, 60] (see also Chapter 31). There are also theoretical objections to the application of this and some other high-throughput techniques to multicellular organisms. A protein–protein interaction is dependent on the simultaneous expression of both proteins in the appropriate subcellular compartment. Whether this occurs in the nucleus of a genetically manipulated yeast strain is of questionable relevance to metazoan biology. To avoid these issues we recommend to only select interactions identified by rigorous biochemical methods and verified by functional measurements. The limitation of this approach is that such rigorous described systems are incomplete. Additionally, for Boolean models, the type of interaction (stimulation/inhibition) must be known, and this is not available from any high-throughput interaction techniques; dynamic models necessitate still more accurate data.

3.3 Quantitative Specifications

Dynamic models of cell signaling networks ideally require experimentally measured catalytic and binding rates for the interactions they include. These can be measured by a range of enzymology techniques, which require expertise and a considerable investment of time. However, it is often possible to extract kinetic data from the biochemical literature. Sometimes direct measurements are available. In other cases, kinetic parameters may need to be inferred or fitted using a model. In both situations, accuracy and precision are not guaranteed, so a careful and critical appraisal of the published data is required. Some guidelines and recommendations are suggested here.

Terms such as $V_{\max}$ and k_{cat} are not always used in strict accordance with standard enzymology parlance. Care should be taken to assess that the methods used are consistent with the conclusions presented. Note that, even if nonstandard terminology is present, the appropriate numbers can often be extracted from the raw data.

When several papers describe a given interaction, apparently contradictory or inconsistent data may be reported and again one must be careful to examine the experimental methods used. In some cases, a simple factor such as temperature can account for the difference between reported values. A useful rule of thumb here is that rate constants tend to double for every 10 °C increase in temperature. This guideline is derived from the Arrhenius equation [35] and it holds only over the limited range of temperatures in which the interacting proteins are conformationally stable. Fortunately, in order to be meaningful, enzyme and binding kinetics should be measured in this appropriate range, so the rule is widely applicable.

In addition to temperature, other aspects of the experimental methodology can greatly affect the findings. Many kinetic parameters are measured *in vitro*, using purified proteins, which are often recombinant. In some cases, recombinant proteins display reduced enzyme activity or affinity for other proteins, due to missing or inappropriate post-translational modifications. For example, the affinity of rabbit liver $G\alpha_s$ for adenylylcyclase is around 100-fold greater than that of recombinant $G\alpha_s$ prepared from *Escherichia coli*. This occurs because $G\alpha_s$ derived from *E. coli* lacks a critical covalent modification [32]. *In vitro* measurements of enzyme activity may also be sensitive to parameters such as buffer composition (ion concentrations, pH, etc.). In some cases, enzymes are only partially purified for assay. These measurements do not always correspond to numbers derived from "purer" systems. The presence of unidentified accessory proteins, such as chaperones or scaffolds, may cause the observed kinetics to deviate from the "true" activity of the enzyme being studied. If the model does not contain explicit information about the influence of the accessory proteins – if they are unknown – then their presence in the experimental system may actually result in more realistic simulation results. Since a biochemical kinetic model is really just a mathematical representation of coupled input–output relationships, the precise details of the reaction mechanism may not be important. On the other hand, if the mechanistic details *are* of interest, then simulations can provide insight into the failings of the model, and what additional information should be sought experimentally.

Measurements of enzyme activity or binding affinity can also be made *in vivo*, e.g. by the construction of phosphorylation time courses on an immunoblot. These often require the fitting of data to a model, and, before using such results, a critical eye should be cast over the model and fitting technique that were used. One should also be careful when using data derived from populations of cells, because averaging effects can obscure the single-cell mechanism. Sometimes it is necessary to perform model fitting using raw published data. In this case, the freely available NIH image analysis program, ImageJ, is useful for quantifying responses from a graph, and programs such as Gepasi, Berkeley Madonna or MATLAB can be used to fit the extracted data.

There are a number of assumptions underlying the fitting of data to a function in order to extract useful parameters – principally involving the mechanism behind the observation. For example, association and dissociation data usually follow exponential curves, as these are the functions that result from the integration of the mass-action binding equations in Box 1. At times, the observations will be attributable to a more complex mechanism than what can be fitted. In this case, the modeler must decide whether a black box simplification is acceptable or whether experiments should be conducted to investigate the details of interactions.

In addition to kinetic parameters, quantitative modeling requires initial or total concentrations of signaling molecules. In some cases, as with kinetic parameters, these have been estimated directly and can be found in the literature. In other cases, biochemical characterization studies may be amenable to back-calculation of concentration from protein standard curves, enzyme purification tables and cell numbers used (usually one must assume a cell volume, which should be estimated according to cell type). In some cases, one can simulate an enzymatic reaction using Michaelis–Menten kinetics, so concentration and k_{cat} as individual parameters are not even necessary. Enzyme purification and activity tables frequently give the "fold" purification (*FP*; no units) and enzyme activity (*A*; typically expressed in μmol min^{-1} mg^{-1}); these, combined with an assumed protein yield and a few units-conversions, give the V_{max} in μM s^{-1}.

At times, it is not feasible to derive model parameters of interest from the experimental literature and it may be almost impossible to access it experimentally. In these cases, the kinetics of homologous enzymes, or the affinities of proteins with identical interacting motifs, may be used as a starting point for parameter estimation. Thus estimates are then validated by comparing the systems-level behavior of the model with an appropriate experimental assay.

4 Model Validation

4.1 Parameter Variation and Sensitivity Analysis

Once a model has been built, it should be validated. As discussed above, some parameters may not be as critical as others or there may be potentially important connections that were excluded for pragmatic reasons. The principal means of testing whether the behavior of the model system is realistic is through comparison with experimental observations. Time courses for the activation of various model components are often measurable. Phosphorylation, which is commonly an activation step at some point in the system (in cell signaling, usually several), can be detected using phospho-specific antibodies, ^{32}P incorporation or by looking at molecular weight shifts in protein immunoblots. It is preferable to conduct such experiments in-house, in order to control for the variation in experimental factors that can affect response reproducibility, but it may be possible to find the necessary data in the literature. Essentially, this is similar to model fitting and some parameters may need to be "tweaked" (varied by a small amount) in order to reproduce the experimental findings. This differs from the quantification of kinetics by model fitting, which is used to find parameters for the model in its construction. Time course comparisons, by contrast, compare effects that are produced by combinations of many parameters, as is typically of interest in modeling a biological problem.

In addition to testing the conformity of the model with experimental data, parameter variation can be used to identify which parameters are the main determinants of system behavior. Ideally, one should aim to have reliable estimates of these key parameters, whereas less accuracy may be sufficient for noncritical parameters. A more formal type of parameter variation may also be performed, using sensitivity analysis. There are many sophisticated techniques for performing this analysis [22], but all estimate the sensitivity of the output to variations in a particular input variable. Sensitivity analysis is typically sampling based – an algorithm performs the simulation several times with automatic variation across a random or assumed distribution of an input parameter and assesses the effect on the output parameter. It is particularly useful if one is interested in a single, well-defined, output parameter, but a more informal approach to parameter variation can also be very informative if one wishes to obtain a mechanistic understanding of the system as a whole.

4.2 Constraints and Predictions

In some situations, there is inadequate information to model a system with precise mechanistic accuracy. During the process of validation, one may identify an input–output relationship in the model that is behaving unrealistically. One must then decide whether the model needs refining by experimental investigation, i.e. whether the components and reactions in the problematic region are of particular relevance or interest. If not, or if the correct mechanism is experimentally inaccessible, it is possible to constrain the model at that particular level using experimentally derived input–output curves, essentially putting a small "black box" into a peripheral part of the system. In this way, technical limitations need not prevent insight into system dynamics.

Mathematical modeling should be able to make useful predictions that cannot be surmised intuitively. A major advantage to having a model is the ease with which it can be manipulated, and this can yield insights into complex system dynamics. Thus, one can identify key parameters or components that control network behavior. These predictions can then be tested by genetic manipulations that change the concentration of cellular components, and with pharmacological inhibitors of enzymes, which change their kinetic parameters (k_{cat} and/or K_{M}). One long-range goal is to identify network control points that may be utilized to manipulate signaling networks in a clinical setting, to diagnose or treat disease.

5 Perspective

The signaling network connects functionally dedicated cellular “machines”, not only by passing information across the cell via signaling pathways, but also processing information as it traverse the network by network connectivity that results in regulatory motifs. In this way, the system context is taken into account to ensure an appropriate response. In some cases, the signaling system has evolved a limited range of responses and so “switches” between predetermined states. In other cases, signaling is analog, conferring response flexibility.

Signaling systems are undeniably complex, but their elucidation will no doubt prove highly valuable in the understanding and treatment of disease. In many cases, the number of permutations to be investigated experimentally is daunting. Mathematical modeling can offer a formal and convenient approach for discovering systems-level behavior; for determining the roles not only of signaling molecules, but of their “circuitry”. Many insights revealed by modeling are nonintuitive to the biologist and would therefore be difficult to arrive at without a mathematical description of the system. Of course, mathematical predictions need to be confirmed experimentally, but modeling enables us to choose the right types of experiment to understand systems-level behaviors. All understanding is, in a sense, modeling. Textbooks and reviews are replete with cartoons of mechanisms. Implicit in the derivation of these from raw laboratory data is the implementation of a model. The use of mathematics to make explicit predictions constrains the modeling process strictly within the bounds of logic. Specifically, in the field of cell signaling, biochemical kinetic modeling is the gold standard for making predictions. Deterministic modeling is currently the standard approach, while stochastic modeling is often used in situations where the deterministic assumptions are violated.

The technological strides of the last decades are being felt in all realms of biology. Thus, as techniques for experimental measurement improve, the need for more penetrating analysis grows. No doubt the greatest insights into cell signaling will come from advances in systems-level analysis, in which mathematical modeling must necessarily play a leading role.

Glossary

Bistability/multistability The existence of two (bistability) or more (multistability) steady states of activity for a system. This can confer switching behavior, comparable with analog-to-digital signal conversion.

CaMK I–IV Calmodulin-binding protein kinases that require activated calmodulin for their kinase activity.

Coherent/incoherent feedforward loop A feedforward loop is a network motif made up of three or more nodes (see Section 1.2.3) arranged such that there is one input and one output node. These nodes are connected through two separate cascades where the signal splits at the input node and converges at the output node. The feedforward loop is said to be coherent if these two "arms" have the same overall sign (positive or negative) and incoherent if the arms differ qualitatively in their influence on the output.

Compartmental model A model in which space is represented as compartments – discrete mathematical systems, sometimes connected by fluxes of components. Normally, ordinary differential equations are used to represent the reactions in and between the compartments.

Cybernetics A field of science dealing with communication and control in nature and in man-made engineered systems.

Diacylglycerol (DAG) A second messenger generated by the hydrolysis of inositol phospholipids typically by the enzyme phospholipase C. Due to its hydrophobic properties, DAG is in the plasma membrane.

Deterministic model The representation of reactions by rate equations (ordinary differential equations or partial differential equations) such that the outcome of running the model is determined absolutely by the input variables, with no random fluctuations or chance occurrences.

Guanine nucleotide exchange factor (GEF) A regulator that catalyzes the release of guanosine diphosphate, permitting guanosine triphosphate to bind.

GTPase-activating protein (GAP) A protein that stimulates the hydrolysis of guanosine triphosphate to guanosine diphosphate.

Hybrid model The representation of a reaction system by a combination of deterministic and stochastic reaction equations.

Mitogen-activated protein kinase (MAPK) A family of ubiquitous kinase enzymes, regulated by phosphorylation, which control many important cellular functions, such as gene transcription.

Network motif A characteristic pattern of connections between network components that have the potential to perform information processing functions and are statistically enriched in network abstraction of real-world complex systems. Examples include feedback and feedforward loops.

Ordinary differential equation (ODE) A rate equation that describes the change in dependent variables (in biochemical kinetic modeling, concentrations) with respect to one independent variable (usually time).

Partial differential equation (PDE) A rate equation that describes the change of dependent variables (usually concentrations) with respect to two or more independent variables (usually time plus one to three spatial dimensions).

Protein kinase A (PKA or cAMP-dependent protein kinase) A ubiquitous signaling enzyme that has serine/threonine kinase activity. PKA modulates the activity of its targets by covalently attaching a phosphate group to its substrate. PKA phosphorylates a range of targets, depending on cell type, in response to elevated intracellular concentrations of cAMP (adenosine $3',5'$-cyclic monophosphate).

Protein kinase B (PKB or Akt) Serine/threonine protein kinase which mostly acts as a promoter for survival signals. The kinase acts downstream of lipid signaling pathways, e.g. in the insulin receptor signal transduction pathway.

Protein kinase C (PKC) A family of protein serine/threonine kinases divided into two subfamilies: conventional and atypical. Conventional PKCs require calcium and diacylglycerol, and are activated through the Gq and phospholipase C pathway.

Protein kinase D (PKD) Calcium-independent diacylglycerol-dependent serine/threonine kinase; belongs to the PKC family of protein kinases.

Protein kinase G (PKG or cGMP-dependent kinase) A serine/threonine protein kinase activated by cGMP and mostly known for its function in regulating smooth muscle relaxation.

Stochastic model A model in which reactions are simulated according to probability of occurrence rather than rates.

23 Dynamics of Virus–Host Cell Interaction

Udo Reichl and Yury Sidorenko

1 Introduction

For little more than 100 years viruses have been known as small, infectious, obligate intracellular parasites, which efficiently use a wide range of host cells for their reproduction. It was not until the early 20th century when their structural simplicity was revealed by electron microscopy and a first rational classification of viruses based on their morphology was proposed. Over the following decades steady technical advances and enormous progress in molecular biology not only allowed to precisely define structure, molecular composition and synthesis of virus particles, but also to investigate their relationship with their host cells.

The main interest in viruses derives from the understanding of their role as agents responsible for epidemics of contagious diseases. Reports on viral diseases can be found in numerous ancient records, e.g. rabies, polio, smallpox and, probably, influenza. From the earliest times efforts have been undertaken to understand viral pathogenesis, and to prevent and control epidemics. Today, the main focus of academic and pharmaceutical research is on the identification and molecular biology of new and emerging viruses such as human immunodeficiency virus (HIV), hepatitis virus or influenza virus. In addition, enormous efforts are undertaken to prevent viral diseases by vaccines and to develop new vaccine technologies and antiviral drugs.

Viral pathogenesis and virus spreading can be analyzed on several levels (Figure 1), which comprise

- Structural aspects and detailed molecular level interactions of virus and host cell components.
- The interaction of virions with a single host cell.
- The spreading of infectious agents within populations of cells, tissues and organs.
- The infection of an individual resulting in an immune defense.
- The establishment of a viral disease in a host population.

Figure 1 Modeling hierarchy. Virus dynamics can be investigated at different levels ranging from the detailed description of molecular mechanisms relevant for the interaction of viral components with their host cells (e.g. conformational changes of the influenza surface protein HA required for the fusion of viral and host cell membrane) to the spreading of virions in individuals (micro-epidemiology [44]) and populations (traditional epidemiology). Inner box: levels discussed in this chapter.

This chapter focuses on the mathematical modeling of virus replication in single cells and the (intracellular) interaction of virus components with their host cell (structured, unsegregated models; see Section 3). Aspects covered are virus attachment and entry, transcription and translation of viral mRNA, genome replication, assembly, and virus release. Additionally, aspects of host cell defenses, interference with cellular signal transduction networks and the impact of infections on host cell gene expression are addressed. Many of the experimental results required for these models have been derived from one-step growth experiments [10] in static cultures, shake flasks and bioreactors under controlled cultivation conditions where populations of cells are infected at different multiplicity of infection (m.o.i., i.e. the number of infectious units per cell). Therefore, mathematical models describing virus spreading from cell to cell are also discussed briefly (unstructured, unsegregated models; see Section 3).

Mathematical models for intracellular virus–host cell interactions have been developed for a limited number of viruses including bacteriophages, baculoviruses, HIV, Semliki Forest virus and influenza A virus [7, 13, 25, 48, 50, 52]. Most of the existing models address only specific aspects of virus replication such as virus binding, endocytosis or viral RNA synthesis. So far, the impact of viral infections on mammalian cells with regard to their signal transduction processes, genome expression or apoptosis is being investigated mainly experimentally. No attempt has been made to include these results obtained for eukaryotic cells into existing models, e.g. to develop mathematical models, which include virus attachment and viral genome replication as well as aspects of virus-induced apoptosis. However, to cope with the increasing amount of quantitative and semiquantitative data obtained from infection studies and to organize this information into a coherent whole the rigorous use of mathematical modeling and the development of appropriate modeling and simulations tools seems to be indispensable. Therefore, the existing models (even with their limitations and drawbacks) should be considered as a first step towards a quantitative and integrative understanding of virus–host cell interaction and a key factor to establish a systems biology platform for virus dynamics. This platform should allow:

- Simulating virus replication on a cellular level.
- Investigating requirements and limitations of viral growth in a host cell.
- Identifying targets for antiviral compounds.
- Evaluating new therapeutic strategies.
- Optimizing viral-based production systems.

2 Viral Infection of Cells

According to the latest report of the International Committee on Taxonomy of Viruses (ICTV) [4] there are about 3000 identified virus species that infect bacteria, fungi, plants, animal and human cells. The classification of these viruses is based on their shared properties [15], which include the nature of the nucleic acid (DNA, RNA), the symmetry of the capsid, the presence or absence of an envelope and their size (virion diameter, genome length). As obligate intracellular parasites, all viruses have to undergo a series of steps for the successful completion of their life cycle inside their host cell:

- Cell attachment
- Internalization
- Release of viral genome
- Decoding of viral genome information
- Viral protein synthesis
- Viral genome replication
- Virus assembly
- Release of newly produced virions

In addition, the transport of viral genome into the nucleus (most DNA viruses, retroviruses, influenza viruses, etc.), the supply of cellular precursors for viral genome replication and protein synthesis, the intracellular transport of viral components as well as host cell-specific defense mechanisms have to be considered.

Typically, the one-step growth cycle of viruses is experimentally studied in cell cultures under defined conditions. Therefore, their host cells are grown in suspension or monolayer cultures to their optimal growth phase (late logarithmic phase). After the removal of the cell culture medium the virus seed is added with a m.o.i. $>$ 5–10 to guarantee rapid infection of all cells. In a next step the cells are washed to remove any unabsorbed virions, fresh medium is added and the kinetics of virus production is monitored. As an example a one-step growth curve for lytic bacteriophages in *Escherichia coli* is shown in Figure 2. It starts with a lag phase (eclipse period) during which attachment, uncoating, phage synthesis and the intracellular formation of the first complete phages takes place. During this period of time no infectious particles can be detected in the cell culture supernatant (except for a more or less low constant level of infectivity resulting from phages which only attached to their host cells without internalization). After a brief period of exponential increase the number of intracellular infectious particles increases at a constant rate (rise period) due to limitations in the supply of cellular precursors or other limitations in bacterial synthesis capacity. Eventually, metabolism and cell structure of infected bacteria breaks down, and progeny phages are released into the extracellular medium. The burst size corresponds to the number of progeny phages produced per cell. In the following two subsections viral infections in prokaryotic and eukaryotic cells are discussed in more detail.

2.1 Viral Infection of Prokaryotic Cells

Since the 1930s, when the life cycle of bacteriophages in cell cultures was first quantitatively analyzed in *Staphylococcus aureus* [28] and *E. coli* [10], enormous progress has been achieved towards the understanding of bacteriophage–host cell interaction. Mainly, this is due to the vast amount of information available on the molecular biology of the host cells. In particular, for *E. coli*, which was selected as one of the model organisms in systems biology [14], an extensive set of data on macromolecular composition, cellular synthesis rates, signal transduction, gene expression, etc., is available (e.g. Ref. [3]). In addition, bacteria allow for detailed phage growth experiments under well-defined conditions in shake flasks and bioreactors to investigate phage replication with respect to the physiological status of the host cell (e.g. Refs. [23, 64]).

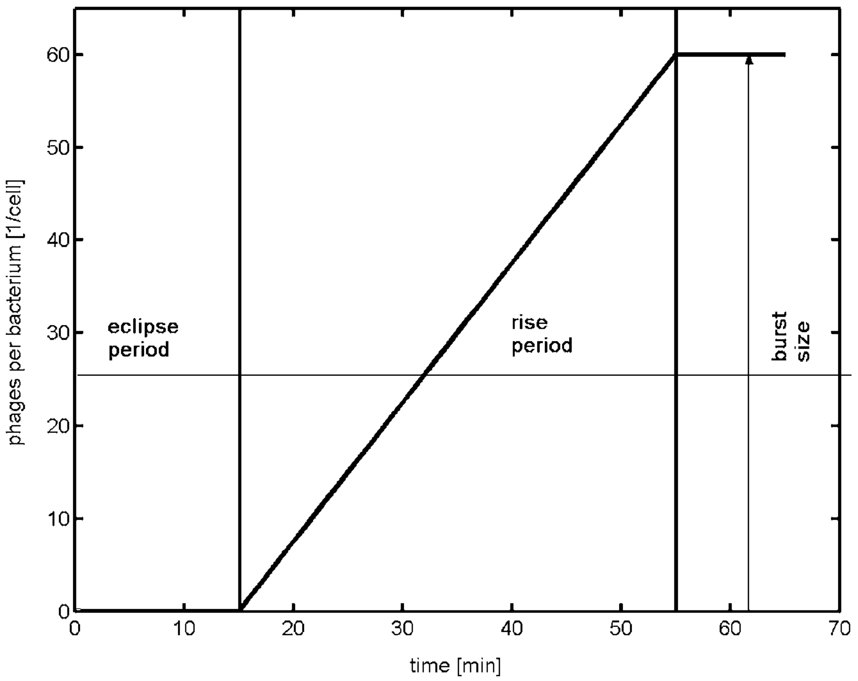

Figure 2 Schematic: intracellular one-step growth cycle of bacteriophages in *E. coli*. After about 15 min p.i. (eclipse period) the intracellular number of progeny phages increases (rise period; assumed rise rate α = 1.5 phages min^{-1}) until phage synthesis ceases due to lysis of the host cell. Here, the burst size is about 60 phages cell^{-1}.

Consequently, mathematical models that describe the intracellular growth cycle of bacteriophages have been developed for more than 15 years at various levels of complexity. Rabinovitch and coworkers [48], for instance, show that simple mathematical relations can be used to describe one-step growth experiments for bacteriophage T4 development in *E. coli* (see Section 3.1). In addition, the influence of bacterial growth rate on phage development [47] and the kinetics of bacterial lysis by phages are investigated in detail in Ref. [49]. In contrast, highly structured models (see Section 3.1) for the intracellular growth of other bacteriophages (T3/T7) in *E. coli* have been developed by various research groups (e.g. Refs. [5,13,65]). With such models a first attempt has been made to quantitatively understand phage replication at a molecular level. Based on the extensive set of data available for the genetics, physiology and macromolecular composition of host cells, aspects of phage gene replication, phage protein synthesis, phage assembly and its dependence on host physiology were investigated. Other mathematical models have been developed to describe the use of intracellular resources and energy consumption for the growth of phage Qβ in *E. coli* [27]. Here, it could be shown that protein synthesis of phages, particularly translation at the ribosomes, dominates phage growth. This observation is in agreement with the energy requirements of exponentially growing bacteria [56] as well as with the influence of ribosome number and protein synthesis rate per ribosome on the growth rate of exponential cultures [3]. Furthermore, it could be shown that phages efficiently use host cell resources and that overall yields are comparatively insensitive to changes in model parameters such as RNA-to-ribosome or RNA-to-replicase binding.

2.2 Viral Infection of Eukaryotic Cells

Research on growth characteristics and genetic properties of viruses infecting eukaryotic cells dates back into early 1950s when Dulbecco analyzed plaques of western equine encephalomyelitis virus in primary chicken fibroblast cultures [9]. Over the following years continuous improvements in the cultivation of cells, the generation of immortal cell lines and advances in assay techniques allowed us to investigate the life cycle of plant, animal and human viruses under precisely controlled conditions in analogy to the one-step growth cycle experiments of bacteriophages. Since then, our understanding of the molecular basis of virus–host cell interaction in eukaryotic cells has improved considerably. In particular, viruses infecting animals and humans have attracted enormous research efforts to prevent and treat viral infections as well as to avoid the spread of viral diseases. Today, highly efficacious vaccines are available against a number of viral diseases such as smallpox, polio, influenza or hepatitis A. In addition, new vaccine technologies, e.g. viral vectors and DNA vaccines, are being developed to complement existing vaccines or as potential candidates for HIV vaccines (see Chapter 39). Eventually, research concerning the molecular mechanisms of virus–host cell interaction has become a prerequisite for the development of antiviral drugs and serves as a powerful tool for understanding fundamental aspects of cellular functions.

So far, most mathematical models which describe the intracellular virus life cycle in eukaryotic cells focus either on the initial steps of the virus infection cycle or omit some intermediate steps of the replication cycle such as transport processes across cell compartments or turnover of cellular pools of precursors required for viral genome and protein synthesis. Mainly, these models have been developed for biotechnology and biomedical applications.

In biotechnology, the majority of these mathematical models have been developed to describe dynamic aspects relevant for the production of viruses or recombinant viral proteins in cell cultures. A model from Dee and coworkers in 1995 [7] for the early steps of the infection cycle of Semliki Forest virus considers the initial steps of virus trafficking in baby hamster kidney cells (BHK-21). In addition to the binding of the viruses to the cell surface receptors, endocytosis and RNA synthesis are taken into account. However, neither viral protein synthesis nor assembly or release of progeny virus particles are considered. A similar model was used later by the same group to investigate options to design infection strategies for baculovirus production in insect cell cultures [8]. In a further modeling approach baculovirus replication in insect cells for the manufacturing of recombinant proteins was investigated by Jang and coworkers in 2000 [25]. The model considers cellular metabolism and key features of the infection cycle of baculovirus, but focuses mainly on recombinant protein production. Therefore, attachment kinetics, cellular transport or available pools of amino acids, nucleotides and energy requirements for virus synthesis are not addressed.

Mathematical models of intracellular virus growth can also be useful for biomedical applications, e.g. to support the evaluation of anti-HIV strategies or to improve our understanding of virus-mediated diseases on a cellular level. Based on the extensive information available on molecular aspects of HIV-1 replication, Reddy and Yin [50] have formulated a highly structured model of the virus growth cycle in CD4$^+$ T lymphocytes. The model covers most of the key features of the replication cycle from the reverse transcription of the viral genome and its integration into the host genome to virus budding in maturation. Based on the model it was not only possible to quantitatively describe the dynamics of transcription, translation and virion production, but also to investigate the influence of potential drug targets for anti-HIV therapies.

In contrast to the replication of phages in bacteria, a quantitative understanding of the interaction of viruses with eukaryotic cells is more difficult to obtain for a number of reasons. First, cellular growth, gene expression, protein synthesis, transport processes and metabolism in eukaryotes are far more complex compared to bacteria. Second, eukaryotic cells are highly structured containing various specialized compartments relevant for virus replication, e.g. the different compartments of the secretory pathway required for covalent modifications, transport and apical sorting of influenza virus membrane proteins. Third, several cellular key processes required for a comprehensive understanding of virus–host cell interaction are the subject of current research activities and are not elucidated in sufficient detail to be used in mathematical models for virus dynamics. These include cellular signal transduction processes, in particular the specific interaction of viruses or viral proteins with signal transduction networks of their host cell, and specific and unspecific defense mechanisms of host cells, such as the production of interferon and the impact of viral gene products on programmed cell death (apoptosis) of infected cells [35, 36]. Fourth, comprehensive data sets (and mathematical models) available for growth and physiological status of "model organisms" such as *E. coli* are not available for higher cells, except for the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* [14]. So far, no animal or human "model cell" has been selected and thoroughly characterized with respect to general aspects of its structure, growth, metabolism and, specifically, virus–host cell interaction. For example, while the first steps have been made to develop detailed mathematical models for the replication of HIV in $CD4^+$ T lymphocytes [50] or influenza A virus in animal cells [52], most kinetic parameters, synthesis and degradation rates as well as quantitative information on cellular composition had to be taken from numerous publications and textbooks. An additional problem is the fact that present data is derived from experiments performed under various cultivation conditions, obtained from different cell lines, virus strains and subtypes. Therefore, the status of mathematical models available for the description of key processes of the host cells themselves is still far from being satisfactory. However, despite all the complexity of eukaryotic host cells and the considerable diversity of viruses, it can be expected that extensive research efforts in this exciting field will finally allow us to derive fundamental laws that govern virus–host cell interaction and understand at least part of its enormous complexity.

3 Mathematical Models of Virus Dynamics

Mathematical modeling plays a crucial role for a quantitative understanding of intracellular virus dynamics. Based on the theoretical framework of such a model it is possible to systematically structure experimental data, to analyze biological systems of high complexity and to predict the system's behavior at any moment of time. Additionally, a model allows the investigation of parameter sensitivity and robustness of biological systems, e.g. to examine the influence of changes in intracellular metabolite concentrations, protein synthesis and degradation rates or attachment rates on virus yield per cell. Based on a model it is eventually possible to identify key components and their relationships as well as bottlenecks within biological systems, and to use this information for optimization and design of bioprocesses. However, no matter what approach is finally used one key question should be always answered beforehand: "what its use is and what problem it is intended to help to solve" [2].

Quantitative mathematical models of biological systems can be set up in several ways, ranging from mechanistic descriptions based on algebraic expressions and differential equations to stochastic approaches. A classification for cell populations, which has found general acceptance in biochemical engineering, was introduced by Frederickson [2,16,58]. In this context, the simplest models of virus dynamics can be formulated by *unstructured* or *structured* approaches [32]. An “unstructured” model does not consider intracellular phenomena. For example, the basic dynamics of viral growth in a bioreactor would be modeled by a system of three differential equations which describe how the number of uninfected cells, infected cells and free virus particles changes over time. Assuming that cells do not differ in composition, cell cycle phase, etc. (“average cell”), the cell population is designated “unsegregated”. In contrast, in a “structured” approach, different state variables are used to model virus replication in different cellular compartments such as the membrane, endosome, cytoplasm or nucleus. Based on genetic and molecular mechanistic data, rate equations are expressed for viral transcription, translation, protein expression and reactions catalyzed by virus-encoded enzymes. The most complex description is obtained by detailed models of intracellular virus growth and spreading in a population of heterogeneous individual cells [24]. Obviously, such a “structured segregated” approach represents the most realistic scenario to describe the progression of viral infections in populations of cells or individuals.

3.1 Unstructured Models of Virus Dynamics

Basic intracellular virus dynamics can be described by an approach developed by Rabinovitch and coworkers for the replication of bacteriophage T4 in *E. coli* [48]. The infection cycle is described by three parameters: an eclipse period ν until the first phage is completed in the bacterium, a constant rise rate α at which intracellular phages accumulate and a latent period λ (eclipse period + rise period) when the bacterium bursts and phages are released into the extracellular medium (Figure 2). The burst size B that corresponds to the number of released phages after cell lysis is defined by:

$$B = \alpha(\lambda - \nu).$$

Typical values for the burst size B are in the range of 10 to several hundred bacteriophages produced per infected bacterium after an eclipse period ν of 18–42 min at a rise rate α of 2–47 phages min^{-1} depending on experimental conditions and corresponding *E. coli* strain. Similar results were obtained by You and coworkers [64] who investigated the growth of phage T7 in *E. coli* in continuous culture under different dilution rates in a chemostat.

Another unstructured approach comprises the description of virus dynamics in a population of host cells by a system of differential equations. As an example, a basic model that describes the replication of influenza A virus in adherent Madin-Darby canine kidney (MDCK) cells in a bioreactor for inactivated vaccine production is briefly discussed in the following [39]. The time-delayed model considers three variables: the number of uninfected cells

U_C, infected cells I_C and free virus particles V. The number of uninfected cells U_C increases with a specific cell growth rate μ, while cells die with a specific cell death rate k_{cdf} due to process conditions. The rate of infection is proportional to the product of the concentration of uninfected cells U_C, the concentration of free virions V, and the virus infection rate k_{vi}:

$$\frac{\mathrm{d}U_\mathrm{C}}{\mathrm{d}t} = \mu \cdot U_\mathrm{C} - k_\mathrm{cdf} \cdot U_\mathrm{C} - k_\mathrm{vi} \cdot U_\mathrm{C} \cdot V \; .$$

Infected cells I_C disintegrate with a specific cell death rate k_{cdv}, mainly due to virus induced cell damage:

$$\frac{\mathrm{d}I_\mathrm{C}}{\mathrm{d}t} = k_\mathrm{vi} \cdot U_\mathrm{C} \cdot V - k_\mathrm{cdv} \cdot I_\mathrm{C} \; .$$

After a time delay τ (for m.o.i. > 1 corresponding to the latent period defined above) infected cells start to release progeny virus into the extracellular medium. The specific virus replication rate is μ_{vir}. Released virions are either degraded with a specific rate k_{vd} or adsorbed by uninfected, susceptible cells U_C with a specific attachment rate k_{va}:

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \mu_\mathrm{vir} \cdot I_\mathrm{C}(t - \tau) - k_\mathrm{vd} \cdot V - k_\mathrm{va} \cdot U_\mathrm{C} \cdot V \; .$$

Adherent MDCK cells only proliferate in a bioreactor if attached to a microcarrier and growth slows down by contact inhibition. Main substrates of energy metabolism such as glucose and glutamine, as well as inhibiting metabolites such as lactate and ammonium, do not reach critical levels during virus replication [20]. Therefore, the degree of contact inhibition, determined by the maximum number of cells supported by the surface area of the carriers C_{max} (about 500) and the capacity used by infected and uninfected cell, is regarded as the only influence reducing the maximum growth rate μ_{max}:

$$\mu = \mu_\mathrm{max} \cdot \frac{C_\mathrm{max} - (U_\mathrm{C} + I_\mathrm{C})}{C_\mathrm{max}} \; .$$

Experimental results show that it takes about 4–6 h before visibly infected cells can be identified by light microscopy followed by a strong increase in virus titers [measured by a hemagglutination (HA) assay, an indirect method to quantify virus particles in suspension] after 10–12 h in the supernatant (Figure 3). After infection at low m.o.i. and typical process conditions, the maximum virus yield V_{max} is about 5×10^9–1×10^{10} virions ml^{-1} with a burst size of about 10 000–20 000 virus particles per infected cell. Simulation results show that small variations (below 10%) in initial values and specific rates do not influence V_{max} significantly. The main parameters relevant for obtaining maximal virus yields are specific virus replication rate and specific

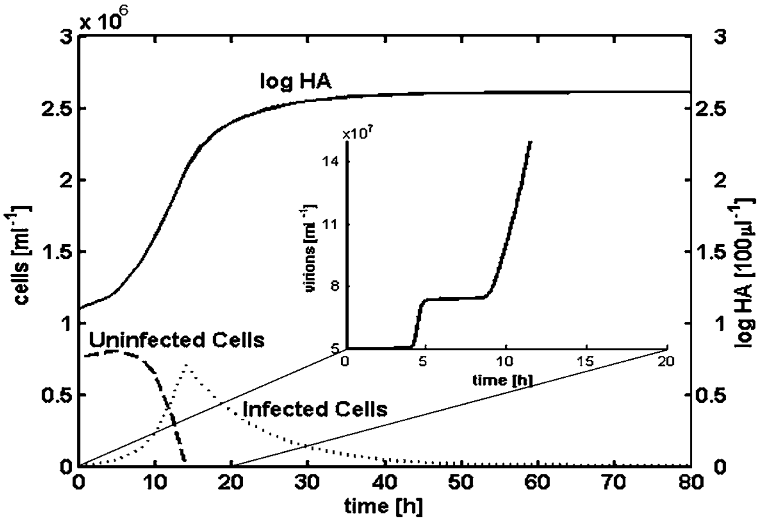

Figure 3 Unstructured time delay model for influenza A virus infection of a population of MDCK cells in a bioreactor at low m.o.i.: uninfected cells (dashed line), infected cells (dotted line) and the total number of virions produced (solid line) expressed in log HA units [39]. Inset: increase in virus particle number during the first hours post infection.

cell death rate due to infection. Similar models focusing on biotechnological applications of baculoviruses have been developed by Licari and Bailey [32], Nielsen [43], Enden and coworkers [12], and others. In addition, models with an equivalent structure have been introduced by Gilchrist and coworkers [21] and Nelson and coworkers [41] to describe immunological aspects and infectious diseases. An excellent overview on virus dynamics in micro-epidemiology is given by Nowak and May [44].

3.2 Structured Models of Virus Dynamics

Structured approaches have been developed to investigate one-step virus infection cycles in bacteria, insect and animal cells. A mathematical model for bacterial viruses, considered by Endy and coworkers [13], examines the replication of bacteriophage T7 in *E. coli*. The model provides a complete picture of the phage growth cycle. It describes individual steps of infection, including transcription of DNA, translation of mRNA and progeny phage assembly. In a similar way the quantitative intracellular kinetics of HIV type 1 was modeled by Reddy and Yin [50]. Typically, these models consist of a system of coupled differential equations comprising 10–50 differential equations and a minimum of 40–100 parameters and initial conditions. In addition, models that include stochastic events have been introduced (e.g. Ref.

[55]). As an example for structured models of virus replication, a dynamical model for the life cycle of influenza A virus in animal cells is discussed in more detail in the following Section.

4 Influenza Virus as an Example for Virus–Host Cell Interaction

Influenza virus is a lipid-enveloped negative-strand RNA virus that belongs to the Orthomyxoviridae family. Among the three types of influenza (A, B and C), influenza A virus is the best characterized. It causes respiratory infections that result in severe human and animal suffering with high economic losses. Conservative estimations indicate that in case of a human influenza pandemic 2–7 million people would die and tens of millions would need medical attention [61]. During the annual epidemics about 5–15% of the world population is affected with 250 000–500 000 deaths [60]. Influenza virus replication was thoroughly investigated by many groups, and a number of excellent books and reviews give a detailed description of its biological properties, the molecular composition of virions and the life cycle in its host cells [15,31,36,42,59].

Due to the detailed characterization of structure and life cycle of the influenza A virus, the availability of well-characterized cell systems for studying virus propagation in animal and human cell lines under controlled conditions and its relevance as a human pathogen, influenza A virus is (next to bacteriophages and HIV) an excellent “model virus” for systems biology. So far, the overwhelming number of studies on the influenza A virus life cycle have focused on the qualitative characterization of virus attachment, endocytosis, protein expression, genome replication, budding and release. In addition, a few mathematical models are available which describe molecular mechanisms of individual steps such as virus binding and endocytosis (e.g. Refs. [22, 38, 45]). In the following a first step towards a structured mathematical model, which describes the complete influenza A life cycle in animal cells is presented. The purpose of this model is 2-fold: (i) to analyze the key processes of virus replication at a cellular level, and (ii) to better understand rate-determining steps and factors limiting intracellular virus growth in mammalian cells for the design and optimization of virus-related production processes for recombinant proteins, classical vaccines and viral vectors for gene therapy. In the following sections key steps of the influenza A virus life cycle are described in more detail (Section 4.1). Then a structured mathematical model is introduced (Section 4.2) with simulation results for influenza virus growth dynamics (Section 4.3). The section ends with a discussion and an outlook on several aspects of influenza–host cell interaction not included into mathematical models so far (Section 4.4).

4.1 The Influenza A Virus Life Cycle

A schematic overview on the key steps of influenza A virus replication in animal cells, for example in adherent MDCK cell used for vaccine production [20], is given in Figure 4. The influenza A virus life cycle comprises the following steps:

1) Attachment to the apical membrane of the host cell and receptor-mediated endocytosis.
2) Uncoating and transfer of viral ribonucleoprotein complexes (vRNPs) into the nucleus.
3) Viral genome replication: transcription of (–) strand viral RNA [vRNA(–)] to (+) strand viral messenger RNA [vmRNA(+)].
4) Synthesis of complementary (+) strand RNAs [cRNAs(+)] and then vRNAs(–).
5) Translation of viral capsid, nonstrucctural and matrix proteins from vmRNAs(+).
6) Translation of viral envelope proteins from vmRNAs(+).
7) Packaging of progeny vRNPs and export to apical cell membrane.
8) Budding and release of progeny virions from the plasma membrane.

Influenza A virus infects humans and a wide variety of animals, including pigs, horses, ferrets and birds. In mammals, the virus replicates in epithelial cells of the upper respiratory tract, but *in vitro* it can also infect many other cell types that possess sialic acid-containing cellular surface proteins. The genome of influenza A virus is segmented and consists of eight vRNAs(–) of different size associated with nucleoproteins (NP) and three polymerases (PB1, PB2 and PA) involved in viral RNA transcription and viral genome replication. PB1 is a catalytic subunit of the viral RNA transcriptase and replication complex which catalyses the nucleotide addition during the elongation of the vmRNA(+) transcript. In addition, it has endonuclease activity. PB2 is a cap-dependent endonuclease, which is responsible for both binding and cleavage of capped cellular mRNA to generate primers for vmRNA(+) synthesis. PA is essential for viral genome replication; however, its actual role is not fully understood. The arrangement of vRNAs(–), NP proteins and the three associated polymerase proteins is called the vRNP or nucleocapsid. The vRNP complexes are enclosed within a shell composed of matrix protein (M1, the major component of virions) associated with a lipid membrane derived from the host cell. Embedded in the plasma membrane are three envelope proteins:

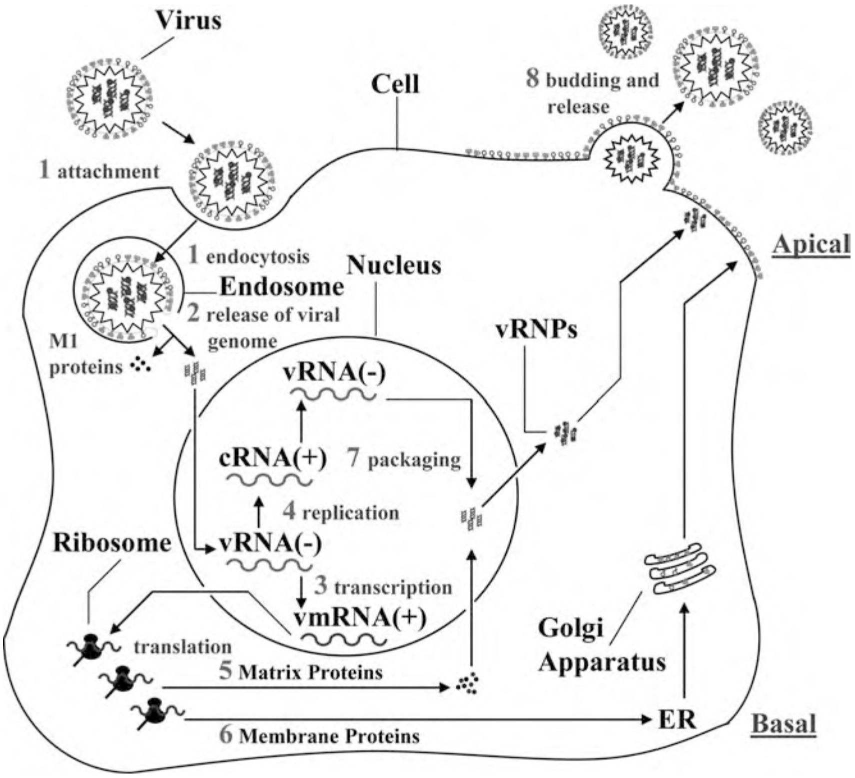

Figure 4 Single-cell reproductive cycle of influenza A virus. Different steps are numbered according to the virus life cycle discussed in Section 4 (adapted from Ref. [52] with permission).

HA, the major surface protein with sialic acid binding and membrane fusion activity at low pH, neuraminidase (NA) involved in virus release and an ion channel protein (M2). In addition, influenza virions contain NS2 proteins, also called *nuclear export proteins*.

Each of the viral genes has been sequenced completely for influenza A virus PR/8/34 and many other isolates of the different virus subtypes [19]. Eight genome segments encode 10 viral proteins. Nine of them are incorporated into the virus particle, except for the nonstructural protein NS1 – a regulatory factor with several activities which include the inhibition of cellular pre-mRNA 3′-end cleavage and polyadenylation, the inhibition of cellular pre-mRNA splicing in the nucleus, and the inhibition of the interferon-mediated cellular response to virus infection. Six genome segments encode one viral protein. The others contain two open reading frames (ORF), encoding for M1 and M2 proteins and NS1 and NS2 proteins, respectively. Recently a novel protein PB1-F2 was discovered, which is encoded by a second ORF, within the viral

RNA of PB1. The protein seems to participate in the induction of apoptosis and also seems to be involved in killing host immune cells responding to influenza virus infections. This protein was shown to be nonessential for virus replication *in vitro* and is therefore not considered in the model.

The following individual steps of the virus life cycle (Figure 4) including modeling assumptions concerning initial conditions, cellular resources and replication mechanisms are considered in the model.

(i) *Virus entry into the host cell.* Influenza virus particles attach to *N*-acetylneuraminic (sialic) acid-containing receptors on their host cell via the viral HA glycoprotein. In a next step, the virions are taken up into the cell by a clathrin-dependent receptor-mediated endocytosis. While several other entry pathways for influenza virus are also reported [53, 54], the model considers only the endocytic pathway, which seems to be the most common.

(ii) *vRNP uncoating and transport into the nucleus.* The delivery of the vRNPs into the cytoplasm of their host cell is a multistep process. After a pH drop in the endosome to approximately pH 5.0, viral M2 ion channels are activated, which allows protons to enter the interior of the virus particle. Upon acidification, HA molecules undergo conformational rearrangements mediating the fusion of the viral membrane with the endosomal membrane. Acidification also facilitates the dissociation of vRNPs from M1 matrix proteins. As a consequence, individual vRNPs are released into the cytoplasm of their host cells. The import of vRNPs into the nucleus is mediated by nuclear localization signals, carried by NP proteins. Since M1 proteins inhibit the import into the nucleus through the nuclear pore complexes (NPCs), their detachment from vRNPs plays a crucial role at this step. Virus particles, which do not fuse with the membrane, e.g. virions with defective M2 ion channels, are eventually degraded by lysosomes.

(iii) *Transcription [vmRNA(+) production].* Three types of viral RNAs are synthesized in the cellular nucleus: viral mRNAs of positive polarity [vmRNA(+)], viral genomic RNAs of negative polarity [vRNAs(–)] and complementary RNAs of positive polarity [cRNAs(+)]. Influenza virus vmRNAs(+) contain a cap structure at the 5′ end and a poly(A) tail at the 3′ end, which are derived from cellular precursor mRNAs. Their synthesis is catalyzed by the viral polymerase complex and comprises several steps. Splicing of M and NS vmRNAs(+) also occurs in the nucleus, and seems to be regulated by NS1 proteins. Newly synthesized vmRNAs(+) are exported from the nucleus to the ribosomes in the cytoplasm via nuclear pore complexes (NPCs) or degraded.

(iv) *Viral genome replication.* Viral genome replication involves the synthesis of full-length cRNAs(+), which serve as templates for vRNA(–) strands. Newly replicated vRNAs(–) are used for the production of further vmRNAs(+) and cRNAs(+) as well as for the assembly of vRNP complexes. While PB1 and PB2 proteins carry out transcription, genome replication requires PB1 and PA subunits of the viral polymerase complex. It was also shown that NP proteins not only mediate the nuclear import of vRNPs, but also participate in the switch from vmRNA(+) synthesis to viral genome replication. In addition it is assumed that all viral RNAs are degraded to a certain extent in the nucleus.

(v) *Capsid, nonstructural and matrix protein production.* Viral proteins (PB1, PB2, PA, NP, NS1, NS2 and M1) are synthesized at maximum rate by ribosomes organized in polysome complexes. At the same time the translation of cellular mRNAs seems to be inhibited. The mechanisms of a selective translation of vmRNAs(+) are poorly understood so far. There are three possible mechanisms for the inhibition of cellular protein synthesis [46]. One of them involves the degradation of cellular precursor mRNAs in the nucleus. Another option is the inhibition of the translation of cellular mRNAs at the initiation and elongation steps. Finally, cellular protein production seems to be inhibited by retarding the transport of cellular mRNAs to the cytoplasm. The newly synthesized polymerases as well as matrix and nonstructural proteins are transported to the nucleus, where they participate in M and NS mRNA splicing, transcription and viral genome replication. Additionally, they are consumed for the production of new vRNP complexes.

(vi) *Envelope protein production.* M2, HA and NA protein synthesis is carried out by membrane-bound ribosomes. Newly synthesized envelope proteins are translocated across the membrane of the endoplasmic reticulum (ER), glycosylated and transported out of the ER to the Golgi apparatus. Finally, they are delivered to the apical membrane of their host cell for the assembly with vRNP complexes and budding.

(vii) *Packaging.* The formation of vRNP complexes takes place in the cellular nucleus. Newly synthesized PB1, PB2, PA, NP and NS2 proteins associate with vRNAs and M1 proteins forming vRNP–M1–NS2 complexes, which mediate nuclear export. M1 proteins inhibit the re-import of vRNP complexes, while nuclear export signals of NS2 proteins seem to be required to overcome the nuclear import signals of NP proteins.

(viii) *Virus budding and release.* In the last step vRNP–M1–NS2 complexes interact with the cytoplasmic tails of M2, HA and NA proteins, which leads to the formation of a bud at the apical membrane of polarized epithelial cells. Host cell membrane proteins seem to be excluded from the newly formed progeny virions. Eventually, buds separate from the cellular surface and virions are released to the extracellular medium. The model assumes that eight influenza virus vRNP complexes are packaged per virion.

4.2 Mathematical Model of the Influenza A Virus Life Cycle

The model considers an "average" cell, which is immersed in a small volume of medium (1 nL) and infected by a low number of influenza virus particles (10 virions cell^{-1}), which survives about 10–12 h post-infection (p.i.). Only one replication cycle is taken into account without re-infection of the cell by newly released progeny virus. Additionally, it is assumed that cellular protein synthesis is shut off after infection and that infected cells do not divide. The model is represented by a system of 43 nonlinear ordinary differential equations (ODE) and 81 parameters. About half of these parameters (42) are confirmed by our own experiments or taken from literature. The non-confirmed parameters (39), e.g. degradation rate coefficients and parameters describing the switch from vmRNA(+) synthesis to viral genome replication, were estimated according to the average duration of individual replication steps and overall virus dynamics. In the following only aspects of the virus life cycle that are relevant for the results presented later (Section 4.3) are briefly discussed. A complete list of all equations, initial conditions, and kinetic parameters is given in the Appendix.

Infection starts with the virus entry into the host cells (also see Appendix, 1):

$$\frac{\mathrm{d}V_{\mathrm{ex}}}{\mathrm{d}t} = -k_{\text{ex-s},V_{\mathrm{ex}}} V_{\mathrm{ex}} + k_{\text{s-ex},V_{\mathrm{ex}}} V_{\mathrm{s}}$$

$$\frac{\mathrm{d}V_{\mathrm{s}}}{\mathrm{d}t} = k_{\text{ex-s},V_{\mathrm{s}}} V_{\mathrm{ex}} + k_{\text{s-ex},V_{\mathrm{s}}} V_{\mathrm{s}} - k_{\text{s-end}} V_{\mathrm{s}}$$

where t is the time measured in hours, V_{ex} and V_{s} represent the number of virus particles in the extracellular medium and on the cellular surface. The rate coefficient of virus binding to the cellular surface receptors is $k_{\text{ex-s},V_{\mathrm{ex}}}$. The rate constant of virus dissociation from the surface is $k_{\text{s-ex},V_{\mathrm{ex}}}$. The rates $k_{\text{ex-s},V_{\mathrm{s}}}$ and $k_{\text{s-ex},V_{\mathrm{s}}}$ are related to $k_{\text{ex-s},V_{\mathrm{ex}}}$ and $k_{\text{s-ex},V_{\mathrm{ex}}}$, respectively, via $k_{\text{s-ex},V_{\mathrm{s}}} V_{\mathrm{s}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}} k_{\text{ex-s},V_{\mathrm{ex}}}$, and $k_{\text{s-ex},V_{\mathrm{s}}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}} k_{\text{s-ex},V_{\mathrm{ex}}}$, where U_{r} is the medium volume, containing N_{cells} cells ($N_{\mathrm{cells}} = 1$). Usually, cells are infected with a small number of virions. Therefore, the number of cellular receptors, which is in the range of 10^4–10^5 receptors per cell (see Appendix, Table A1), significantly exceeds the number of virus particles binding to the cell surface and does not represent a limiting factor for virus entry. Consequently, a Michaelis–Menten-type kinetics is not considered and it is assumed that $k_{\text{ex-s},V_{\mathrm{ex}}}$ as well as $k_{\text{s-ex},V_{\mathrm{ex}}}$ is constant. Virus uptake via clathrin-coated pits is omitted in the model and viruses attached to the cellular membrane are assumed to penetrate directly into endosomes. Typically, there are several hundred endosomes per cell. Therefore, their number significantly exceeds the number of endosomes containing virus and the rate of endocytosis is assumed constant.

The next steps comprise vRNP uncoating and transport into the nucleus (see Appendix, 2) via NPCs, which is in the range of 3000–4000 pores per cell. At low m.o.i. only a small percentage of the NPCs is involved in the transfer of vRNPs into the nucleus at time of infection. With the transfer of vRNPs into the nucleus the synthesis of vmRNAs(+) starts (also see Appendix, 3):

$$\frac{\mathrm{d}C_{i,\mathrm{nuc}}}{\mathrm{d}t} = k_{\mathrm{v\text{-}vm},i} P_{\mathrm{Pol,nuc}} - k_{\mathrm{vm},i,\mathrm{nuc\text{-}cyt}} C_{i,\mathrm{nuc}} - k_{\mathrm{vm},i,\mathrm{nuc\text{-}degr}} C_{i,\mathrm{nuc}}$$

$$\frac{\mathrm{d}C_{i,\mathrm{cyt}}}{\mathrm{d}t} = k_{\mathrm{vm},i,\mathrm{nuc\text{-}cyt}} C_{i,\mathrm{nuc}} - k_{\mathrm{vm},i,\mathrm{cyt\text{-}degr}} C_{i,\mathrm{cyt}}$$

$$i \in [\mathrm{Pol, NP, M1, NS1, NS2, M2, HA, NA}]\,,$$

where $C_{i,\mathrm{nuc}}$ is the number of vmRNAs(+) encoding the i-th protein in the nucleus, $C_{i,\mathrm{cyt}}$ is the number of vmRNAs(+) in the cytoplasm, and $P_{\mathrm{Pol,nuc}}$ is the number of polymerase complexes in the nucleus. The first term ($C_{i,\mathrm{nuc}}$) in the right-hand side of the first equation is the rate of vmRNA(+) synthesis in the nucleus. All three polymerase subunits and their corresponding vRNA(–) are considered as one unit. The polymerase complexes are assumed to operate at the same speed, so the first term is proportional to $P_{\mathrm{Pol,nuc}}$. The rate coefficient $k_{\mathrm{v\text{-}vm},i}$ of vmRNAs(+) synthesis depends on the number of vRNAs(–) in the nucleus C_{v} (see Appendix, 4.2) and on $P_{\mathrm{NP,nuc}}$, the number of NP molecules in the nucleus which are assumed to regulate the switch from vRNA(–) transcription to viral genome replication depending on their nuclear concentration (see Appendix, 5.2). In addition, it is assumed that the rate of the process is not limited by C_{v}. Every polymerase complex is involved in transcription and all polymerase complexes operate at the same speed. As mentioned above, NP proteins are assumed to inhibit the production of vmRNAs(+). Consequently, $k_{\mathrm{v\text{-}vm},i}$ should be maximal when $P_{\mathrm{NP,nuc}} = 0$ and should tend to zero when $P_{\mathrm{NP,nuc}} \to \infty$. Taking all this into account, it is assumed that $k_{\mathrm{v\text{-}vm},i} = k_{\mathrm{v\text{-}vm},i,\mathrm{max}} \frac{1}{1+a_{\mathrm{NP}} P_{\mathrm{NP,nuc}}}$, where a_{NP} is a positive parameter. Here, a_{NP} represents an inverse concentration of NP proteins at which $k_{\mathrm{v\text{-}vm},i} = \frac{1}{2} k_{\mathrm{v\text{-}vm},i,\mathrm{max}}$. It is a_{NP} that defines the influence of NP proteins on vmRNA(+) production. The rate coefficients of viral mRNA nuclear export and degradation are $k_{\mathrm{vm},i,\mathrm{nuc\text{-}cyt}}$ and $k_{\mathrm{vm},i,\mathrm{nuc\text{-}degr}}$, respectively. The rate constant of cytoplasmic vmRNA(+) degradation is $k_{\mathrm{vm},i,\mathrm{cyt\text{-}degr}}$. A splicing of M and NS mRNAs is not considered in the model.

Viral genome replication is modeled in a similar way (see Appendix, 4):

$$\frac{\mathrm{d}C_{\mathrm{c}}}{\mathrm{d}t} = k_{\mathrm{v\text{-}c}} P_{\mathrm{Pol,nuc}} - k_{\mathrm{c\text{-}degr}} C_{\mathrm{c}}$$

$$\frac{\mathrm{d}C_{\mathrm{v}}}{\mathrm{d}t} = k_{\mathrm{c\text{-}v}} P_{\mathrm{Pol,nuc}} + k_{\mathrm{spl},C_{\mathrm{v}}} S_{\mathrm{nuc}} - k_{\mathrm{un},C_{\mathrm{v}}} C_{\mathrm{v}} \prod_{l} P_{l,\mathrm{nuc}} - k_{\mathrm{v\text{-}degr}} C_{\mathrm{v}}\,,$$

$l \in [\mathrm{Pol}, \mathrm{NP}, \mathrm{M}, \mathrm{NS2}]$,

where C_c is the number of cRNAs(+), C_v is the number of vRNAs(–) and $P_{l,\mathrm{nuc}}$ is the number of molecules of the l-th protein in the nucleus. The rate coefficients of cRNA(+) and vRNA(–) synthesis are $k_{\text{v-c}}$ and $k_{\text{c-v}}$, respectively. Assuming that all vRNA molecules are synthesized at similar rates [63], it is not necessary to describe their numbers by different functions. Furthermore, it is assumed that every polymerase complex participates in either positive or negative strand synthesis. Neither C_v nor C_c limit the rate of the corresponding process because their number exceeds the number of polymerase complexes. Since a high concentration of NP proteins activates genome replication, $k_{\text{v-c}}$ and $k_{\text{c-v}}$ should have maximum values when $P_{\mathrm{NP,nuc}} \to \infty$ and be equal to zero when $P_{\mathrm{NP,nuc}} = 0$. Thus, it is assumed that $k_{\text{v-c}} = k_{\text{v-c,max}} \frac{P_{\mathrm{NP,nuc}}}{b_{\mathrm{NP}} + P_{\mathrm{NP,nuc}}}$ and $k_{\text{c-v}} = k_{\text{c-v,max}} \frac{P_{\mathrm{NP,nuc}}}{b_{\mathrm{NP}} + P_{\mathrm{NP,nuc}}}$. Here, b_{NP} is a positive parameter that defines the influence of NP proteins on viral genome replication. It represents the concentration of NP proteins at which $k_{\text{v-c}} = \frac{1}{2} k_{\text{v-c,max}}$ and $k_{\text{c-v}} = \frac{1}{2} k_{\text{c-v,max}}$. The rate constants of cRNA(+) and vRNA(–) degradation are $k_{\text{c-degr}}$ and $k_{\text{v-degr}}$, respectively. The rate constants of vRNP splicing $k_{\mathrm{spl},C_\mathrm{v}}$ and $k_{\mathrm{spl},S_\mathrm{nuc}}$ (see Appendix, 2.2) are given by $k_{\mathrm{spl},C_\mathrm{v}} = C_{\mathrm{seg}} k_{\mathrm{spl},S_\mathrm{nuc}}$ and $k_{\mathrm{spl},P_{i,\mathrm{nuc}}} = P_{i,\mathrm{seg}} k_{\mathrm{spl},S_\mathrm{nuc}}$, respectively, where C_{seg} is the average number of nucleotides contained in one segment. [Influenza A (A/PR/8/34) consists of about $C_{\mathrm{vir}} = 13588$ nucleotides [31]; therefore one segment has an average of $C_{\mathrm{seg}} = C_{\mathrm{vir}} / N_{\mathrm{seg}} = 1699$ nucleotides.] The rate constant of the assembly of new vRNPs is $k_{\mathrm{un},C_\mathrm{v}}$.

Translation of viral proteins includes the synthesis of capsid, nonstructural and matrix proteins (polymerase, NP, M1, NS1 and NS2; see Appendix, 5), which are transported from the cytoplasm back into the nucleus. Newly synthesized envelope proteins (HA, NA, M2; see Appendix, 6) are further processed via the ER and Golgi apparatus. The influence of the number of cellular ribosomes on viral protein synthesis is neglected, assuming that a cell contains about $R_0 = 5 \times 10^6$ ribosomes, which is significantly higher than the number of vmRNA(+) molecules to be processed. In addition, it is assumed that the ribosomes are organized in polysome complexes with an average distance of about 80 nucleotides. Furthermore, it is assumed that rate coefficients of the synthesis of viral proteins do not depend on the cellular pool of free amino acids P_{cell} for the following reasons: (i) consumption of amino acids for cellular protein synthesis ceases soon after infection [46]; (ii) uninfected cells contain a pool of approximately $P_{\mathrm{cell}} = 3.1 \times 10^{10}$ free amino acids (0.4% of cellular wet weight, 138 Dalton average weight of amino acids; [1, 40], which is sufficient to produce about 1.3×10^4 virions (about 2.4×10^6 amino acids per virion, influenza A/PR/8/34) even when assuming that after infection cellular energy and amino acid metabolism is not switched off and there could be an additional supply of amino acids for viral protein synthesis [20]. Thus, the influence of virus infection on the pool of cellular amino acids and therefore on the rate of viral protein synthesis seems to be negligible.

While envelope proteins are incorporated into the apical membrane of the cell vRNPs associate in the nucleus and are being transported to the budding site (see Appendix, 7). It is assumed that vRNPs are packaged randomly with eight segments each. Finally, the assembly of virions is completed and virus particles are released into the medium (see Appendix, 8):

$$\frac{\mathrm{d}V_{\mathrm{bud}}}{\mathrm{d}t} = k_{\mathrm{bud},V_{\mathrm{bud}}} S_{\mathrm{un,bud}} \prod_{l} P_{l,\mathrm{bud}} - k_{\text{bud-rel},V_{\mathrm{bud}}} V_{\mathrm{bud}}$$

$$l \in [\mathrm{M2}, \mathrm{HA}, \mathrm{NA}]$$

$$\frac{\mathrm{d}V_{\mathrm{rel}}}{\mathrm{d}t} = k_{\text{bud-rel},V_{\mathrm{rel}}} V_{\mathrm{bud}} \ ,$$

where V_{bud} and V_{rel} are the number of budding and released virions, respectively. The rate constant of the assembly of progeny virus particles $k_{\mathrm{bud},V_{\mathrm{bud}}}$ is related to $k_{\mathrm{bud},P_{j,\mathrm{bud}}}$ and $k_{\mathrm{bud},S_{\mathrm{un,bud}}}$ via $k_{\mathrm{bud},P_{j,\mathrm{bud}}} = P_{j,\mathrm{vir}} k_{\mathrm{bud},V_{\mathrm{bud}}}$ and $k_{\mathrm{bud},S_{un,bud}} = N_{\mathrm{seg}} k_{\mathrm{bud},V_{\mathrm{bud}}}$ (see Appendix, 6.2 and 7.2). Here $P_{j,\mathrm{vir}}$ is the number of molecules of the j-th envelope protein in the virus particle and $k_{\text{bud-rel}}, V_{\mathrm{bud}}$ is the rate constant of progeny virus release. The rates $k_{\text{bud-rel},V_{\mathrm{rel}}}$ and $k_{\text{bud-rel},V_{\mathrm{bud}}}$ are related via $k_{\text{bud-rel},V_{\mathrm{bud}}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}} k_{\text{bud-rel},V_{\mathrm{rel}}}$.

4.3 Influenza A Virus Growth Dynamics

Simulation results of the mathematical model discussed above for the influenza A virus dynamics are shown in Figures 5–10. Immediately after the infection the number of extracellular virions decreases and within about 2 h more than 90% are taken up by the cell (Figure 5). Correspondingly, both the number of virions attached to the surface and, with a short delay, the number of virions incorporated into endosomes increases and a maximum is achieved for virions attached to the surface and endosomal virions after 14 and 19 min, respectively (Figure 5). From the endosomes individual vRNPs are released into the cytoplasm and start to accumulate in the nucleus (Figure 6). The maximum number of parental vRNPs in the cytoplasm and in the nucleus is found 38 and 99 min p.i., respectively.

After about 25–27 min p.i. first vmRNAs(+) are synthesized in the nucleus and between 1 and 2 h p.i. the number of vmRNAs(+) in the nucleus increases significantly before it achieves a steady state due to continuous export into the cytoplasm and degradation (Figure 7). About 40–44 min p.i., first vmRNAs(+) are found in the cytoplasm, where they accumulate. The switch from vmRNA(+) production to viral genome replication starts about 55 min p.i. when

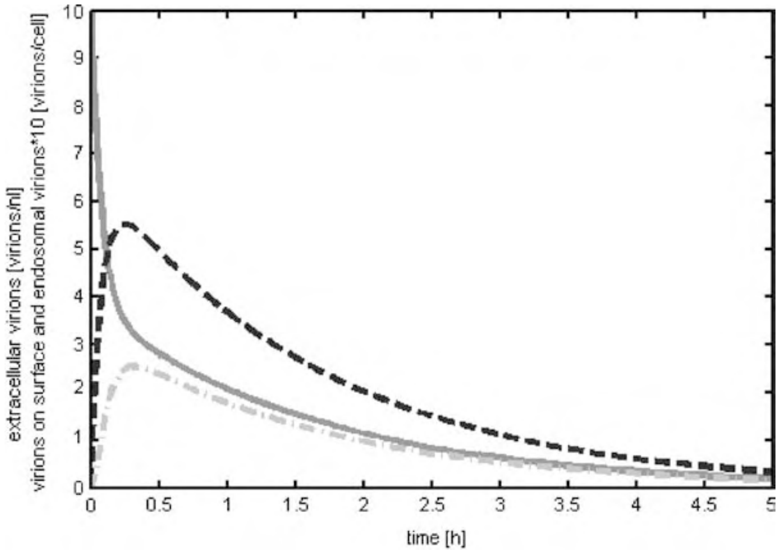

Figure 5 Virus attachment and endocytosis: free extracellular virions (solid line), virions attached to the cellular surface membrane (dashed line) and virions (dash/dotted line) incorporated by endocytosis.

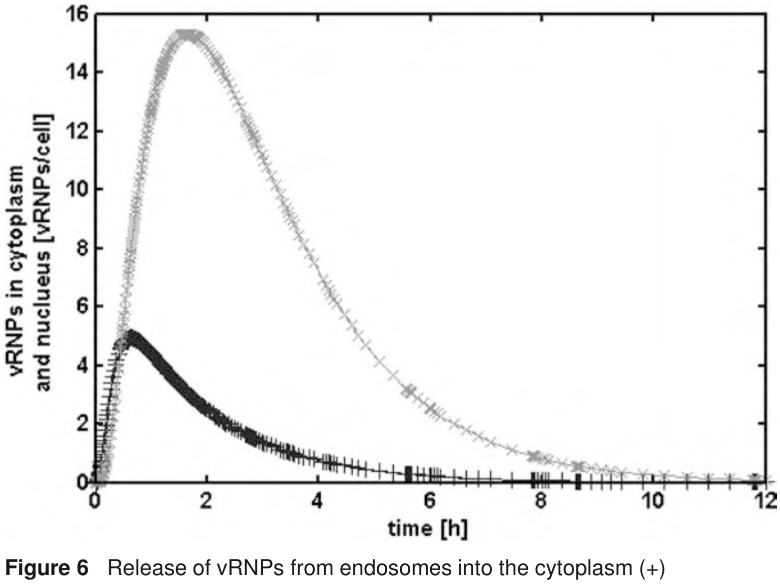

Figure 6 Release of vRNPs from endosomes into the cytoplasm (+) and accumulation of individual vRNPs in the nucleus (×).

a significant amount of newly produced NP proteins have accumulated in the nucleus (Figure 8). About 4 h p.i. cRNA(+) is synthesized at almost maximum rate. As a consequence, viral genome is replicated and the assembly of new vRNP complexes starts in the nucleus (Figure 9).

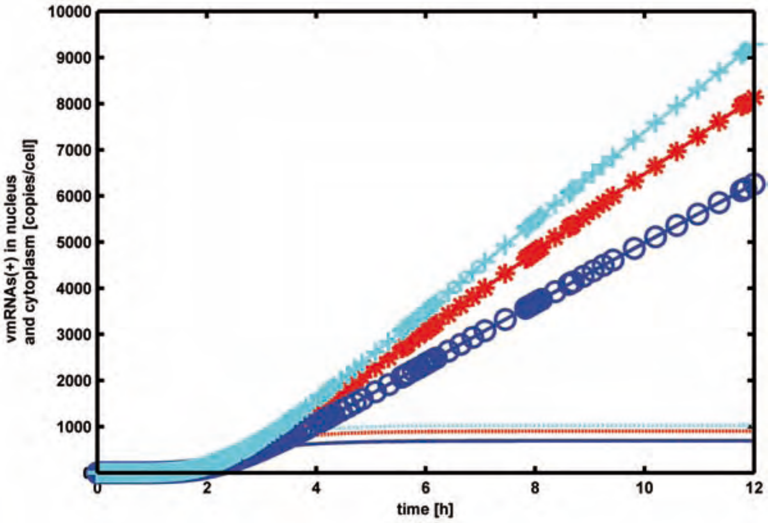

Figure 7 Transcription of viral genes. Accumulation of vmRNAs (+) in nucleus [NP (-· — ·-), HA (- - -), polymerase (—)] and cytoplasm [NP (+), HA (×), polymerase (○)].

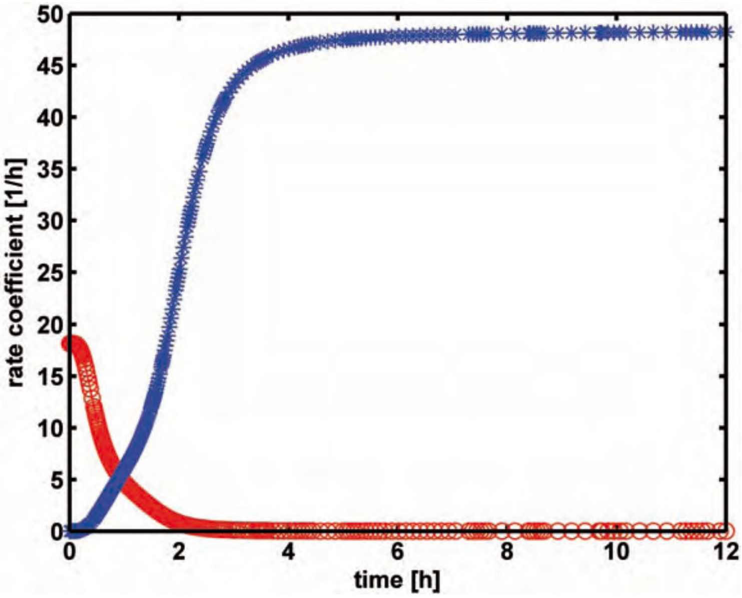

Figure 8 Switch from viral transcription to viral genome replication: rate coefficients of vmRNA (+) synthesis (○) and cRNA (+) production (×).

Approximately 2.5 h p.i., first virions are released into the extracellular medium. Initially, the number of released virions increases exponentially

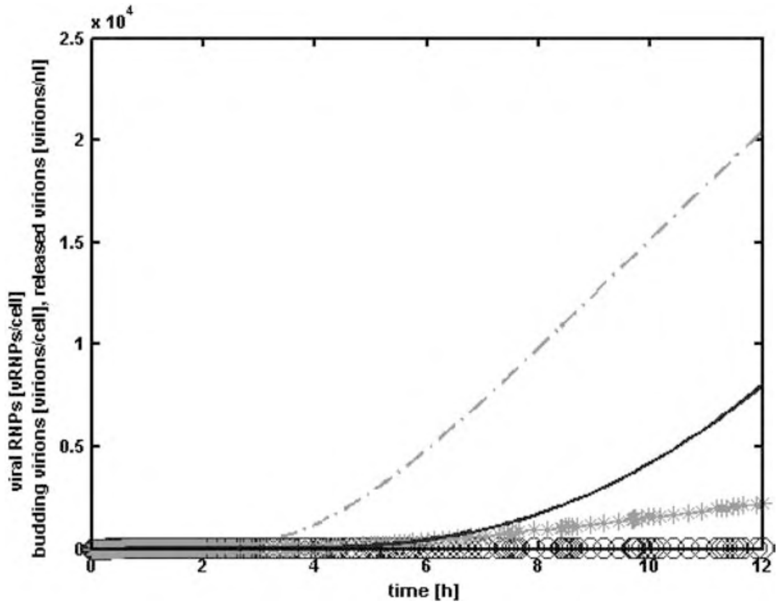

Figure 9 Dynamics of vRNPs: In the nucleus, vRNPs (–·–·–) accumulate while virion formation is limited by the number of vRNPs in the cytoplasm (-o-o-) during budding. Progeny virions are formed at the surface membrane of the host cell (–x–x–), and released into the extracellular medium (—). The maximum number of released virions is about 8000 per cell.

as vRNP formation and budding are not limited in precursor supply. As soon as viral proteins or vRNAs(–) become limiting, viral growth increases proportional to the square of time. [This can be explained by the fact that at the late period of infection, vmRNAs(+) are produced at maximum rate in the nucleus, and, as a result, the total number of all viral proteins and RNAs, as well as the number of budding viruses, increase linearly with time.] In total the cell produces about 8000 virions within 12 h (Figure 9) before it dies due to the virus interfering with basic cellular processes or virus induced apoptosis.

During the replication cycle several cellular resources [surface receptors, endosomes, transport capacity for vRNPs, vmRNAs(+) and viral proteins via the NPCs, precursors for viral protein and genome synthesis, ATP and redox equivalents in form of NAD(P)H, cellular plasma membrane] are required to a varying extent. During the early steps of virus replication neither the number of cellular surface receptors nor the number of endosomes is a limiting factor. Both resources exceed by far the capacities for virus internalization at low m.o.i. Virus attachment and detachment kinetics itself also does not seem to influence overall virus dynamics on the cellular level. Even drastic changes

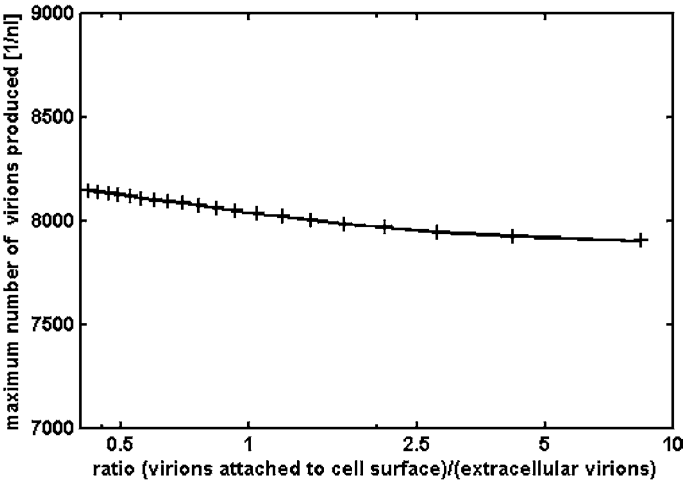

Figure 10 Influence of binding kinetics. Variations of the ratio (virions attached to the surface)/(extracellular virions) at steady-state have almost no influence on the maximum number of virus particles released 12 h p.i. (+).

in attachment kinetics have almost no impact on the total number of virions released during virus replication (Figure 10).

Transfer of vRNPs via the NPCs, which is in the range of 3000–4000 nuclear pores in mammalian cells, also does not seem to limit virus replication. Assuming a transfer rate of 10^2–10^4 molecules s^{-1}, typical for membrane transport proteins [34], 10^9–10^{11} viral molecules [vmRNAs(+), vRNPs, viral proteins] could cross the nuclear membrane per hour. Simulation results clearly demonstrate that NPCs are mainly used for the transfer of newly synthesized viral proteins, e.g. M1 and NP, from cytoplasm into the nucleus. The maximum rate of this process is about 10^7 molecules h^{-1} and therefore negligible with respect to total transfer capacity of the cell. The bottleneck during early steps of infection seems to depend on the virus itself. For a successful infection the fusion of the viral membrane with the endosomal membrane and the release of the viral genome into the cytoplasm of the cell is essential. According to Martin and Helenius [37], the genome of only 65–70% of all endosomal viruses is finally released into the cytoplasm. Additionally, packaging of the correct number and distribution of vRNPs is required to successfully infect a cell. Both factors together explain the comparatively low number of successful infections in influenza A virus infectivity studies. Depending on the cell system, cultivation conditions and assay (plaque forming units, tissue culture infectivity dose), the ratio of infectious to noninfectious virus particles varies in the range of 1/50–1/20 [15].

During the first hour of virus replication the total number of free cellular nucleotides and amino acids consumed for virus production makes up only a small part of the total cellular pool of these components. Even under the very restricting assumption that the cellular biosynthesis of nucleotides and amino acids as well as any uptake of these precursors from the medium is stopped early during infection, their total number is much higher than necessary for synthesizing about 4000–8000 virus particles within the average life-time of an infected cell which is in the range of 10–12 h. Assuming a cellular pool size of 1.3×10^{10} nucleotides and 3.1×10^{10} amino acids (Appendix, Table A1) at most 0.8% of the available nucleotides and 60.8% of the free amino acids are consumed for virion production.

The maximum number of vmRNAs(+) in the cytoplasm never exceeds 10^4 molecules cell^{-1} (not shown). Therefore, the number of ribosomes involved in the synthesis of viral proteins is significantly smaller than the total number of cellular ribosomes (approximately 10^7). Consequently, the number of cellular ribosomes does not seem to limit viral protein production. Also, the number of heterogeneous nuclear precursor mRNAs, which is about 2.2×10^5 molecules cell^{-1} [26], is not limiting for vmRNA(+) synthesis (not shown).

Simulations show that during vRNP assembly, as well as during virus budding, one of the newly produced viral components is completely consumed for the virion formation. Under the current modeling assumptions it is the number of M1 proteins that represents a limiting factor for the formation of new vRNP–M1–NS2 complexes in the nucleus while the number of all other viral proteins increases linearly with time (not shown). A similar situation takes place during virus budding where newly synthesized vRNPs represent the limiting factor (Figure 9). In contrast, viral membrane proteins seem to accumulate at the budding sites.

What factors mainly limit virus production? Simulation studies show that the total number of virus particles produced during the life-time of an infected cell mainly depends on the efficiency of viral polymerase complexes required for vmRNA(+) and therefore for viral protein synthesis. Even drastic variations in the parameters of all other steps during virus attachment/detachment, endocytosis, transfer of vRNPs into the nucleus result in only modest changes in infection dynamics, e.g. a time delay before vmRNA(+) synthesis starts or an initial reduction in the number of vRNPs entering the nucleus. However, as soon as the infection is successfully initiated the total number of virions produced during a fixed period of time is more or less constant. Changes in the ratio (virions attached to the surface)/(extracellular virions) at steady-state in the range of 0.4–8.4 (standard 2.8), for instance, result in differences of less than 2.5% in the total number of virus particles produced (Figure 10). In addition, the protein synthesis capacity of the infected cell itself has a major influence. Even when the number of ribosomes and the number of precursors itself do not seem to be limiting factors for viral protein synthesis the translation efficiency at the ribosomes clearly influences overall virus production. For example, an increase of the corresponding rate coefficient by a factor of 2 (k_{Rib}, see Appendix, Table A2) increases the total number of virus particles produced by a factor of 2.15. Overall, it seems that the capacity for influenza virus production in eukaryotic cells is mainly determined by the efficiency of protein synthesis at the ribosomes and the synthesis rate of vmRNAs(+) defined by the viral polymerase complexes. Cellular resources such as the number of ribosomes, the number of nucleotides and the number of available amino acids do not seem to limit virion formation during the average life-time of infected cells.

4.4 Discussion and Outlook

The structured model for the complete single-cell reproductive cycle of influenza A virus in mammalian cells presented takes into account most steps from virus entry into the host cell to progeny virus release. The overall virus dynamics agrees well with results obtained for other structured models, for example HIV-1 infection of lymphocytes [50] or the replication of bacteriophage T7 in *E. coli* [13].

However, even with the time-course of virus entry, vmRNA(+) synthesis, viral genome replication, virus budding and release reasonably represent overall virus dynamics on a cellular level there are several aspects of the virus replication cycle which should be quantitatively characterized in more detail. First of all, the control of vmRNA(+) synthesis is not completely understood. According to Lamb and Choppin [30], similar amounts of vmRNAs(+) and corresponding viral proteins are produced during the very first hours of infection only. Later in infection vmRNAs(+) coding for NP and NS1 proteins seem to be synthesized in higher amounts than those required for polymerases. After the onset of vRNA(–) production and vRNP association, the synthesis of vmRNAs(+) seems to dominate. Therefore, the assumption of the present model that all vmRNAs(+) as well as all viral proteins are produced in equal amounts is oversimplified. In addition, the vRNAs(–) seem to be produced in nonequivalent amounts. As mechanisms regulating a selective synthesis of viral proteins and genome segments are not understood quantitatively, no attempts have been made so far to introduce corresponding control factors into the existing model. A similar problem is the discussed switch from viral protein synthesis to viral genome replication. It seems that the number of NP proteins in the nucleus is regulating this switch, but the exact mechanism is not clear. Correspondingly, the parameters controlling the switch from vmRNA(+) production to cRNA(+) synthesis (see Appendix, 3 and 4) are more or less arbitrarily selected to follow the overall time course of virus replication. Clearly, more experiments are needed to better understand these complex phenomena. Finally, viral genome packaging itself is still a subject of discussion. So far, it is not clear whether genome segments are selectively incorporated into a progeny virus particle or packaging of genome segments is a purely random process. Experimentally, a ratio of infectious to noninfectious virus particles was confirmed to be in the range of 1/50–1/20 favoring selective mechanisms [15,17]. On the other hand, assuming that virus particles can contain more than eight genome segments [11, 42] results in similar ratios (1/90–1/50 for nine segments). So far, for simplicity it is assumed in the model that all virus particles contain eight genome segments. However, if required this can be easily modified to cope with corresponding experimental results.

Cells infected with influenza virus die at about 10–12 h p.i. So far, the mechanisms of cell death are not fully understood. As shown before, cellular resources consumed for virus replication are used only to a limited degree for virion formation. Therefore, cell death is probably not directly linked with the exhaustion of cellular pools. Also the number of nuclear precursor mRNAs [their poly(A) tail] used for vmRNA(+) production does not to seem to be a limiting factor (Section 4.3). The most likely reason for cell death is virus-induced apoptosis, an active process of cellular self-destruction. For influenza A virus several factors have been identified which activate apoptosis pathways [35] including caspase activation by double-strand vRNAs of infected cells [33, 57, 66], activation of the latent transforming growth factor-β by viral membrane proteins HA and NA [51] and the interaction with mitochondrial-dependent apoptotic pathways of a newly described influenza A virus gene product PB1-F2 [6]. In addition, host defense mechanisms such as interferon-mediated antiviral responses and virus induced cellular gene expression play important roles in virus replication [18,29,35,36]. However, while these topics are being studied in an increasing number of experimental systems, their kinetics as well as the precise mechanisms of apoptotic factors and virus-induced stimulation of cellular defense on virus replication still have to be elucidated in more detail before incorporation into mathematical models of virus replication.

5 Conclusions

Mathematical models of virus replication in single cells are a crucial step towards a quantitative understanding of virus–host cell interaction. Most models developed so far focus on kinetics of virus attachment and entry, transcription and translation of viral mRNAs, genome replication, assembly, and virus release. In particular, the overall growth dynamics of bacteriophages, the influence of the physiological status of the host bacterium and the interaction of phage components with the regulatory networks of their host cells have been analyzed in detail. Models of viruses infecting eukaryotic cells, especially mammalian cells, are adding a further level of complexity. Apart from the impact of virus replication on cellular metabolism, the impact of viral components on host cell defenses as well as on cellular signal transduction networks and gene expression have to be considered to fully understand the multiple facets of virus–host cell interaction. However, existing mathematical models developed for the simulation of HIV, influenza A virus and baculovirus dynamics neglect most of these aspects which differ eukaryotes from prokaryotes. Therefore, these models can be considered only as a first step towards a quantitative and integrative understanding of virus replication on a cellular level. For further progress, virus–eukaryotic cell systems should be selected as models for systems biology approaches to cope with these challenges and to improve our understanding on virus–host cell interactions. Eventually, this will allow us not only to reveal basic laws that control virus replication in cells and to identify molecular targets for virus-related diseases, but also to optimize viral-based production systems for vaccines and pharmaceuticals required for gene or cancer therapy.

Acknowledgments

The authors wish to thank Dietrich Flockerzi, Yvonne Genzel and Lars Möhler for thoughtful comments and discussions on virus–host cell interaction, and for providing experimental data as well as modeling and simulation results for influenza A virus replication.

Nomenclature

a_{NP}	influence of the NP protein on vmRNA production (cell NP^{-1})
b_{NP}	influence of the NP protein on genome replication (NP cell^{-1})
B	burst size (phages bacterium^{-1})
$C_{\max}$	maximum cell concentration due to contact inhibition (cells mL^{-1})
C_{c}	cRNA (nucleotides cell^{-1})
C_{cell}	number of free cellular nucleotides (nucleotides cell^{-1})
$C_{\mathrm{m,cell}}$	number of cellular mRNAs (nucleotides cell^{-1})

$C_{i,\mathrm{nuc}}$	vmRNA, encoding the *i*-th protein in the nucleus (nucleotides cell^{-1})
$C_{i,\mathrm{cyt}}$	vmRNA, encoding *i*-th protein in the cytoplasm (nucleotides cell^{-1})
C_{seg}	the average number of nucleotides of one vRNA segment (nucleotides)
C_{v}	number of vRNA nucleotides (nucleotides cell^{-1})
C_{vir}	number of nucleotides in a virus particle (nucleotides)
d_{rib}	distance between ribosomes processing a vmRNA (nucleotides)
E	number of cellular endosomes (endosomes cell^{-1})
H	number of nuclear pores (pores cell^{-1})
I_{C}	concentration of infected cells (cells mL^{-1})
$k_{\mathrm{bud\text{-}rel},V_{\mathrm{bud}}}$	rate constant of progeny virus release (h^{-1})
$k_{\mathrm{bud\text{-}rel},V_{\mathrm{rel}}}$	rate constant of progeny virus release (nL^{-1} h^{-1})
$k_{\mathrm{bud},P_{j,\mathrm{bud}}}$	rate constant of progeny virus particles assembly (h^{-1})
$k_{\mathrm{bud},S_{\mathrm{un,bud}}}$	rate constant of progeny virus particles assembly (h^{-1})
$k_{\mathrm{bud},V_{\mathrm{bud}}}$	rate constant of progeny virus particles assembly (h^{-1})
k_{cdf}	specific cell death rate due to cultivation conditions (h^{-1})
$k_{\mathrm{c\text{-}degr}}$	rate constant of cRNA degradation (h^{-1})
k_{cdv}	specific cell death rate due to viral infection (h^{-1})
$k_{\mathrm{c\text{-}v}}$	rate coefficient of vRNA synthesis (h^{-1})
$k_{\mathrm{cyt\text{-}nuc}}$	rate coefficient of vRNP nuclear import (h^{-1})
$k_{\mathrm{end\text{-}cyt},S_{\mathrm{cyt}}}$	rate coefficient of endocytosis (h^{-1})
$k_{\mathrm{end\text{-}cyt},V_{\mathrm{end}}}$	rate constant of vRNP uncoating (h^{-1})
$k_{\mathrm{end\text{-}degr}}$	rate constant of virus degradation within endosomes (h^{-1})
$k_{\mathrm{ex\text{-}s},V_{\mathrm{ex}}}$	rate coefficient of virus binding (nL h^{-1})
$k_{\mathrm{ex\text{-}s},V_{\mathrm{s}}}$	rate coefficient of virus binding (h^{-1})
$k_{i,\mathrm{cyt\text{-}degr}}$	rate constant of the degradation of the *i*-th protein in cytoplasm (h^{-1})

$k_{i,\text{cyt-nuc}}$ rate coefficient of nuclear import of the *i*-th protein (h^{-1})

$k_{i,\text{nuc-degr}}$ rate constant of the degradation of the *i*-th protein in the nucleus (h^{-1})

$k_{i,\text{synt}}$ rate coefficient of the synthesis of the *i*-th protein (h^{-1})

$k_{j,\text{bud-degr}}$ rate constant of the degradation of the *j*-th protein at the budding site (h^{-1})

$k_{j,\text{ER-bud}}$ rate constant of the transport of the *j*-th protein to the budding site (h^{-1})

$k_{j,\text{ER-degr}}$ rate constant of the degradation of the *j*-th protein in the ER (h^{-1})

k_{Pl} rate of the synthesis of RNA (nucleotides h^{-1})

k_{Rib} rate of the elongation of a peptide chain (amino acids h^{-1})

$k_{\text{s-end}}$ rate coefficient of the endocytosis (h^{-1})

$k_{\text{s-ex},V_{\text{ex}}}$ rate constant of virus dissociation from the surface (h^{-1})

$k_{\text{s-ex},V_{\text{s}}}$ rate constant of virus dissociation from the surface (h^{-1})

$k_{\text{spl},C_{\text{v}}}$ rate constant of vRNP splicing (h^{-1})

$k_{\text{spl},P_{i,\text{nuc}}}$ rate constant of vRNP splicing (h^{-1})

$k_{\text{spl},S_{\text{nuc}}}$ rate constant of vRNP splicing (h^{-1})

$k_{\text{un},C_{\text{v}}}$ rate constant of the assembly of new vRNP (h^{-1})

$k_{\text{un,nuc-bud}}$ rate coefficient of the export of new vRNP (h^{-1})

$k_{\text{un},P_{i,\text{nuc}}}$ rate constant of the assembly of new vRNP (h^{-1})

$k_{\text{un},S_{\text{un,nuc}}}$ rate constant of the assembly of new vRNP (h^{-1})

k_{va} specific virus attachment rate (mL h^{-1})

$k_{\text{v-c}}$ rate coefficient of cRNA synthesis (h^{-1})

k_{vd} specific virus degradation rate (h^{-1})

$k_{\text{v-degr}}$ rate constant of vRNA degradation (h^{-1})

k_{vi} specific virus infection rate (mL h^{-1})

$k_{\text{v-vm},i}$	rate coefficient of vmRNA synthesis (h^{-1})
$k_{\text{vm},i,\text{cyt-degr}}$	rate constant of cytoplasmic vmRNA degradation (h^{-1})
$k_{\text{vm},i,\text{nuc-cyt}}$	rate coefficient of vmRNA nuclear export (h^{-1})
$k_{\text{vm},i,\text{nuc-degr}}$	rate constant of nuclear vmRNA degradation (h^{-1})
N_{cells}	number of cells (cells)
P_{cell}	number cellular amino acids (amino acids cell^{-1})
$P_{i,\text{cyt}}$	number of the *i*-th protein in the cytoplasm (amino acids cell^{-1})
$P_{i,\text{nuc}}$	number of the *i*-th protein in the nucleus (amino acids cell^{-1})
$P_{j,\text{bud}}$	number of the *j*-th protein at the budding site (amino acids cell^{-1})
$P_{j,\text{ER}}$	number of the *j*-th protein in the ER (amino acids cell^{-1})
$P_{\text{NP,nuc}}$	number of NP proteins in the nucleus (amino acids cell^{-1})
$P_{\text{Pol,nuc}}$	number of polymerase complexes in the nucleus (amino acids cell^{-1})
R	number of cellular ribosomes (ribosomes cell^{-1})
R_{sf}	number of cellular receptors (receptors cell^{-1})
S_{cyt}	number of vRNPs in the cytoplasm (vRNPs cell^{-1})
S_{nuc}	number of vRNPs in the nucleus (vRNPs cell^{-1})
$S_{\text{un,bud}}$	newly synthesized vRNPs at the budding site (vRNPs cell^{-1})
$S_{\text{un,nuc}}$	newly synthesized vRNPs in the nucleus (vRNPs cell^{-1})
t	time (h)
U_C	concentration of uninfected cells (cells mL^{-1})
U_{r}	volume of medium containing N_{cells} cells *(nL)*
V	concentration of virus particles (virions mL^{-1})
V_{bud}	number of budding viruses (virions cell^{-1})
V_{end}	number of endosomal viruses (virions cell^{-1})
V_{ex}	number of extracellular viruses (virions nL^{-1})
V_{rel}	number of released viruses (virions nL^{-1})

V_s	number of surface viruses (virions cell^{-1})

Greek

α	rise rate (phages min^{-1})
λ	latent period (min)
μ	specific cell growth rate (h^{-1})
μ_max	maximum specific cell growth rate (h^{-1})
μ_vir	specific virus replication rate (h^{-1})
ν	eclipse period (min)
τ	time delay (h)
ω_i	fraction of *i*-th mRNA nucleotides (–)

Appendix

Model equations

The model is represented by a system of nonlinear ODEs, which represent the key steps of the influenza A virus infection cycle (Figure 4).

1 Virus Entry into the Host Cell

$$\frac{\mathrm{d}V_{\mathrm{ex}}}{\mathrm{d}t} = -k_{\text{ex-s},V_{\mathrm{ex}}} V_{\mathrm{ex}} + k_{\text{s-ex},V_{\mathrm{ex}}} V_{\mathrm{s}} \tag{1.1}$$

$$\frac{\mathrm{d}V_{\mathrm{s}}}{\mathrm{d}t} = k_{\text{ex-s},V_{\mathrm{s}}} V_{\mathrm{ex}} - k_{\text{s-ex},V_{\mathrm{s}}} V_{\mathrm{s}} - k_{\text{s-end}} V_{\mathrm{s}} \tag{1.2}$$

$$\frac{\mathrm{d}V_{\mathrm{end}}}{\mathrm{d}t} = k_{\text{s-end}} V_{\mathrm{s}} - k_{\text{end-cyt},V_{\mathrm{end}}} V_{\mathrm{end}} - k_{\text{end-degr}} V_{\mathrm{end}} \tag{1.3}$$

and

$$k_{\text{ex-s},V_{\mathrm{s}}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}} k_{\text{ex-s},V_{\mathrm{ex}}}$$

$$k_{\text{s-ex},V_{\mathrm{s}}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}} k_{\text{s-ex},V_{\mathrm{ex}}} \,.$$

2 vRNP Uncoating and Transport into the Nucleus

$$\frac{\mathrm{d}S_{\text{cyt}}}{\mathrm{d}t} = k_{\text{end-cyt},S_{\text{cyt}}} V_{\text{end}} - k_{\text{cyt-nuc}} S_{\text{cyt}} \tag{2.1}$$

$$\frac{\mathrm{d}S_{\text{nuc}}}{\mathrm{d}t} = k_{\text{cyt-nuc}} S_{\text{cyt}} - k_{\text{spl},S_{\text{nuc}}} S_{\text{nuc}} \tag{2.2}$$

and:

$$k_{\text{end-cyt},S_{\text{cyt}}} = N_{\text{seg}} k_{\text{end-cyt},V_{\text{end}}} \,. \tag{2.3}$$

3 Transcription [vmRNA(+) Production]

$$\frac{\mathrm{d}C_{i,\text{nuc}}}{\mathrm{d}t} = k_{\text{v-vm},i} P_{\text{Pol,nuc}} - k_{\text{vm},i,\text{nuc-cyt}} C_{i,\text{nuc}} - k_{\text{vm},i,\text{nuc-degr}} C_{i,\text{nuc}} \tag{3.1}$$

$$\frac{\mathrm{d}C_{i,\text{cyt}}}{\mathrm{d}t} = k_{\text{vm},i,\text{nuc-cyt}} C_{i,\text{nuc}} - k_{\text{vm},i,\text{cyt-degr}} C_{i,\text{cyt}} \tag{3.2}$$

$i \in [\text{Pol, NP, M1, NS1, NS2, M2, HA, NA}]$,

with the following assumption concerning the kinetic coefficients:

$$k_{\text{v-vm},i} = k_{\text{v-vm},i,\text{max}} \frac{1}{1 + a_{\text{NP}} P_{\text{NP,nuc}}} \,.$$

4 Viral Genome Replication

$$\frac{\mathrm{d}C_{\text{c}}}{\mathrm{d}t} = k_{\text{v-c}} P_{\text{Pol,nuc}} - k_{\text{c-degr}} C_{\text{c}} \tag{4.1}$$

$$\frac{\mathrm{d}C_{\text{v}}}{\mathrm{d}t} = k_{\text{c-v}} P_{\text{Pol,nuc}} + k_{\text{spl},C_{\text{v}}} S_{\text{nuc}} - k_{\text{un},C_{\text{v}}} C_{\text{v}} \prod_{l} P_{l,\text{nuc}} - k_{\text{v-degr}} C_{\text{v}} \tag{4.2}$$

$i \in [\text{Pol, NP, M1, NS2}]$,

with the following assumptions concerning the kinetic coefficients:

$$k_{\text{v-c}} = k_{\text{v-c,max}} \frac{P_{\text{NP,nuc}}}{b_{\text{NP}} + P_{\text{NP,nuc}}}$$

$$k_{\text{c-v}} = k_{\text{c-v,max}} \frac{P_{\text{NP,nuc}}}{b_{\text{NP}} + P_{\text{NP,nuc}}}$$

$$k_{\text{spl},C_{\text{v}}} = C_{\text{seg}} k_{\text{spl},S_{\text{nuc}}} \,.$$

5 Capsid, Nonstructural and Matrix Protein Production

$$\frac{\mathrm{d}P_{i,\text{cyt}}}{\mathrm{d}t} = k_{i,\text{synt}} \frac{C_{i\text{cyt}}}{\mathrm{d}_{\text{rib}}} - k_{i,\text{cyt-nuc}} P_{i,\text{cyt}} - k_{i,\text{cyt-degr}} P_{i,\text{cyt}} \tag{5.1}$$

$$\frac{\mathrm{d}P_{i,\mathrm{nuc}}}{\mathrm{d}t} = k_{i,\mathrm{cyt\text{-}nuc}}P_{i,\mathrm{cyt}} + k_{\mathrm{spl},P_{i,\mathrm{cyt}}}S_{\mathrm{nuc}} - k_{\mathrm{un},P_{i,\mathrm{nuc}}}C_{\mathrm{v}}\prod_{l}P_{l,\mathrm{nuc}} - k_{i,\mathrm{nuc\text{-}degr}}P_{i,\mathrm{nuc}} \tag{5.2}$$

$i \in [\mathrm{Pol, NP, M1, NS1, NS2}]$ $l \in[\mathrm{Pol, NP, M1, NS2}]$,

and:

$k_{\mathrm{spl},P_{i,\mathrm{nuc}}} = P_{i,\mathrm{seg}}k_{\mathrm{spl}S_{\mathrm{nuc}}}$

$k_{i,\mathrm{synt}} = k_{\mathrm{Rib}}$ (k_{Rib} rate of peptide chain elongation, Table A2).

6 Envelope Protein Production

$$\frac{\mathrm{d}P_{j,\mathrm{ER}}}{\mathrm{d}t} = k_{j,\mathrm{synt}}\frac{C_{j,\mathrm{cyt}}}{\mathrm{d}_{\mathrm{Rib}}} - k_{j,\mathrm{Er\text{-}bud}}P_{j,\mathrm{ER}} - k_{j,\mathrm{ER\text{-}degr}}P_{j,\mathrm{ER}} \tag{6.1}$$

$$\frac{\mathrm{d}P_{j,\mathrm{bud}}}{\mathrm{d}t} = k_{j,\mathrm{ER\text{-}}bud}P_{j,\mathrm{ER}} - k_{\mathrm{bud},P_{j,\mathrm{bud}}}S_{\mathrm{un,bud}}\prod_{l}P_{l,\mathrm{bud}} - k_{j,\mathrm{bud\text{-}degr}}P_{j,\mathrm{bud}} \tag{6.2}$$

$j, l \in [\mathrm{M2, HA, NA}]$

7 Packaging

$$\frac{\mathrm{d}S_{\mathrm{un,nuc}}}{\mathrm{d}t} = k_{\mathrm{un},S_{\mathrm{un,nuc}}}C_{\mathrm{v}}\prod_{l}P_{l,\mathrm{nuc}} - k_{\mathrm{un,nuc\text{-}bud}}S_{\mathrm{un,nuc}} \tag{7.1}$$

$$\frac{\mathrm{d}S_{\mathrm{un,bud}}}{\mathrm{d}t} = k_{\mathrm{un,nuc\text{-}bud}}S_{\mathrm{un,nuc}} - k_{\mathrm{bud},S_{\mathrm{un,bud}}}S_{\mathrm{un,bud}}\prod_{s}P_{s,\mathrm{bud}} \tag{7.2}$$

$l \in [\mathrm{Pol, NP, M1, NS2}]$ $s \in [\mathrm{M2, HA, NA}]$,

and:

$k_{\mathrm{un},C_{\mathrm{v}}} = C_{\mathrm{seg}}k_{\mathrm{un},S_{\mathrm{un,nuc}}}$

$k_{\mathrm{un}P_{i,\mathrm{nuc}}} = P_{i,\mathrm{seg}}k_{\mathrm{un},S_{\mathrm{un,nuc}}}$.

8 Virus Budding and Release

$$\frac{\mathrm{d}V_{\mathrm{bud}}}{\mathrm{d}t} = k_{\mathrm{bud},V_{\mathrm{bud}}}S_{\mathrm{un,bud}}\prod_{l}P_{l,\mathrm{bud}} - k_{\mathrm{bud\text{-}rel},V_{\mathrm{bud}}}V_{\mathrm{bud}} \tag{8.1}$$

$l \in [\mathrm{M2, HA, NA}]$

$$\frac{\mathrm{d}V_{\mathrm{rel}}}{\mathrm{d}t} = k_{\mathrm{bud\text{-}rel},V_{\mathrm{rel}}}V_{\mathrm{bud}} , \tag{8.2}$$

and:

$k_{\mathrm{bud},P_{j,\mathrm{bud}}} = P_{j,\mathrm{vir}}k_{\mathrm{bud},V_{\mathrm{bud}}}$

$k_{\mathrm{bud},S_{\mathrm{un,bud}}} = N_{\mathrm{seg}}k_{\mathrm{bud},V_{\mathrm{bud}}}$

$k_{\mathrm{bud\text{-}rel},V_{\mathrm{bud}}} = \frac{U_{\mathrm{r}}}{N_{\mathrm{cells}}}k_{\mathrm{bud\text{-}rel},V_{\mathrm{rel}}}$

Initial Conditions and Kinetic Parameters

Initial conditions, kinetic parameters and assumptions are summarized in the following two tables. ODEs were solved using MATLAB version 6.5 release 13 (Mathworks, Natick, MA, USA).

Table A1 Basic assumptions on host cell and virus composition used for simulation studies of the structured mathematical model of the influenza A virus life cycle (Section 4.3)

Parameter	Value	Source
Host cell		
number of receptors (receptors cell^{-1})	10^4–10^5	[62]
number of endosomes (endosomes cell^{-1})	200	[1]
number of ribosomes (ribosomes cell^{-1})	5×10^6	[1]

Part 7 Analysis of Expression Data

24
DNA Microarray Technology and Applications – An Overview

John Quackenbush

1 Introduction to DNA Microarrays

The Human Genome Project promised to transform biology and medicine by providing us with a complete human genome sequence and a catalogue of all human genes. However, neither the 2001 announcement of completion of a draft human genome sequence by the competing public and private efforts to sequence the genome [50, 93] nor the 2004 publication of a "finished" human genome sequence [1] have delivered on that promise. Rather, genomics has transformed biology by providing technologies such as DNA microarrays, proteomics and metabolomics that are allowing us to generate holistic data on patters of gene, protein or metabolite expression. These approaches are seeing increasing applications in the study of human disease. There have been a number of promising studies in which microarray data, in particular, have been useful for discovering new molecular classes of previously well-studied diseases. The molecular fingerprints that emerge from such analyses can also be used for classification of disease, with the expression profiles, rather than the presence or levels of specific proteins, serving as biomarkers for diagnostic and prognostic classification.

2 Microarrays and Clinical Applications

In 1995, DNA microarrays were first reported as a tool for probing transcriptional levels on a genomic scale [54, 78] and the research community quickly seized upon this approach as a means of identifying genes that might provide

insight into a wide range of biological processes. Most of the early experiments adopted as simple, yet powerful design – comparing two biological classes in order to identify genes that were differentially expressed between them. These experiments generally sought to gain insight into the underlying biology and microarrays were used as a tool for gene discovery; many of the early applications were to the analysis of gene expression in human cancers [25,46,97].

It did not take long, however, for many to realize that the utility of microarray-based approaches extended beyond mechanistic studies; arrays could be used to find new subclasses in disease states [3, 66], to identify new biomarkers that could be associated with disease [60] and even that the expression patterns themselves could be used as biomarkers to distinguish subclasses of disease [34]. This realization resulted in a proliferation of studies that searched for patterns of expression that could be used to classify tumor types [82], and to predict outcome [12,92] and response to chemotherapy [91].

Many of the earliest microarray publications on classification of cancer focused on cluster analysis of tumor samples and genes, including applications of hierarchical clustering [2,3,13,66,67,73,82] and partitioning methods such as self-organizing maps (SOMs) [34, 67]. These unsupervised data mining approaches have proven useful for class discovery as they take an unbiased approach to looking for patterns in the data to look for consistent subgroups in the data. Alizadeh and coworkers [2] used hierarchical clustering of cDNA microarray expression data from lymphoma samples to identify two previously unrecognized and transcriptionally distinct subclasses of diffuse large B cell lymphomas (DLBCLs) that were eventually related to different stages of B cell differentiation. One class expressed genes characteristic of germinal B cells (germinal center B-like DLBCL class), while the other expressed genes normally induced during *in vitro* activation of peripheral blood B cells (activated B-like DLBCL class). Their analysis also showed that patients within these subclasses had distinct clinical prognoses. Bhattacharjee and coworkers [13] used a similar approach to identify lung adenocarcinoma subclasses with different patient outcome. Hierarchical clustering of cDNA microarray expression data was also used by Ross and coworkers [73] to analyze the 60 cell lines form the National Cancer Institute's anticancer drug screening panel (the NCI 60 cell lines). Their analysis showed that cell line expression could be used to group samples based on their tissue of origin as well as to find genes that had similar patterns of expression across the samples.

However, in a clinical setting, the goal is generally not to look for new disease subtypes, but rather to use new techniques to provide better diagnostic and prognostic evidence to the clinician. In that light, the ability of gene expression profiles to distinguish different disease subtypes suggests that these same profiles can be used to classify samples based on the patterns of expression that are observed. Golub and coworkers [34] were the first to extend the class discovery approach to classification. Starting with expression profiles on acute lymphoblastic leukemia (ALL) and acute myeloblastic leukemia (AML) samples collected using Affymetrix GeneChips^{TM}. These samples were analyzed using SOMs and the tumor groups discovered based on expression patterns were compared to known classes. Their ability to partition the data into distinct ALL/AML groups prompted them to use the expression profiles as a means of classifying the samples. They proposed a weighted gene voting scheme for classification that is a variant on linear discriminant analysis methods. Since that time, there have been a large number of other studies describing classification approaches. Ramaswamy and colleagues [70] used support vector machines (SVMs) to demonstrate that expression profiles from microarrays could be used to separate tumors from 14 different organ sites, and Bloom and coworkers [14] used artificial neural networks (ANNs) to extend the approach to include 21 different tumor types profiled on both cDNA and Affymetrix GeneChips^{TM}, and further demonstrated that the same approach could be used to predict the primary source for metastatic lesions. Pomeroy and coworkers [67] profiled embryonic tumors of the central nervous system (CNS) on Affymetrix GeneChips^{TM}, and applied a range of unsupervised and supervised learning methods to investigate whether gene expression data could be used to distinguish between new and existing CNS tumor classes and for patient prognosis. Beer and coworkers [12] used an approach based on the Cox regression model to identify marker genes for predicting the survival of patients with lung adenocarcinoma.

Although mechanistic and discovery-based analyses of gene expression using microarrays continue to have widespread use, it is becoming increasingly clear that the use of array-based expression profiles for classification and class discovery will continue to be major applications for microarrays, as well as a broad range of other "omic" technologies, including proteomics, metabolomics and others. Fundamentally, all of these technologies can be used to ask a simple question: "Can we find a pattern that we can use to distinguish biological samples based on some inherent property?". To better understand how and when this question can be answered, it is useful to review some of the basic issues related to use of microarray data for the classification of human cancer and to point out some of the potential limitations of this approach.

3 Microarray Data Collection, Transformation and Representation

DNA microarray technology is relatively simple. Gene-specific probes, representing thousands of individual genes, are arrayed on an inert substrate (such as glass) and used to assay gene expression levels in selected biological samples. RNA is extracted from tissues of interest, converted into an appropriate target nucleic acid mixture labeled with a detectable marker (typically a fluorescent dye) and allowed to hybridize to the arrays. Individual RNA species hybridize to complementary gene-specific probes and hybridization is assayed by measuring fluorescence for each probe using a confocal laser scanner. These hybridization intensities, in turn, are used as estimates of gene-expression levels.

Microarray technology can be divided into two broad classes based on the way in which gene expression data is generated and how samples are compared. In a "two-color" microarray assay, two RNA samples, each labeled with a different dye, are simultaneously hybridized to a single array (Figure 1A). The sample of interest (or "query" sample), e.g. tissue from a cancerous colon tumor, is labeled with one dye and a control sample, e.g. normal colon mucosa, is labeled with another dye, and the two samples mixed in an approximate 1:1 ratio based on the quantity of labeled sample. Such as assay compares the expression levels between paired samples and reports expression levels as the logarithm of the ratio [the "$\log_2$(ratio)"] of the query to the control sample for each gene represented on the array. For single-color arrays, such as the widely-used Affymetrix GeneChip^{TM}, each sample is individually labeled and hybridized to a single array (Figure 1B). The expression for each gene is then reported as a single fluorescence intensity that represents an estimated expression level, less nonspecific background, although these measures can be used to derive others such as the $\log_2$(ratio) of expression levels in samples that one wishes to compare.

There are, of course, many variants of the various basic technologies and many commercial vendors. Two-color assays generally use either cDNA or long (50- to 70-mer) oligonucleotide probes while single-color assays typically are based on short (25-mer) or long (50- to 70-mer) oligonucleotide probes. Manufacturers of gene expression arrays include Affymetrix, Agilent, Illumina, Combimatrix, Nimblegen and a host of others, as well as "homebrew" arrays printed in individual laboratories. Labeling approaches use a variety of approaches including reverse transcription of RNA to cDNA (often used in two-color approaches), creation and fragmentation of antisense RNA (a protocol used on Affymetrix GeneChips), and various amplification approaches, most notably variations on Eberwine's T7 amplification. However, regardless of the approach or technology, the fundamental data used in all subsequent analyses are expression measures for each gene in each sample.

Following collection, the data are usually normalized to facilitate comparison between individual hybridization assays, and to compensate for differences in labeling, hybridization and detection efficiencies. There are several approaches to data normalization; the most appropriate approach depends on the type of array and assumptions regarding about biases in the data [40, 68, 76, 99, 100]. The data are then generally filtered using some set of objective criteria (e.g. eliminating those genes with minimal variance across samples or those with signals approaching background levels) or using some statistical analyses to select genes whose expression levels are correlated with particular groups of samples. These normalization and filtering transformations must be carefully applied as they can have a profound effect on the results obtained. Different statistical analysis methods applied to the very same data set can often produce different (but usually overlapping) sets of "significant" genes. Not surprisingly, the best way to deal with these "high-dimensional" data sets, in which there are often more measurements (genes) than samples, is an area of active research and debate. Chapter 25 gives a detailed account of current methods for preprocessing expression data. It should be noted that, to date, there is no single "right" way to analyze microarray data as even a single data set may reveal different features that are biologically relevant if a new analysis method is applied to the data. Extracting meaning from expression data really requires active participation of an expert in the biological system who is willing to explore the features contained within the data.

Once the normalized and filtered expression data are assembled, they are typically represented in an "expression matrix" in which each row represents a particular gene and each column represents a specific biological sample (Figure 1C). Each row is a "gene expression vector" where the individual entries are the expression levels of a specific gene across all of the samples and each column is a "sample expression vector" that records the expression of all genes in that sample. To ease interpretation of the results of multiple hybridizations, these data are often represented as a matrix in which individual elements are colored to indicate the expression level of each gene in each sample (Figure 1C), creating a visual representation of gene expression patterns across the collection of samples. The most common approach colors genes based on the $\log_2$(ratio) for each sample measured relative to some control, with $\log_2$(ratio) values close to zero colored black, those with $\log_2$(ratio) values greater than zero colored red (indicating "upregulated" genes) and those with negative values colored green (for "downregulated" genes), although other color schemes are kinder to those to those who are "red–green" colorblind (Figure 1C). The relative intensity of each element indicates the relative expression of the gene that it represents, with brighter elements indicating a higher level of expression. For any particular group of samples, the expression matrix generally appears without any apparent

pattern or order (Figure 1D). Clustering programs generally reorder the rows, or columns, or both, such that patterns of expression become visually apparent (Figure 1E and F). While we will focus on using DNA microarray data, it should be noted that any data which can be placed into a "genes by samples" expression matrix format (e.g. "proteins by samples") can be analyzed using exactly the same techniques. This applies also to proteomics data discussed in Chapter 28, for instance.

4 Identifying Patterns of Expression

In doing microarray analysis, we are generally looking for genes that exhibit patterns of expression correlating with the biological states of the system being analyzed or that have "similar" patterns of expression across multiple samples; alternatively, we may look for samples that exhibit "similar" profiles. To facilitate this process, we need to define a measure of similarity between samples by defining distance measures. Although this might seem esoteric, there are a variety of distance measures that can be used and each can reveal different features in the data. Two of the most commonly used are Euclidean distance and Pearson correlation coefficient distances. Euclidean distance is important if the "magnitude" of expression levels is important as genes are scored as "close" if they are, for example, upregulated by same amount. On

←

Figure 1 An overview of DNA microarray analysis. (A) Single-color analysis, such as that using the Affymetrix GeneChip^{TM}, hybridizes labeled RNA from each biological sample to a single array in which a series of "perfect match" (PM) gene-specific probes are arrayed. Gene expression levels are estimated by measuring hybridization intensities are for each probe and background is measured using a corresponding set of "mismatch" (MM) probes. Gene expression levels are reported for each patient sample as a "sample expression vector" summarizing the difference between signal and background for each gene. (B) In two-color analysis approaches, RNA samples from patient and control samples are individually labeled with distinguishable fluorescent dyes and cohybridized to single DNA microarray consisting of individual gene-specific probes. Relative gene expression levels in the two samples are estimated by measuring the fluorescence intensities for each arrayed probe; a sample expression vector summarizing the expression level of each gene in the patient sample (relative to the control) is reported. (C) The collection of sample expression vectors is typically compiled into a single "expression matrix." Each column in the expression matrix represents an individual sample and its measured expression levels for each gene (the sample expression vector); each row represents a gene and its expression levels across all samples (a "gene expression vector"). The expression matrix is often visualized by presenting a colored matrix (typically red/green although other combinations such as blue/yellow are now common). Here, the color and its intensity represent the relative direction and magnitude of a gene expression difference. (D) An unordered data set, subjected to (E) average linkage hierarchical clustering or (F) k-means clustering reveals underlying patterns that can help identify classes in the data set; here the resulting two clusters are shown.

the other hand, Pearson correlation coefficients are useful if the "shape" of the expression profile is important so genes are close if their expression levels are increasing in some samples and decreasing in others, regardless of their absolute levels. Generally, in applications involving classification, we are interested in the pattern of expression across samples, so Pearson correlation coefficient distances are most useful, but not always.

Having recorded the appropriate data, normalized and filtered it, and chosen a means of measuring similarity, there are a variety of approaches we can take to looking for features and the methods we use are generally grouped into two broad classes: supervised and unsupervised methods. Supervised methods use information about the underlying structure of the data to search for patterns, e.g. using clinical classification to search for genes that correlate with class. These approaches are very useful when we know a great deal about the samples, but are not useful if we want to find new disease subclasses. Unsupervised methods are very useful for data exploration and can reveal unexpected patterns in the data, although the danger is that these patterns may be an artifact of the data or the algorithm itself.

5 Class Discovery

A useful first approach in the analysis of microarray data is to use an unsupervised method to explore expression patterns of that exist in the data. The question we are asking is: "Are there unexpected but biologically interesting patterns that exist in the data?". Unsupervised methods do not use the sample classification as input – they do not take into account, for example, whether the samples come from ALL or AML patients. They simply group samples together based on some measure of similarity between then. Two of the most widely used unsupervised approaches are hierarchical clustering and *k*-means clustering.

5.1 Hierarchical Clustering

Hierarchical clustering has become one of the most widely used techniques for the analysis of gene expression data; it has the advantage that it is simple and the result can be easily visualized [30, 59, 98]. Initially, we start with N clusters, where N is the number of genes (or samples) in the target data set. Hierarchical clustering (Figure 2) is an agglomerative approach in which single expression profiles are joined to form nodes, which are further joined until the process has been carried to completion, forming a single hierarchical tree. The algorithm proceeds in a straightforward manner for the clustering of genes (or similarly for samples):

(i) Calculate the pairwise distances for all of the genes to be clustered (using an appropriately selected distance measure).

(ii) Search all of the distances for the two most similar genes or clusters; initially each cluster consists of a single gene. This is the true first stage in the "clustering" process. If several pairs share the same similarity, a predetermined rule is used to decide between alternatives.

(iii) The two selected clusters are merged to produce a new cluster that now contains two or more objects.

(iv) The distances are calculated between this new cluster and all other clusters. There is no need to calculate *all* distances since only those involving the new cluster have changed.

(v) Steps (ii)–(iv) are repeated $N - 1$ times until all objects are in one cluster.

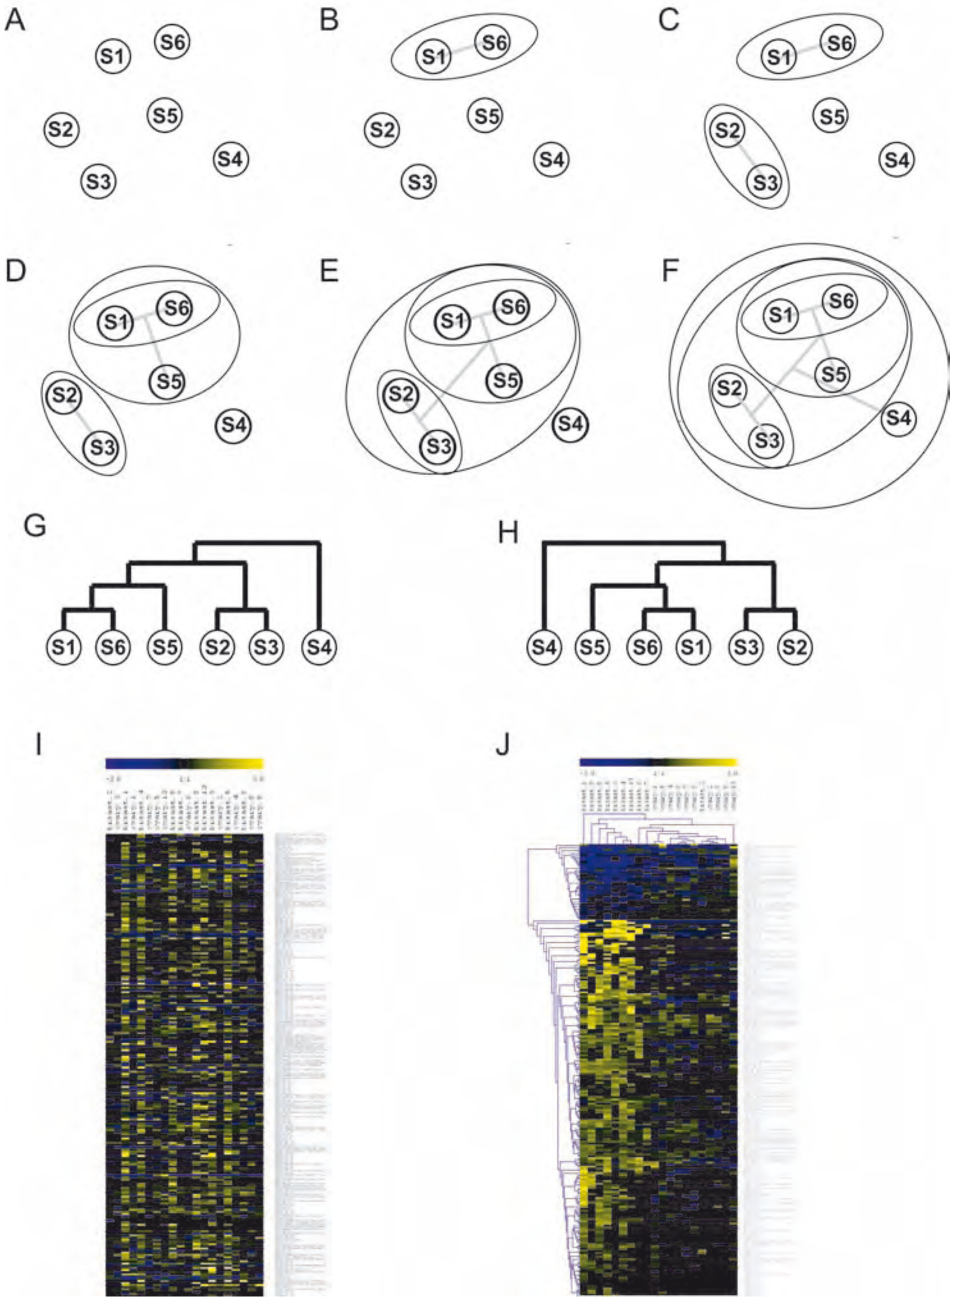
There are a number of variants of hierarchical clustering that reflect different approaches to calculating distances between the newly defined clusters and the other genes or clusters. *Single linkage* clustering determines the distance of two clusters to be the shortest distance between any pair of elements, one in each cluster, *complete linkage* clustering takes the largest distance between any such pair and *average linkage* clustering uses the average distance between all such pairs.

Typically, we represent the relationship between samples using a dendrogram where branches in the tree are built based on the connections determined between clusters as the algorithm progresses. In order to visualize the relationships between samples, we generally use the dendrogram to rearrange the columns (or rows as appropriate) in the expression matrix to better visualize patterns in the data set.

5.2 *k*-means Clustering

If there is prior knowledge regarding the number of clusters that should be represented in the data, *k*-means clustering (Figure 3) is a good alternative to hierarchical methods [5, 83]. In *k*-means, objects are partitioned into a fixed number (k) of clusters such that the clusters are internally similar but externally dissimilar; no dendrograms are produced (but one could use hierarchical techniques on each of the data partitions after they are constructed). The process involved in *k*-means clustering is conceptually simple, but can be computationally intensive:

(i) All initial objects (genes or samples) are randomly assigned to one of k clusters (where k is specified by the user).



A
S1
S6
S2
S5
S3
S4
B
C
D
E
F
G
H
I
J

(ii) An average expression vector is then calculated for each cluster and this is used to compute the distances between clusters.

(iii) Using an iterative method, objects are moved between clusters and intra- and inter-cluster distances are measured with each move. Objects are allowed to remain in the new cluster only if they are closer to it than to their previous cluster.

(iv) Following each move, the expression vectors for each cluster are recalculated.

(v) The shuffling proceeds until moving any more objects would make the clusters more variable, increasing intra-cluster distances and decreasing inter-cluster dissimilarity.

Some implementations of *k*-means clustering allow not only the number of clusters to be specified, but also seed cases for each cluster. This has the potential to allow one to use prior knowledge of the system to help define the cluster output, such as a typical profile for a few key genes known to distinguish classes of patients. Of course, the "means" in *k*-means refers to the use of a mean expression vector for each emerging cluster. As one might imagine, there are variations also use other measures or each cluster, such as *k*-medians clustering.

Although *k*-means uses prior knowledge about the number of clusters, it is unsupervised in the sense that no prior knowledge about cluster membership is used in making the assignments. One can also use measures of cluster compactness to estimate the number of clusters in the data before beginning the process [102]. One important thing to remember about *k*-means clustering is that it is not deterministic – running the algorithm twice is likely to produce different clusters or associations. There are approaches to dealing with this ambiguity, e.g. running *k*-means multiple times at fixed *k* and using the consensus clusters.

←

Figure 2 Hierarchical clustering proceeds by (A) first collecting all of the objects (genes or samples) to be clustered and calculating the pairwise distance between them. The two closest objects are then grouped, reducing the number of objects by one. The distance between this new "cluster" and the remaining objects is calculated. (B–F) The process repeats with the closest objects being fused into a new cluster until all objects are placed in a single cluster. (G) A dendrogram is then drawn representing the relationships between samples. It is important to note that dendrograms are not unique – there are many ways to represent the same relationships. The branch structure defines the relatedness of various samples. (I) An unordered data set, subjected to average linkage hierarchical clustering (J) reveals underlying patterns that can help identify classes in the data set.

5.3 Other Unsupervised Approaches

There are many approaches that have been applied to unsupervised analysis, including SOMs [85, 88, 95], self-organizing trees (SOTA) [36], relevance networks [18], force-directed layouts [47], principal component analysis [71] and others. Fundamentally, each of these uses some feature of the data and a rule for determining relationships to group genes (or samples) that share similar patterns of expression. In the context of disease analysis, all of these can be extremely useful for identifying new subclasses in the data – provided that the classes are reproducible and that they can be related to other clinical data. All of these algorithms will divide data into clusters, but whether the clusters are meaningful requires expert input and analysis. Critical assessment of the results is essential. There are anecdotal reports of clusters being found that separate data based on the hospital in which the sample was collected, the technician who ran the microarray assay or the day of the week on which the array was run. Clearly arrays can be very sensitive – one just has to filter the biological signal from the noise.

Chapter 27 addresses issue of data clustering in the context of elucidating gene function from expression data. Chapter 26 gives a detailed account of more advanced unsupervised methods for classifying expression data.

6 Classification

The goal in classification is to use supervised approaches to first find genes that separate samples into different clinical classes in the data, and then to implement an algorithm that can take the data from a new sample and, based on the patterns observed, assign that new sample to one of the previously identified classes.

One starts by assigning samples to particular biological classes based on some objective criteria. For example, in looking at leukemia samples, I may know for some initial set of data which patients have ALL and which have AML. The first question to be asked is: "Which genes best distinguish the various classes in the data?". The goal at this stage is to find those genes that

Figure 3 k-means clustering (A) begins with a collection of objects that (B) are randomly assigned to some number k of clusters, where k is specified by the user based on some intuition regarding the number of groups represented in the data. For each group, an average expression vector, represented by the hexagons, is calculated. (C) These average vectors are then used as "seeds" to form k new clusters, with objects reassigned to the new cluster whose average they are closest to. (D) Averages are computed for the new clusters, and the process repeats itself (E and F) until it converges with stable clusters. (G) An initial data set representing tumors from two organ sites (H) can be split by tissue type using k-means clustering with $k = 2$.

are most informative for distinguishing the samples based on class. Fortunately, there are a wide variety of statistical tools that can be brought to bear on this question, including t-tests (for two classes) and analysis of variance (ANOVA; for three or more classes) that assign p-values to genes based on their ability to distinguish between groups. One concern with these statistical approaches is the problem of multiple testing. Simply put, in an array with 10 000 genes, applying a 95% confidence limit on gene selection ($p \leq 0.05$) means that, by chance, one would expect to find 500 genes as significant. Clearly, we need to be more stringent in our gene selection. However, the important thing to remember is that what these methods provide are a means for prioritizing genes for further analysis. It should be noted that there are other widely used approaches, such as significance analysis of microarrays (SAM) [89], which uses an adjusted t-statistic (or F-statistic), modified to correct for overestimates arising from small values in the denominator, along with permutation testing to estimate the false discovery rate (FDR) in any selected significant gene set. Chapter 25 goes into detail about the statistics of selecting significantly differentially expressed genes.

The second key element is the selection of an appropriate classification algorithm. There are a wide range of algorithms that have been used for classification, including weighted voting [34], ANNs [14, 31], discriminant analysis [4,52,62,64], classification and regression trees (CART) [15], SVMs [17, 70], and k-nearest neighbors (kNN) [87], as well as a host of others. Essentially each of these uses an original set of samples, or training set, to develop a rule that takes a new test sample from a test set and uses its expression vector sample, trimmed to a previously identified set of classification genes, to place this test sample into the context of the original sample set, thus identifying its class.

6.1 kNN Classification

In many ways, kNN is the simplest approach to doing classification (Figure 4). First, we must assemble a collection of expression vectors for our samples and assign the samples to various experimental classes. We will refer to these samples, about which we have prior knowledge, as our *training set*. It is also useful to have a second collection of samples on which we will test the algorithm, known as the *test set*. Using the training set of samples, we then select genes that separate the various classes using an appropriate statistical test to identify good classification candidate genes, thus reducing the size of the sample classification vectors. This represents a first-pass collection of classification genes. The next step is to identify and eliminate samples that appear to be outliers. These may be important because they possibly represent new subclasses in our original sample classification set; alternatively, they

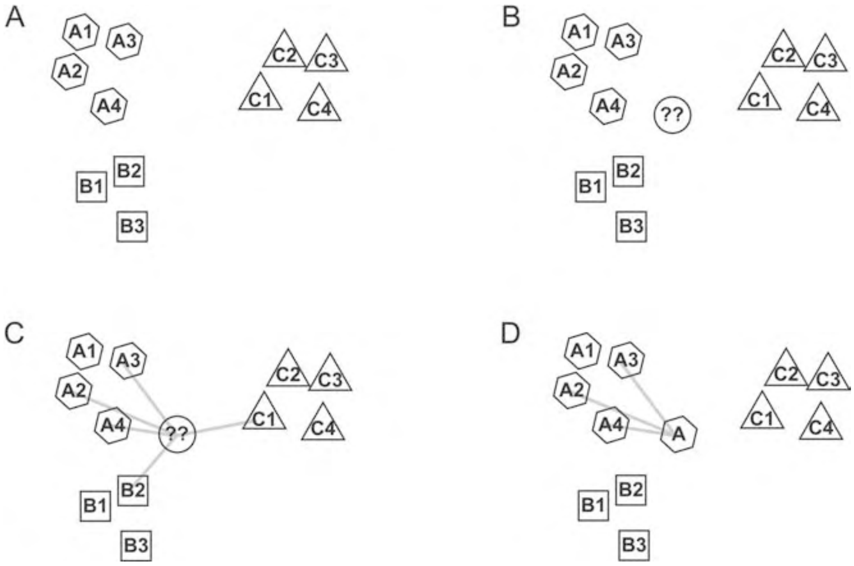

Figure 4 *k*NN classification (A) starts with a well-defined set of training samples that fall into distinct classes. (B) A sample to be classified is added from a test set. (C) The parameter *k* specifies the number of neighbors to be used in classification; for $k = 5$, the five nearest neighbors (based on some distance measure) are found. (D) Among the *k* nearest neighbors, majority rule determines the class of the test sample.

may just represent poor-quality data. The outlying samples are identified by applying a correlation filter to the reduced sample expression vectors:

(i) The Pearson correlation coefficient r is computed between a given vector and each member of the training set; the maximum r identified is called the $r_{\max}$ for that vector.

(ii) The vector is randomized a user-specified number of times, and each time, an $r_{\max}$ is calculated using the randomized vector (call it $r*_{\max}$), just as in step (i).

(iii) The fraction of times $r*_{\max}$ exceeds $r_{\max}$ over all randomizations is used to calculate a p-value for that vector.

(iv) If the p-value for a vector is less than a user-specified threshold (meaning it is well correlated with other samples), that vector is retained for further analysis; otherwise, it is discarded.

(v) Steps (i)–(iv) are repeated for every sample vector in the set.

At this stage, we have a collection of sample vectors, our training set, that represent our prior knowledge of the biological classes represented in the data.

We now turn our attention to the assigning new samples in our test set to classes based on their expression vectors and attempt to classify these test samples. For each new sample in the test set, we reduce its expression vector to include only those genes previously identified as being significant for classification. We then compute the distance between this reduced expression vector and the reduced expression vectors for each and every sample in the training set. As the name *k*NN implies, we choose some number k of nearest neighbors from the training set – those k vectors that have the smallest distances from our test sample. We then simply assign the new test vector to the class most highly represented in its k nearest neighbors. If there is a tie, the new sample is unclassified.

Chapter 26 goes into more detail about how to classify samples of expression data.

7 Validation

Ideally, to validate a classification method, it is most useful to have a set of samples in the test set that is independent of those used in the training set. In practice, microarray studies often have a limited number of samples and these are needed for building and training the algorithm. An alternative to using an independent test set is to do *leave*-k-*out cross-validation* (LKOCV) [81]. As one might guess, this approach leaves out some subset of the initial collection of N samples, develops a classifier using the $(N - k)$ samples that remain and applies it to k samples in the test set. This process is then repeated choosing a new set of k vectors to be left out and classified, and the process repeats itself. The simplest approach is to simply do leave-one-out cross-validation (LOOCV).

While this approach can be extremely useful when we lack an independent test set, it is often applied inappropriately as a partial rather than a full cross-validation. The distinction is the stage in the process where one "leaves k out". Many published studies have used their entire data set to select a set of classification genes, and *then* divide the samples into k and $(N - k)$ sample test and training sets. In fact, this has the potential to bias the results because the test and training sets are not independent as all of the samples were used to select the classification gene set. In particular, the presence of all of the samples in the initial gene selection process may favorably bias the ultimate success of any classifier that is constructed.

In *full* LKOCV, the data is divided into k and $(N - k)$ sample test and training sets, and the $(N - k)$ training set is used to select a classification gene set and then to apply it to creating a classification algorithm and using it to classifying the k test samples. One can then estimate the accuracy of the classification system by simply averaging over the complete set of classifiers.

8 Sample Selection and Classification

The choice of samples for training is an important but often neglected element of developing a classifier. One of the most important issues in sample selection is balancing representation of sample classes, as well as making sure that the analysis is not confounded by other factors. Nearly all algorithms work by a majority consensus rule and if we have two classes, A and B, with eight in class A and two in class B, the simplest classifier would simply assign everything to class A with 80% accuracy – a result that clearly would not be widely applicable. We also need to make sure that the samples are selected such that there are no confounding factors. For example, if we wanted to classify patients based on survival and all of the surviving patients received adjuvant chemotherapy, while the patients in the nonsurviving class did not, it is not likely that the patterns we find and use for classification will be applicable to a more heterogeneous population. It is also clear that selecting a sample of sufficient size to resolve classes is an important consideration [22, 61, 80]. One important aspect of this problem was recently illustrated in a publication by Radich and colleagues [69], which analyzed gene expression levels in peripheral blood and demonstrated significant but reproducible inter-individual variation in expression for a 1130 genes (selected from an array assaying 24 000 transcripts). What this suggests is that a small sample size *may* lead to biases in the gene selection set due to random effects in assigning patients to classes. These differences may be biological in nature or they may be due to systematic effects such as where the experimental population lives or the protocol used for sample collection. A truly independent test set would allow the results from a study to be validated in a much more meaningful and robust manner. Chapter 26 gives a more detailed statistical account of supervised methods for classifying expression data.

9 Limitations and Success of Classification

Although there have been attempts to identify "the best" classification approach, the evidence suggests that there is no single method that will work in all cases and, similarly, that many methods may work in any particular case. What is important is to understand the limitations of the approach. Most of the studies that have been conducted to date have involved relatively small numbers of patients and it is not at all clear how these results will generalize to larger clinical populations, with samples collected across a number of sites, with variations in sample collection and handling that occur outside of a well controlled laboratory-based study.

One potential difficulty in using expression profiles for classification is that very often the signatures that are identified are not easily interpreted causally or mechanistically with respect to the underlying disease. Ultimately, finding genes that can be functionally linked to outcome may provide insight into possible therapeutic interventions. However, the failure to provide a biological interpretation does not diminish the potential clinical utility of well-established biomarkers. It should be noted that there are many examples of biomarkers of unknown function, such as prostate-specific antigen (PSA) or carcinoembryonic antigen (CEA), that are extremely useful as diagnostic or prognostic markers for various diseases. It may be more useful to consider gene lists emerging from classification experiments as nothing more that sets of biomarkers with clinical applications; if they have a biological interpretation, this is simply a bonus.

10 Data Reporting and Comparisons

As noted previously, many microarray studies are underpowered in the sense that they do not include enough samples to draw firm conclusions without the collection of additional samples that can be used for validation. While collecting new samples, particularly patient samples that require significant follow-up, can be a challenge, the increasing number of published microarray studies provides an opportunity for the analysis of additional, independently derived data sets. To facilitate comparisons between studies, the Microarray Gene Expression Data (MGED) society developed a set of standards for data reporting known as MIAME (the Minimal Information About a Microarray Experiment) [7–10, 16].

The MIAME standards attempt to capture all of the information necessary to fully describe a particular microarray experiment. The driving principle in developing MIAME was an attempt to answer the question: “What would an independent scientist need to know to analyze a particular published experiment?”. In discussing this problem, the MGED group came to the realization that answering this question required nearly complete descriptions of all aspects of the experiment, including the composition and construction of the microarray platform itself (and specifically the sequence of the individual probes used on the arrays), the protocols used for RNA labeling and hybridization, the design of the hybridization assays performed (detailing, in two-color assays, which samples are compared on each array), the methods used for data extraction and analysis, and, most importantly, the design and implementation of the method used to assemble the samples including a detailed description of those samples.

Although there was some initial resistance to MIAME (as it required, what some termed, maximal rather than minimal information) the research community came to acknowledge that the requested was essential to effective data interpretation. At a very high level, it is the samples and their annotation that drive the analysis (e.g. what genes separate tumor and normal tissue). However, the genes selected in a study depend on understanding what genes are represented on the array and probe sequence allows the results to evolve as our understanding of the genome does, as well as providing a basis for comparison between studies. Microarrays are sensitive enough that we now know that minor variations in protocols, such as between hospitals or in creating different lots of arrays, can often be detected in the assays, and so even that level of detail is useful. Further, all of the results depend on the methods used for data analysis and different approaches can produce different results.

The major DNA sequence databases have developed gene expression data repositories that require MIAME-compliant data, and most journals now require that both raw and transformed data be submitted to one of these repositories; efforts are ongoing, both in the public and private sectors, to develop software that captures and presents data consistent with the MIAME standards. There is tremendous value in making gene expression data sets publicly available. In addition to serving as a source of independent data that can be used as a means of validating results, larger and more diverse sample populations, including cross-species comparisons, can provide more robust data sets for "meta-analysis" designed to find universal patterns of gene expression that can be associated with a given biological system [57, 84].

One must also exercise caution in comparing data sets between laboratories. Although there have been many successful applications of microarray analysis, often with high rates of validation using an alternate technology such as Northern analysis or quantitative reverse transcription polymerase chain reaction (qRT-PCR), a number of published studies have called into question the validity of microarray assays, in part because of observed disparities between results obtained by different groups analyzing similar samples [48, 55, 56, 65, 72, 79, 90, 101]. However, in many instances, it seems that the failure to find concordance between microarray platforms designed to assay biologically relevant patterns of expression is a failure not of the platform or the biological system, but rather a reflection of metrics used to evaluate concordance. Other meta-analyses focus on overlapping lists of significant genes, neglecting the fact that in many instances these are derived from not only different platforms, but also vastly different approaches to data analysis [42, 55, 86] – an effect can be seen even in looking at a single data set generated on a single platform. When this has been compensated for, the results generally show good concordance between different laboratories and the various array types [11, 19, 38, 44, 94, 103].

This problem of between-platform and -laboratory comparison was systematically dealt with in a series of papers that appeared in the May 2005 issue of *Nature Methods* [41, 51, 96]. Larkin and coworkers [51] analyzed gene expression in a mouse model of hypertension and compared results obtained using spotted cDNA arrays and Affymetrix GeneChips^{TM}. What they found was that for the genes that could be compared, 88% showed expression patterns that were driven by the underlying biology rather than the platform and that these genes also correlated well with real-time qRT-PCR). Surprisingly, the 12% of genes that showed platform-specific effects also correlated poorly with qRT-PCR. When comparing these platform discrepant genes to the platform concordant genes, it was found that the discrepant genes were much more likely to map to poorly annotated regions of the genome and consequently more likely to represent different splice forms. Irizarry and colleagues [41] compared gene expression using pairs of defined RNA samples and looked at a variety of platforms with data generated by a number of laboratories using a variety of microarray platforms. What Irizarry showed is that one can estimate the "lab effect," which encompasses differences in sites, platforms and protocols, and in doing so arrive at estimates of gene expression that can be compared between laboratories. Finally, the Toxicogenomics Research Consortium [96] reported that a careful standardization of laboratory and data analysis protocols resulted in a dramatic increase in concordance between the results obtained by different laboratories. The general conclusion, arrived at by these three groups independently, is that if experiments are done and analyzed carefully and systematically, the results are quite reproducible and provide insight to the underlying biology driving the systems being analyzed.

There are a number of other efforts to improve the overall utility of microarray data. MGED continues to develop standards for data reporting in standardized formats, particularly through the creation of the MGED ontology to describe experiments in a consistent fashion and an MGED working group is also seeking to develop objective quality standards for DNA microarrays. At present, this is seen as one of the greatest challenges in extending the utility of microarray analyses. In many ways, the development of objective quality scores for DNA sequence changed the way in which sequence data were used and the general consensus is that a similar transformation is necessary in the microarray field.

The challenge here, just as in data analysis, is that functional genomics data are much more complex than genome sequence data. One can define quality metrics on the level of the individual array probes, at the level of an entire array or in the context of a particular study comprised of hundreds of arrays. The real questions come down to understanding whether a particular assay is useful for the identification of genes that can be correlated with particular phenotypes and how high a level of confidence one can place in the results. There are various approaches that have been proposed ranging from intrinsic measures starting with signal-to-noise for each probe and analysis of replicates to the use of extrinsic standards, such as exogenous RNAs “spiked” into each assay. Likely, a combination of these approaches will emerge and prove to be useful.

Following the success of MIAME, a number of groups are attempting to extend MIAME to better capture information relevant to their particular disciplines (http://www.mged.org/Workgroups/rsbi/rsbi.html), including a MIAME/Tox for toxicogenomics, MIAME/Env for environmental exposures [75] and MIAME/Nut for nutrigenomics [33]. Work is also ongoing to develop standards for proteomics – the Minimal Information About a Proteomics Experiment (MIAPE [63]) – and for metabolomic/metabolonomic profiling – the Standard Metabolic Reporting Structure ([53]; http://www.smrsgroup.org). Finally, the External RNA Control Consortium (http://www.cstl.nist.gov/-biotech/workshops/ERCC2004/) [24] is attempting to create a set of well-defined RNA samples that can be used in as a control and calibration standard for a wide range of gene expression technologies.

11 Meta-analysis

Regardless of the initial goal of any microarray analysis, the most satisfying analysis yields insight into the underlying biological processes and this tends to be the most significant challenge that one must address in any study. The results of most analyses are a long list of genes that somehow need to be placed into a broader context. Further, additional data sources to the analysis can help provide constraints to mitigate the potential problems of multiple testing by providing independent pieces of evidence that the genes selected from a microarray study really do contribute to the underlying biology.

Fortunately, there is a long history of biological investigation and many tools and techniques that can be used effectively to further classify the data and aid in its interpretation. Some approaches build on relationships found by linking genes to PubMed abstracts or the associated Medical Subject Heading (MeSH) terms [26,28,32,43,58,104]. Others use constraints from the biological system under analysis such as using genetic linkage or quantitative trait locus (QTL) maps to narrow down the set of significant genes to those mapping to regions of the genome associated with appropriate trait [23, 27, 49, 77], although this can miss genes that contain causative mutations but which are not differentially regulated [23]. In solid tumor studies, one can analyze correlations between expression patterns and genome deletions or amplifications as determined by comparative genomic hybridization on arrays (array CGH) [21,35]. In developmental imprinting studies, gene expression may be compared to patterns of methylation [20,29], etc.

Another approach is to use the properties of the array itself to extract additional information. Ideally, each probe on the array should have been designed to query a specific transcript and each array element should carry annotation describing the gene and its known or putative function. There are many sources that can be drawn upon to provide classification that can be used for further analysis.

The Gene Ontology (GO) project (http://www.geneontology.org) attempts to classify gene products, assigning proteins to groups specifying their Molecular Function, the Biological Process to which they contribute, and their Cellular Component [6]. The GO terms in each class form a hierarchy of increasing specificity [formally, a directed acyclic graph (DAG)] so that the broadest classifications provide a general picture of the functional class to which a gene belongs (e.g. a kinase), while more precise terms will specify precisely what a particular gene does (such as specifying the substrate on which a kinase acts). As not all genes have a complete functional classification, increasing specificity reduces the sensitivity for placing genes into a particular functional class. As the functions of many genes have not been fully explored, there are some advantages to using the less-specific classes, which are often assigned based on sequence homology searches, for some analyses. Similarly, using Enzyme Commission (EC) numbers, genes can be mapped to metabolic and signaling pathway databases such as KEGG (Kyoto Encyclopedia of Genes and Genomes, http://www.genome.ad.jp/kegg) [45]. Mapping sequences to the genome sequence available for an increasing number of species can put the data into the context of genetic mapping results (e.g. QTL maps), chromosomal amplification and deletion data (important for the analysis of many forms of cancer), and allow analysis of epigenetic effects (such as promoter analysis from computational searches or chromatin immunoprecipitation analysis of transcription factor binding). Even linking array elements to the associated PubMed abstracts can provide insight given some final significant gene list.

Another very attractive approach is to use the properties of the data and the construction of the array to look for significant functional associations. You will recall that one of the key elements in establishing an array platform is the annotation of the arrayed probe elements. Imagine, for example, that 20% of the genes on the array are annotated as belonging to GO categories representing energy metabolism. If this is the case, then if we were to select, at random, a collection of "significant" genes would most likely have approximately 20% of its elements as belonging to the same energy metabolism class. In fact, we might not be very surprised if 30% of the genes in our significant set were energy metabolism genes; however, if the fraction were 80%, it might suggest that our experiment affected energy metabolism with a much higher frequency than one might expect by chance. Such insight may indeed provide clues as to the mechanisms at work in the biological system under study.

One widely used approach to leverage these classification schemes starts with the genes in a selected "significant" set that was selected based on the biology of phenotype under study. In looking at the classification assigned to these genes, as well as the classification assigned to the collection of genes on the array, one simply asks whether any particular class is overrepresented in the significant set and the Fisher exact test does precisely that. While doing this for any particular class is relatively straightforward, applying this method to a large collection assigned classes such as KEGG pathways or GO terms can be a huge challenge; for GO, what we really want to do is to consider all possible terms in the GO hierarchy. Fortunately, there are some software tools, including MAPPFinder [28], GOMiner [104] and EASE [37] (also implemented in MeV [74]) that calculate p-values for GO, KEGG, GenMAPP, Pfam and SMART protein domain assignments, promoter elements and a range of other classification systems.

The advantage of this approach is that it can provide a high-level view of functional classes or pathways that might be significantly affected in an experiment. However, we have to remember that these are functional classes, not functions, and deciphering these requires significant additional effort. It should also be noted that the only genes on each array that can be analyzed using this approach are those for which we have functional assignments. In any given experiment, one often finds a number of unknown expressed sequence tags (ESTs) and predicted genes that do not have defined functions and these drop out of any category-based meta-analysis. One approach to "rescue" these is to look for functional classes that pass a significance test and then to search the data for other genes that have similar patterns of expression across the sample. This provides a testable hypothesis that the genes of unknown function belong that that particular functional class.

If large, well-curated databases exist, such analysis can be carried out in interesting ways. For example Stuart and colleagues [84] started with gene expression data representing more than 3000 assays collected from a range of experiments in human, *Drosophila*, *Caenorhabditis elegans* and yeast, and stored in a common format in the Stanford Microarray Database (http://genome-www5.stanford.edu). By first identifying likely orthologs across all four species and then searching for orthologs that were highly correlated across the evolutionary history represented in the collection, they were able to test the hypothesis that genes fulfilling core biological functions should have conserved patterns of expression. Among their findings were a set of genes not previously associated with cell proliferation/cell cycle that the exhibit significant association with known genes mapped to these fundamental pathways. In order to test the hypothesis that the unknown genes were, in fact, involved in the cell cycle, Stuart and colleagues first looked at gene expression in a previously published human study comparing pancreatic tumors and normal tissue [39], and discovered that these genes were highly up-regulated in the rapidly dividing cancer cells. To further lend support to the association of these genes with cell cycle and proliferation functions, a RNA interference experiment was performed in *C. elegans* using one of these genes (ZK652.1) and the resulting loss of function phenotype included cells in the germline containing excess nuclei, suggesting the role of the gene is to suppress germline proliferation.

While significant process has been made in this area, our approaches to meta-analysis remain primitive. A great deal of work remains to be done in this area and as well-annotated, high-quality data sets are assembled and stored in databases such as GEO and ArrayExpress, our hope is that these will facilitate the creation of new, flexible software tools that can more effectively be used to discover function.

Part VIII of the book (Chapters 29–35) discusses in detail bioinformatics approaches towards elucidating gene and protein function, starting with approaches that reside upon a certain kind data, e.g. sequence, structure, free text, etc., and ending in a discussion of methods for integrating different kinds of data.

12 The Path Forward

For the time being, it appears that the greatest impact of arrays will remain their use in classification and, although these are still in there infancy, they are starting to see broader applications. One such example is The Netherlands Breast Cancer Study [91], which sought to distinguish between patients with the same stage of disease, but different response to treatment and overall outcome. The study was motivated by the observation that the best clinical predictors for metastasis, including lymph node status and histological grade, did not provide adequate prediction of clinical outcome. As a result many patients receive chemotherapy or hormonal therapy regardless of whether they need this additional treatment. The goal of their analysis was to identify signatures that would allow for individually tailored therapeutic strategies. By profiling tumors from 117 young patients and looking for correlations with clinical outcome, they were able to identify a “poor prognosis” signature comprised of 70 genes that was predictive of a short interval to distant metastasis in lymph node negative patients. Their analysis demonstrated that microarray-based signatures could outperform any clinically based predictions of outcome in identifying those patients who would benefit most from adjuvant therapy. The success of this initial study motivated a more extensive independent follow-up study involving 295 patients [92] that showed that the 70 gene classification profile was a more powerful predictor of the outcome of disease in young patients with breast cancer than standard systems based on clinical and histological criteria. The success of these two studies has led to a nationwide clinical trial in The Netherlands in which gene expression profiles for these 70 classifier genes are being collected on all breast cancer patients and used as an adjunct to classical clinical staging. Although we are still eagerly awaiting the outcome of this study, it is clear that the use of expression profiles as biomarkers to predict disease prognosis and outcome is coming of age.

Low-level Analysis of Microarray Experiments

Wolfgang Huber, Anja von Heydebreck and Martin Vingron

1 Introduction

This chapter gives an overview over the methods used in the low-level analysis of gene expression data generated using DNA microarrays. This type of experiment allows to determine relative levels of nucleic acid abundance in a set of tissues or cell populations for thousands of transcripts or loci simultaneously. Careful statistical design and analysis are essential to improve the efficiency and reliability of microarray experiments throughout the data acquisition and analysis process. This includes the design of probes, experimental design, image analysis of microarray scanned images, normalization of fluorescence intensities, the assessment of the quality of microarray data and incorporation of quality information in subsequent analyses, combination of information across arrays and across sets of experiments, the discovery and recognition of patterns in expression at the single-gene and multiple-gene levels, and assessment of significance of these findings, considering the fact that there is a lot of noise and thus random features in the data. For all of these components, access to a flexible and efficient statistical computing environment is an essential aspect.

1.1 Microarray technology

In the context of the Human Genome Project, new technologies emerged that facilitate the parallel execution of experiments on a large number of genes simultaneously. The so-called *DNA microarrays*, or *DNA chips*, constitute a prominent example. This technology aims at the measurement of nucleic acid levels in particular cells or tissues for many genes or loci at once. Nucleic acids of interest can be polyadenylated RNA, total RNA or DNA. We will in the following use the term *gene* loosely to denote any unit of nucleic acid of interest. Single strands of complementary DNA for the genes to be considered are immobilized on spots arranged in a grid (*array*) on a support which will typically be a glass slide or a quartz wafer. The number of spots can range

Bioinformatics – From Genomes to Therapies Vol. 2. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

from dozens to millions. From a sample of interest, e.g. a tumor biopsy, the nucleic acid is extracted, labeled and hybridized to the array. Measuring the amount of label on each spot then yields an intensity measurement that should be correlated to the abundance of the corresponding gene in the sample. Chapter 24 goes into more detail regarding the experimental technology, therefore we only give a short summary here.

Two schemes of fluorescent labeling are in common use today. One variant labels a single sample. For example, the Affymetrix synthesizes sets of short oligomers on a glass wafer and uses a single fluorescent label ([26], see also www.affymetrix.com). Alternatively, two samples are labeled with a green and a red fluorescent dye, respectively. The mixture of the two nucleic acid preparations is then hybridized simultaneously to a common array on a glass slide. In the case where the probes are polymerase chain reaction (PCR) products from cDNA clones that are spotted on the array, this technology is usually refered to as the Stanford technology [12]. On the other hand, companies like Agilent have immobilized long oligomers of 60–70 bp length and used two-color labeling. The hybridization is quantified by a laser scanner that determines the intensities of each of the two labels over the entire array.

The parallelism in microarray experiments lies in the hybridization of nucleic acids extracted from a single sample to many genes simultaneously. The measured abundances, though, are usually not obtained on an absolute scale. This is because they depend on many hard-to-control factors such as the efficiencies of the various chemical reactions involved in the sample preparation, as well as on the amount of immobilized DNA available for hybridization.

Traditionally, one or a few probes were selected for each gene, based on known information on its sequence and structure. More recently, it has become possible to produce probes for the complete sequence content of a whole genome or for significant parts of it [3,6,32].

1.2 Prerequisites

A number of steps are involved in the generation of the raw data. The *experimental design* includes choice and collection of samples (tissue biopsies or cell lines exposed to different treatments), choice of probes and array platform, choice of controls, RNA extraction, amplification, labeling and hybridization procedures, allocation of replicates, and scheduling of the experiments. Careful planning is needed, as the quality of the experimental design determines to a large extent the utility of the data [7,23,42]. A fundamental guideline is the avoidance of *confounding* between different biological factors of interest or between a biological factor of interest and a technical factor that is anticipated to affect the measurements.

There are many different ways for the outline of a microarray experiment. In many cases, a development in time is studied leading to a series of hybridizations following each other. In a cohort study, different conditions like healthy/diseased or different disease types may be studied. In designed factorial experiments, one or several factors, e.g. treatment with a drug, genetic background and/or tissue type, are varied in a controlled manner. We generally refer to a time point or a state as a condition and typically for each condition several replicate hybridizations are performed. The replicates should provide the information necessary to judge the significance of the conclusions one wishes to draw from the comparison of the different conditions. When going deeper into the subject it soon becomes clear that this simple outline constitutes a challenging program.

1.3 Preprocessing

Preprocessing is the link between the raw experiment data and the higher-level statistical analysis. The five tasks of preprocessing can be summarized as follows: data import, background adjustment, normalization, summarization of multiple probes per transcript and quality control. They are driven by the properties of microarray technology. The data come in different formats and are often scattered across a number of files (or, possibly, database tables), from which they need to be extracted and unified. Part of the hybridization is nonspecific and the measured intensities are affected by noise in the optical detection. Therefore, the observed intensities need to be adjusted to give accurate measurements of specific hybridization. We refer to this aspect of preprocessing as *background adjustment*. Different efficiencies of reverse transcription, labeling or hybridization reactions among different arrays cause systematic technical biases and need to be corrected. We call the task of manipulating data to make measurements from different arrays comparable *normalization*. On some platforms, genes are represented with more than one probe. *Summarizing* the data is necessary when we want to reduce the measurements from various probes into one quantity that estimates the amount of RNA transcript. The reproducibility of measurements is limited by random fluctuations or measurement error. Basically, we can distinguish between two types of fluctuations: (i) those that affect individual measurements, and follow a localized distribution, and (ii) those, that affect whole groups of measurements, and are often drastic, large and irregular. The former type can be described with *error models*, while the latter is best dealt with by *quality control* procedures that try to detect and eliminate the affected measurements.

2 Visualization and Exploration of the Raw Data

A microarray experiment consists of the following components: a set of *probes*, an *array* on which these probes are immobilized at specified locations, a *sample* containing a complex mixture of labeled biomolecules that can bind to the probes and a *detector* that is able to measure the spatially resolved distribution of label after it has bound to the array. The probes are chosen such that they bind to specific sample molecules; for DNA arrays, this is ensured by the high sequence specificity of the hybridization reaction between complementary DNA strands. The array is typically a glass slide or a quartz wafer. The sample molecules are labeled through fluorescent dyes such as phycoerythrin, Cy3 or Cy5. After exposure of the array to the sample, the abundance of individual species of sample molecules can be quantified through the signal intensity at the matching probe sites. To facilitate direct comparison, the spotted array technology developed in Stanford [12] involves the simultaneous hybridization of two samples labeled with different fluorescent dyes, and detection at the two corresponding wavelengths. Figure 1 shows an example.

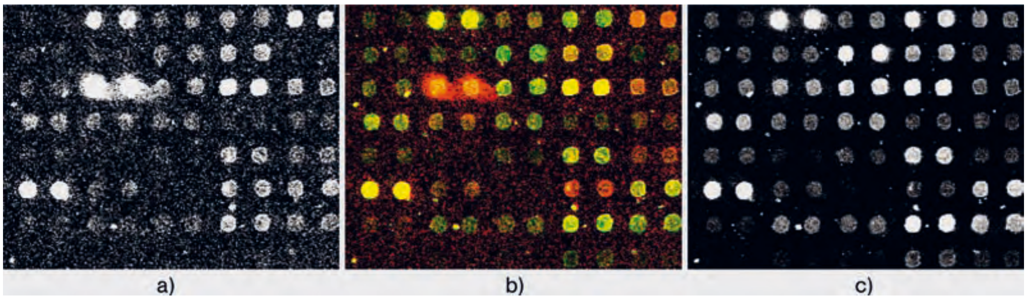

Figure 1 The detected intensity distributions from a cDNA microarray for a region comprising 40 probes spotted in duplicate. The total number of probes on an array may range from a few dozens to tens of thousands. (a) Grey-scale representation of the detected label fluorescence at 635 nm (red), corresponding to mRNA sample A. (c) Label fluorescence at 532 nm (green), corresponding to mRNA sample B. (b) False-color overlay image from the two intensity distributions. The spots are red, green or yellow, depending on whether the gene is transcribed only in sample A, sample B or both.

2.1 Image Analysis

In the *image analysis* step we extract probe intensities out of the scanned images, such as shown in Figures 1 and 2. The images are scanned by the detector at a high spatial resolution, such that each probe is represented by many pixels. In order to obtain a single overall intensity value for each probe, the corresponding pixels need to be identified (segmentation) and the intensities need to be summarized (quantification). In addition to the overall

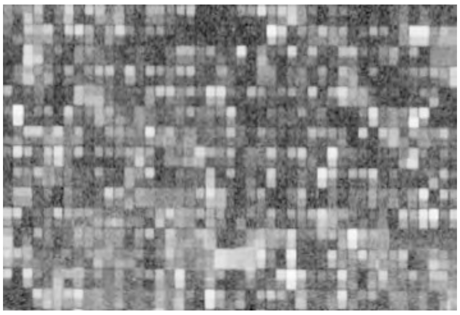

Figure 2 Gray-scale representation of the intensity distribution from a small sector of an Affymetrix HG-U133A genechip.

probe intensity, further auxiliary quantities may be calculated, such as an estimate of apparent unspecific "local background" intensity or spot quality measures.

Various software packages offer a variety of segmentation and quantification methods. They differ in their robustness against irregularities and in the amount of human interaction that they require. Different types of irregularities may occur in different types of microarray technology and a segmentation or quantification algorithm that is good for one platform is not necessarily suitable for another. For instance, the variation of spot shapes and positions that the segmentation has to deal with depends on the properties of the support and how the probes were attached to it (e.g. quill-pen type printing of PCR product, *in situ* oligonucleotide synthesis by ink jetting, *in situ* synthesis by photolithography). Furthermore, larger variations in the spot positioning from array to array can be expected in home-made arrays than in mass produced ones. An evaluation of image analysis methods for spotted cDNA arrays is described by Yang and coworkers [40].

For a microarray project, the image quantification marks the transition in the work flow from "wet-lab" procedures to computational ones. Hence, this is a good point to spend some effort looking at the quality and plausibility of the data. This has several aspects: confirm that positive and negative controls behave as expected, verify that replicates yield measurements close to each other, and check for the occurrence of artifacts, biases or errors. In the following we present a number of data exploration and visualization methods that may be useful for these tasks.

2.2 Dynamic Range and Spatial Effects

A simple and fundamental property of the data is the dynamic range and the distribution of intensities. Since many experimental problems occur at the level of a whole array or the sample preparation, it is instructive to look

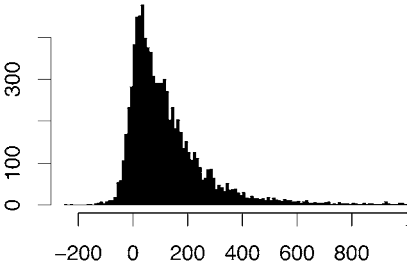

Figure 3 Histogram of probe intensities at the green wavelength for a cDNA microarray similar to the one depicted in Figure 1. The intensities were determined, in arbitrary units, by an image quantification method and "local background" intensities were subtracted. Due to measurement noise, this lead to nonpositive probe intensities for part of the genes with low or zero abundance. The x-axis has been cut off at the 99% quantile of the distribution. The maximum value is about 4000.

at the histogram of intensities from each sample. An example is shown in Figure 3. Typically, for arrays that contain quasi-random gene selections, one observes a unimodal distribution with most of its mass at small intensities, corresponding to genes that are not or only weakly transcribed in the sample, and a long tail to the right, corresponding to genes that are transcribed at various levels. In most cases, the occurence of multiple peaks in the histogram indicates an experimental artifact. To get an overview over multiple arrays, it is instructive to look at the box plots of the intensities from each sample. Problematic arrays should be excluded from further analysis.

Crude artifacts, such as scratches or spatial inhomogeneities, will usually be noticed already from the scanner image at the stage of the image quantification. Nevertheless, to get a quick and potentially more sensitive view of spatial effects, a false-color representation of the probe intensities as a function of their spatial coordinates can be useful. There are different options for the intensity scaling, among them the linear, logarithmic and rank scales. Each one will highlight different features of the spatial distribution. Examples are shown in Figure 4. A more sophisticated and more sensitive method to detect subtle artifacts is to look at the residuals of a probe-level model fitted for a set of arrays instead of the probe intensities themselves [5].

2.3 Scatterplot

Usually, the samples hybridized to a series of arrays are biologically related, such that the transcription levels of a large fraction of genes are approximately the same across the samples. This can be expected, for example, for cell cultures exposed to different conditions or for cells from biopsies of the same tissue type, possibly subject to different disease conditions. Visually, this can

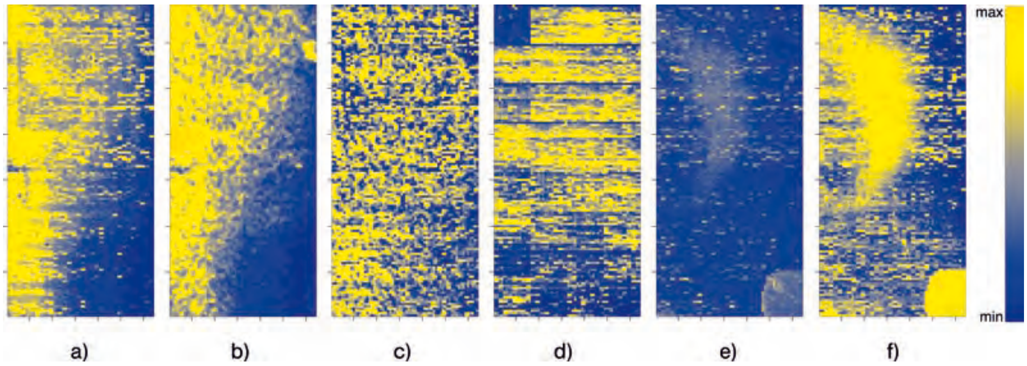

Figure 4 False-color representations of the spatial intensity distributions from three different 64×136 spot cDNA microarrays from one experiment series. The color scale is shown in the panel on the right. (a) Probe intensities in the red color channel, (b) local background intensities and (c) background-subtracted probe intensities. In (a) and (b), there is an artifactual intensity gradient, which is mostly removed in (c). For visualization, the color scale was chosen in each image to be proportional to the ranks of the intensities. (d) For a second array, probe intensities in the green color channel. There is a rectangular region of low intensity in the top left corner, corresponding to one print-tip. Apparently, there was a sporadic failure of the tip for this particular array. Panels (e) and (f) show the probe intensities in the green color channel from a third array. The color scale was chosen proportional to the logarithms of intensities in (e) and proportional to the ranks in (f). Here, the latter provides better contrast. Interestingly, the bright blob in the lower right corner appears only in the green color channel, while the half-moon-shaped region appears both in green and red (not shown).

be examined from the scatterplot of the probe intensities for a pair of samples. An example is shown in Figure 5.

The scatterplot allows us to assess both measurement noise and systematic biases. Ideally, the data from the majority of the genes that are unchanged should lie on the bisector of the scatterplot. In reality, there are both systematic and random deviations from this [33]. For instance, if the label incorporation rate and photoefficiency of the red dye were systematically lower than that of the green dye by a factor of 0.75, the data would be expected not to lie on the bisector, but rather on the line $y = 0.75x$.

Most of the data in Figure 5 is squeezed into a tiny corner in the bottom left of the plot. More informative displays may be obtained from other axis scalings. A frequently used choice is the double-logarithmic scale. An example is shown in Figure 6. It is customary to transform to new variables $A = (\log R + \log G)/2$, $M = \log R - \log G$ [11]. Up to a scale factor of $\sqrt{2}$, this corresponds to a coordinate system rotation by 45°. The horizontal coordinate A is a measure of average transcription level, while the *log-ratio* M is a measure for differential transcription. If the majority of genes are not differentially transcribed, the scatter of the data in the vertical direction may be considered a measure of the random variation. Figure 6(a) also shows a systematic

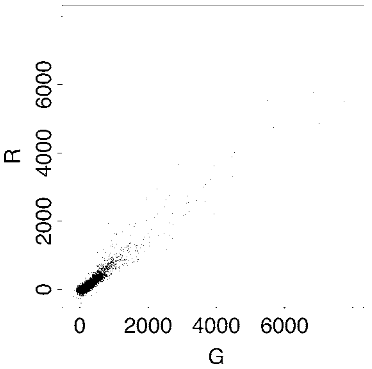

Figure 5 Scatterplot of probe intensities in the red and the green color channel from a cDNA array containing 8000 probes.

deviation of the observed values of M from the line $M = 0$, estimated through a local regression line (we used loess [8] with default parameters span = 0.75, degree = 2). There is an apparent dependence $M_0(A)$ of this deviation on the mean intensity A. However, this is most likely an artifact of applying the logarithmic transformation: as shown in Figure 6(b), the regression line may be modeled sufficiently well by a constant $M_0(A) = M_0$ if an appropriate offset is added to the R values before taking the logarithm. Note that a horizontal line at $M = M_0$ in Figure 6(b) corresponds to a straight line of slope 2^{M_0} and with intercept c in Figure 5.

Figure 6 shows the *heteroskedasticity* of log-ratios: while the variance of M is relatively small and approximately constant for large average intensities A, it becomes larger as A decreases. Conversely, examination of the differences $R - G$, e.g. through plots like in Figure 5, shows that their variance is smallest for small values of the average intensity $R + G$ and increases with $R + G$. Sometimes, one wishes to visualize the data in a manner such that the variance is constant along the whole dynamic range. A data transformation that achieves this goal is called a variance-stabilizing transformation. In fact, *homoskedastic* representations of the data are not only useful for visualization, but also for further statistical analyses. This will be discussed in more detail in Section 5.2.

Two extensions of the scatterplot are shown in Figures 7 and 8. Rather than plotting a symbol for every data point, they use a density representation, which may be useful for larger arrays. For example, Figure 7 shows the scatterplot from the comparison of two tissue samples based on 152 000 probes [the arrays used were RZPD Unigene-II arrays (www.rzpd.de)]. The point density in the central region of the plot is estimated by a kernel density estimator. Three-way comparisons may be performed through a projection such as in Figure 8. This uses the fact that the $(1, 1, 1)$-component of a three-way

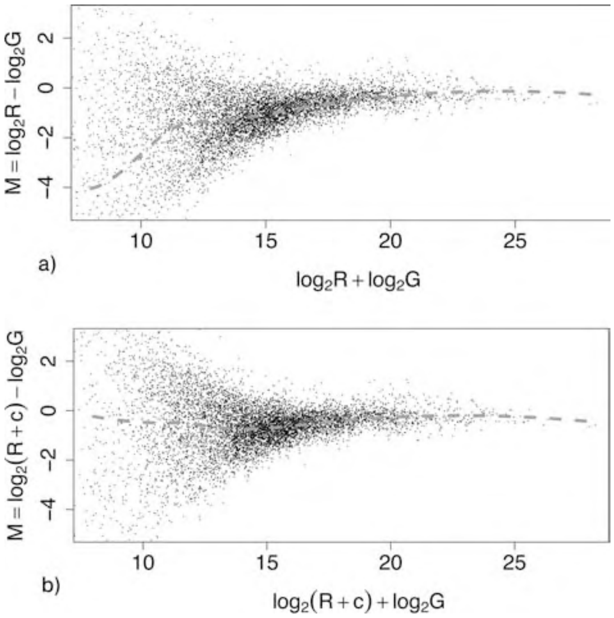

Figure 6 (a) The same data as in Figure 5, after logarithmic transformation and clockwise rotation by 45°. The dashed line shows a local regression estimate of the systematic effect $M_0(A)$, see text. (b) similar to (a); however, a constant value $c = 42$ has been added to the red intensities before log transformation. After this, the estimated curve for the systematic effect $M_0(A)$ is approximately constant.

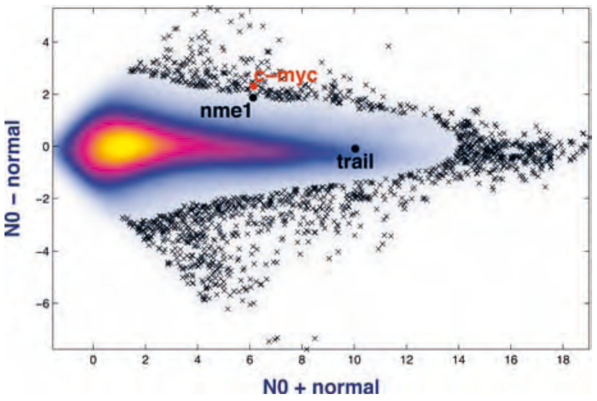

Figure 7 Scatterplot of a pairwise comparison of noncancerous colon tissue and a colorectal tumor. Individual probes are represented by crosses. The x-coordinate is the average of the appropriately calibrated and transformed intensities (see Section 5.2). The y-coordinate is their difference and is a measure of differential transcription. The array used in this experiment contained 152 000 probes representing around 70 000 different clones. Since plotting all of these would lead to an uninformative solid black blob in the center of the plot, the point density is visualized by a color scale and only 1500 data points in sparser regions are individually plotted.

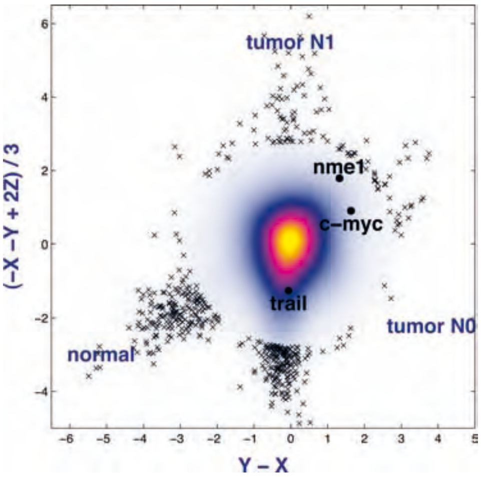

Figure 8 Scatterplot of a triple comparison between noncancerous colon tissue, a lymph node-negative colorectal tumor (N0) and a lymph node-positive tumor (N1). The measurements from each probe correspond to a point in three-dimensional space and are projected orthogonally on a plane perpendicular to the (1,1,1)-axis. The three coordinate axes of the data space correspond to the vectors from the origin of the plot to the three labels "normal", "tumor N0" and "tumor N1". The (1,1,1)-axis corresponds to average intensity, while differences between the three tissues are represented by the position of the measurements in the two-dimensional plot plane. For instance, both c-*myc* and *nme1* (nucleoside diphosphate kinase A) are higher transcribed in the N0 and in the N1 tumor, compared to the noncancerous tissue. However, while the increase is approximately balanced for c-*myc* in the two tumors, *nme1* is more upregulated in the N1 tumor than in the N0 tumor, a behavior that is consistent with a gene involved in tumor progression. On the other side, the apoptosis-inducing receptor *trail-r2* is downregulated specifically in the N1 tumors, while it has about the same intermediate-high transcription level in the noncancerous tissue and the N0 tumor. Similar behavior of these genes was observed over repeated experiments.

microarray measurement corresponds to average intensity and hence is not directly informative with respect to differential transcription. Note that if the plotted data was preprocessed through a variance-stabilizing transformation, its variance does not depend on the $(1, 1, 1)$-component.

2.4 Batch Effects

Present day microarray technology measures abundances only in terms of relative probe intensities and generally provides no calibration to absolute physical units. Hence, the comparison of measurements between different studies is difficult. Moreover, even within a single study, the measurements are highly susceptible to *batch effects*. By this term, we refer to experimental factors that (i) add systematic biases to the measurements and (ii) may vary between different subsets or stages of an experiment. Some examples are [33]:

(i) *Spotting.* To manufacture spotted microarrays, the probe DNA is deposited on the surface through spotting pins. Usually, the robot works with multiple pins in parallel, and the efficiency of their probe delivery may be quite different [e.g. Figure 4(d) or [11]]. Furthermore, the efficiency of a pin may change over time through mechanical wear and the quality of the spotting process as a whole may be different at different times, due to varying temperature and humidity conditions.

(ii) *PCR amplification.* For cDNA arrays, the probes are synthesized through PCR, whose yield varies from instance to instance. Typically, the reactions are carried out in parallel in 384-well plates, and probes that have been synthesized in the same plate tend to have correlated variations in concentration and quality. An example is shown in Figure 9.

(iii) *Sample preparation protocols.* Reverse transcription and labeling are complex biochemical reactions, whose efficiencies are variable and may depend sensitively on a number of hard-to-control circumstances. Furthermore, RNA can quickly degrade, hence the outcome of the experiment can depend sensitively on when and how conditions that prevent RNA degradation are applied to the tissue samples.

(iv) *Array coating.* Both the efficiency of the probe fixation on the array, as well as the amount of unspecific background fluorescence strongly depend on the array coating.

(v) *Scanner and image analysis.* Different scanners can produce slightly different intensity images even from identical slides and the performance of the same scanner can drift over time. Different image analysis programs can use different algorithms to calculate probe summaries and the same program, in particular when it requires human interaction, can produce different results from the same image.

These considerations have important consequences for the experimental design. First, any variation that can be avoided by any means within an experiment should be avoided. Second, any variation that cannot be avoided should be organized in such a manner that it does not confound the biological question of interest. Clearly, when looking for differences between two tumor types, it would not be wise to have samples of one tumor type processed by one laboratory, and samples of the other type by another laboratory.

Points (i) and (ii) are specific for spotted cDNA arrays. To be less sensitive against these variations, the two-color-labeling protocol is used, which employs the simultaneous hybridization of two samples to the same array [12]. Ideally, if only ratios of intensities between the two color channels are considered, variations in probe abundance should cancel out. Empirically,

they do not quite do so, which may, for example, be attributed to the fact that observed intensities are the sum of probe-specific signal and unspecific background [43]. Furthermore, in the extreme case of total failure of the PCR amplification or the DNA deposition for probes on some, but not all arrays in an experimental series, artifactual results are hardly avoidable.

If any of the factors (iii)–(v) is changed within an experiment, there is a good chance that this will show up later in the data as one of the most pronounced sources of variation. A simple and instructive visual tool for exploring such variations is the correlation plot: given a set of d arrays, each represented through a high-dimensional vector $\vec{Y}_i$ of suitably transformed and filtered probe intensities, calculate the $d \times d$ correlation matrix $\mathrm{corr}(\vec{Y}_i, \vec{Y}_j)$, sort its rows and columns according to different experimental factors, and visualize the resulting false-color images.

2.5 Along Chromosome Plots

Visualization of microarray data along genomic coordinates can be useful for many purposes, e.g. to detect genomic aberrations (deletions, insertions) or regulatory mechanisms that act at the level of genomic regions [35]. Here, we show an example from the application of a genome tiling microarray to transcription analysis.

While conventional microarrays contain only a preselected set of one or a few probes for each of a set of known or putative transcripts, more recent microarray designs provide probes for the complete genomic sequence content of an organism. Rather than relying on a manufacturer's assignment of probes to genes (or, more exactly, target transcripts), it can become part of the analysis to make the assignment on the basis of the data themselves. An example is shown in Figure 10.

←

Figure 9 (a) Scatterplot of logarithmized intensities from a pair of single-color cDNA arrays, comparing renal cell carcinoma to matched noncancerous kidney tissue. Similar to Figure 7, the x-coordinate represents average and the y-coordinate differential signal. In the bottom of the plot, there is a cloud of probes that appear to represent a cluster of strongly downregulated genes. However, closer scrutiny reveals that this is an experimental artifact: (b) shows the box plots of the intensities for the two arrays, separately for each of the 41 PCR plates (see text). Probes from plates no. 21, 22, 27 and 28 have extraordinarily high intensities on one of the arrays, but not on the other. Since the clone selection was quasi-random, this points to a defect in the probe synthesis that affected one array, but not the other. The discovery of such artifacts may be facilitated by coloring the dots in the scatterplot by attributes such as PCR plate of origin or spotting pin. While the example presented here is an extreme one, caution towards batch artifacts is warranted whenever arrays from different manufacturing lots are used in a single study.

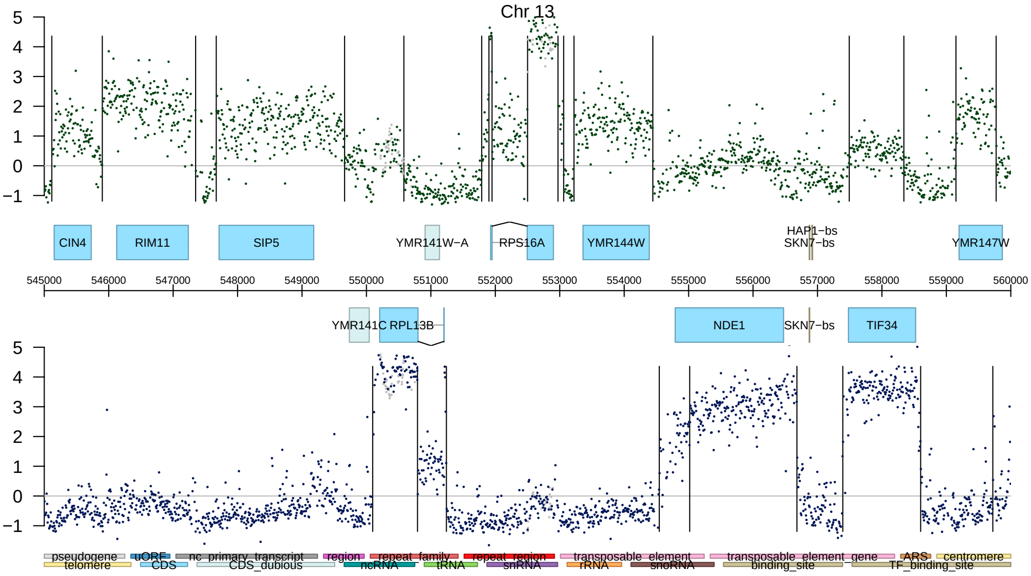

Figure 10 Along chromosome plot of the data from an Affymetrix genechip that contains 25-mer oligonucleotide probes covering the whole genome of *Saccharomyces cerevisiae* in steps of 8 bases, on both strands. The displayed values are the base 2 logarithms of the ratios between intensities from hybridization with a poly(A) RNA sample and with a genomic DNA sample. Also shown are genomic coordinates and annotated genomic features. The vertical bars show the segmentation of the intensity signal into an approximately piecewise constant function [9a, 18a, 28]. The data allows for the mapping of $5'$ and $3'$ untranslated regions, the deconvolution of populations of overlapping transcripts of different lengths, and the detection of novel transcripts.

2.6 Sensitivity and Specificity of Probes

The probes on a microarray are intended to measure the abundance of the particular transcript or locus that they are assigned to. However, probes may differ in terms of their sensitivity and specificity. Here, sensitivity means that a probe's fluorescence signal indeed responds to changes in the abundance of its target; specificity means that it does not respond to other targets or other types of perturbations.

Probes may lack sensitivity. Some probes initially identified with a gene do not actually hybridize to any of its products. Some probes will have been developed from information that has been superseded. In some cases, the probe may correspond to a different gene or it may in fact not represent any gene. In other cases, a probe may match only certain transcript variants of a given gene, which makes it more complicated to derive statements on the gene's expression (e.g. NDE1 and CIN4 in Figure 10). There is also the possibility of human error [15, 24].

A potential problem, especially with short oligonucleotide technology, is that the probes may not be specific, i.e. in addition to matching the intended transcript, they may also match others. In this case, we expect the observed intensity to be a composite from all matching transcripts. Note that, particularly in the case of higher eukaryotes, we are limited by the current state of knowledge of the transcriptomes. As our knowledge improves, the information about specificity of probes should also improve.

3 Error Models

3.1 Motivation

With a microarray experiment, we aim to make statements about the abundances of specific molecules in a set of biological samples. However, the quantities that we measure are the fluoresence intensities of the different elements of the array. The measurement process consists of a cascade of biochemical reactions and an optical detection system with a laser scanner or a CCD camera. Biochemical reactions and detection are performed in parallel, allowing millions of measurements on one array. Subtle variations between arrays, the reagents used and the environmental conditions lead to slightly different measurements even for the same sample.

The effects of these variations may be grouped in two classes. *Systematic effects* affect a large number of measurements (e.g. the measurements for all probes on one array or the measurements from one probe across several arrays) simultaneously. Such effects can be estimated and, to good approximation, be removed. Other kinds of effects are random, with no well-understood pattern. These effects are commonly called *stochastic effects* or *noise*. This classification is not a property of the variations *per se*, but rather reflects our understanding of them and our modeling effort. The same kind of variation can be considered stochastic in one analysis and systematic in another.

So what is the purpose of constructing error models for microarrays? There are three aspects as outlined below.

3.1.1 **Obtaining Optimal Estimates**

Stochastic models are useful for preprocessing because they permit us to find *optimal* estimates of the systematic effects. We are interested in estimates that are precise and accurate. However, given the noise structure of the data we sometimes have to sacrifice accuracy for better precision and *vice versa*. An appropriate stochastic model will aid in understanding the accuracy-precision, or bias-variance, trade-off.

3.1.2 **Biological Inference**

Stochastic models are also useful for statistical inference from experimental data. Consider an experiment in which we want to compare gene expression in the colons of mice that were treated with a substance and mice that were not. If we have many measurements, we can simply compare their empirical distributions. For example, if the values from 10 replicate measurements for the DMBT1 gene in the treated condition are all larger than 10 measurements from the untreated condition, the Wilcoxon test tells us that with a p-value of 10^{-5} the level of the transcript is really elevated in the treated mice. However, often it is not possible, too expensive or unethical to obtain so many replicate measurements for all genes and for all conditions of interest. Often, it is also not necessary. If we have some confidence in a model, we are able to draw significant conclusions from fewer replicates.

3.1.3 **Quality Control**

Quality control is yet another example of the usefulness of stochastic models: if the distribution of a new set of data greatly deviates from the model, this may direct our attention to quality issues with these data.

3.2 The Additive–Multiplicative Error Model

3.2.1 **Induction from Data**

Different hybridizations will result in more or less different signal intensities even if the biological sample is the same. To see this, let us look in Figure 11 at the empirical distribution of the intensities from six replicate Affymetrix genechips. The data are part of the Latin Square Data for Expression Algorithm Assessment provided by Affymetrix (http://www.affymetrix.com/support/technical/sample_data/datasets.affx).

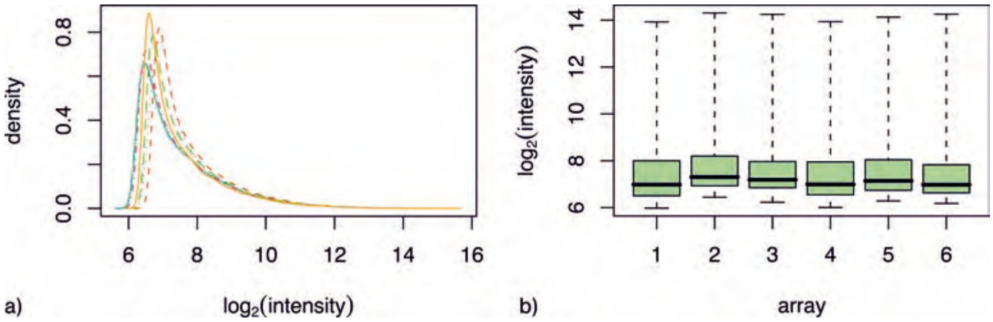

Figure 11 (a) Density estimates of probe intensity data from six replicate Affymetrix arrays. The x-axis is on a logarithmic scale (base 2). (b) Box plots of the same data.

One task of error modeling is to deal with background noise. Notice in Figure 11 that the smallest values attained are around 64, with slight differences between the arrays. We know that many of the probes are not supposed to be hybridizing to anything (as not all genes are expressed), so many measurements should indeed be 0. A bottom-line effect of not removing background noise is that estimates of differential expression are biased. Specifically, the ratios are attenuated toward 1. This can be seen using the Affymetrix spike-in experiment, where genes were spiked in at known concentrations. Figure 12(a) shows the observed concentrations versus nominal concentrations of the spiked-in genes. Measurements with smaller nominal concentrations appear to be affected by attenuation bias. To see why, notice that the curve has a slope of about 1 for high nominal concentrations, but becomes flat as the nominal concentration gets closer to 0. This is consistent with the additive background noise model which we will discuss in the next section. Mathematically, it is easy to see that if s_1/s_2 is the true ratio, and b_1 and b_2 are approximately equal positive numbers, then $(s_1 + b_1)/(s_2 + b_2)$ is closer to 1 than the true ratio, and the more so the smaller the s_i are compared to the b_i.

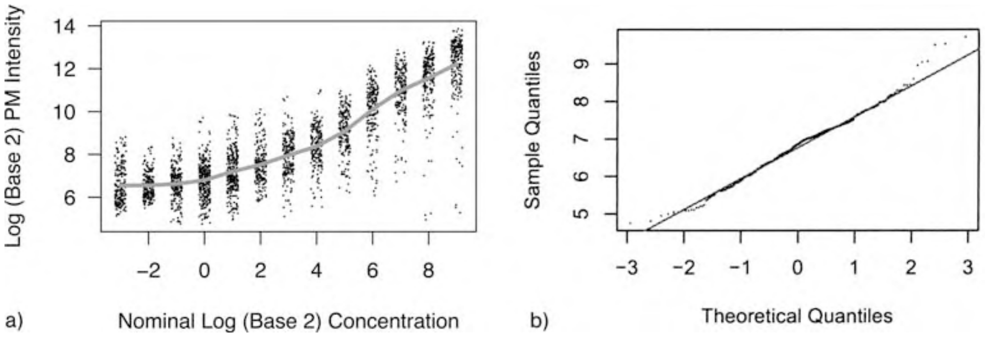

Figure 12 (a) Plot of observed against nominal concentrations. Both axes are on the logarithmic scale (base 2). The curve represents the average value of all probes at each nominal concentration. Nominal concentrations are measured in picomoles. (b) Normal quantile–quantile plot of the logarithmic (base 2) intensities for all probes with the same nominal concentration of 1 pmol.

Figure 12(b) shows a normal quantile–quantile plot of logarithmic intensities of probes for genes with the same nominal concentration. Note that these appear to roughly follow a normal distribution. Figure 12 supports the multiplicative error assumption of the model that we formulate in the next section.

3.2.2 A Theoretical Deduction

Consider the generic observation equation $z = f(x, y)$, where z is the outcome of the measurement, x is the true underlying quantity that we want to measure, the function f represents the measurement apparatus and $y = (y_1, \ldots, y_n)$ is a vector that contains all other parameters on which the functioning of the apparatus may depend. The functional dependence of f on some of the y_i may be known; on others, it may not. Some of the y_i are explicitly controlled by the experimenter; some are not. For a well-constructed measurement apparatus, f is a well-behaved, smooth function and we can rewrite the observation equation as:

$$z = f(0, y) + f'(0, y)\, x + O(x^2), \tag{1}$$

where $f(0, y)$ is the baseline value that is measured if x is zero, f' is the derivative of f with respect to x, $f'(0, y)$ is a gain factor and $O(x^2)$ represents nonlinear efffects. By proper design of the experiment, the nonlinear terms can be made negligibly small within the relevant range of x. Examples for the parameters y in the case of microarrays are the efficiencies of mRNA extraction, reverse transcription, labeling and hybridization reactions, amount and quality of probe DNA on the array, unspecific hybridization, dye quantum yield, scanner gain, and background fluorescence of the array.

Ideally, the parameters y could be fixed once and forever exactly at some value $\bar{y} = (\bar{y}_1, \ldots, \bar{y}_n)$. In practice, they will fluctuate around $\bar{y}$ between repeated experiments. If the fluctuations are not too large, we can expand:

$$f(0, y) \approx f(0, \bar{y}) + \sum_{i=1}^{n} \frac{\partial f(0, \bar{y})}{\partial y_i} (y_i - \bar{y}_i) \tag{2}$$

$$f'(0, y) \approx f'(0, \bar{y}) + \sum_{i=1}^{n} \frac{\partial f'(0, \bar{y})}{\partial y_i} (y_i - \bar{y}_i). \tag{3}$$

The sums on the right-hand sides of Eqs. (2) and (3) are linear combinations of a large number n of random variables with mean 0. Thus, it is a reasonable approximation to model $f(0, y)$ and $f'(0, y)$ as normally distributed random variables with means $a = f(0, \bar{y})$ and $b = f'(0, \bar{y})$ and variances σ_a^2 and σ_b^2, respectively. Thus, omitting the nonlinear term, Eq. (1) leads to:

$$z = a + \varepsilon + b\, x(1 + \eta), \tag{4}$$

with $\varepsilon \sim N(0, \sigma_a^2)$ and $\eta \sim N(0, \sigma_b^2 / b^2)$. This is the *additive–multiplicative error model* for microarray data, which was proposed by Ideker and coworkers [29]. Rocke and Durbin [29] proposed it in the form:

$$z = a + \varepsilon + b\, x \exp(\eta), \tag{5}$$

which is equivalent to Eq. (4) up to first-order terms in η. Models (4) and (5) differ significantly only if the coefficient of variation σ_b/b is large. For microarray data, it is typically smaller than 0.2, thus the difference is of little practical relevance.

One of the main predictions of the error model (4) is the form of the dependence of the variance of z on its mean $\mathrm{E}(z)$:

$$\mathrm{Var}(z) = v_0^2 + \frac{\sigma_b^2}{b^2}\,(\mathrm{E}(z) - z_0)^2\,, \tag{6}$$

that is, a strictly positive quadratic function. In the following we will assume that the correlation between ε and η is negligible. Then the parameters of Eq. (6) are related to those of Eq. (4) via $v_0^2 = \sigma_a^2$ and $z_0 = a$. If the correlation is not negligible, the relationship is slightly more complicated, but the form of Eq. (6) remains the same.

4 Normalization

A parametrization of Eq. (5) that captures the main factors that play a role in current experiments is:

$$z_{ip} = a_{i,s(p)} + \varepsilon_{ip} + b_{i,s(p)} B_p\, x_{j(i),k(p)} \exp(\eta_{ip}). \tag{7}$$

Let us dissect this equation. The index p labels the different probes on the array and $k = k(p)$ is the transcript or locus that probe p maps to. Each probe is intended to map to exactly one k, but one transcript or locus may be represented by several probes. B_p is the probe-specific gain factor of the p-th probe. i counts over the arrays and, if applicable, over the different dyes. $j = j(i)$ labels the biological conditions (e.g. normal/diseased). $a_{i,s(p)}$ and $b_{i,s(p)}$ are normalization offsets and scale factors that may be different for each i and possibly for different groups ("strata") of probes $s = s(p)$. Probes can be stratified according to their physicochemical properties [39] or array-manufacturing parameters such as print-tip [41] or spatial location. In the simplest case, $a_{i,s(p)} = a_i$ and $b_{i,s(p)} = b_i$ are the same for all probes on an array. The noise terms ε and η are as above.

On an abstract level, much of the literature on normalization can be viewed as an application of Eq. (7) to data, employing various choices for probe stratification, making simplifying assumptions on some of its parameters, rearranging the equation and using different, more or less robust algorithms to estimate its parameters [2, 16–18, 21, 22, 25, 33, 38].

There is an alternative approach to normalization, which focuses on non-parametric methods and the algorithmic aspects. In this approach, one identifies those statistics (properties) of the data that one would like to be the same, say, between different arrays, but observes empirically in the raw data that they are not. One then designs an algorithm that transforms the data so that the desired statistics are made the same in the normalized data. The intention is that the interesting, biological signal is kept intact in the process [4,31,41].

For example, the *loess* normalization [41] calculates log-ratios M between the red and the green intensities on one array, plots them versus A, the logarithm of the geometric mean (see Figures 6 and 7), and postulates that a nonparametric regression line, calculated by a so-called loess scatterplot smoother [8] ought to look straight. In order to achieve this, the loess-fitted regression values for M are subtracted from the observed values and the residuals are kept as the normalized data.

In *quantile* normalization, one plots the histogram of log-transformed intensities for each array and postulates that they all should look the same. Bolstad and coworkers [4] have introduced an algorithm that achieves this by rank-transforming the data and then mapping the ranks back to a consensus distribution. The result is a monotonous nonlinear transformation for each array which assures that the distribution function of the transformed data is the same for all arrays.

These nonparametric methods are popular because they always "work", by construction, and usually in a fully automatic manner. In contrast, in model-based approaches it may turn out that a given set of data does not fit. Also, the assessment of goodness of fit is not easily automated, and often requires some human interaction. If the fit is bad, the data cannot be normalized, thus not be further analysed, and an expensive and time-consuming experiment would be left hanging.

However, there is a caveat: experiments may contain failed hybridizations, degraded samples and nonfunctioning probes. The goodness-of-fit criteria from a model-based normalization method can serve as relevant criteria to detect these. With a method that "always works", there is the risk of overlooking these aspects of the data, to normalize them away and move on to further analysis pretending that everything was fine. Conversely, one needs a sophisticated and largely nonautomatic quality control step. So, if we consider normalization and quality control together as one task, the balance between model-based and nonparametric methods is more even.

Furthermore, parametric methods have, if they are appropriate, better power than nonparametric ones. They provide better sensitivity and specificity in the application of detecting differentially expressed genes. Given the typically small sample size and the expense of microarray experiments, this is a consequential point. It has been verified in comparison studies [9,16].

5 Detection of Differentially Expressed Genes

5.1 Stepwise versus Integrated Approaches

Most commonly used is the *stepwise* approach to microarray data analysis. It takes a collection of raw data as input and produces an *expression matrix* as output. In this matrix, rows correspond to gene transcripts and columns to conditions. Each matrix element represents the abundance, in certain units, of a transcript under a condition. Subsequent biological analyses work off the expression matrix and generally do not consider the raw data. The preprocessing itself is largely independent of the subsequent biological analysis. In some cases, the preprocessing is further subdivided into a set of sequential instructions, e.g. subtract the background, then normalize the intensities, then summarize replicate probes, then summarize replicate arrays. By its *modularity*, the stepwise approach allows us to structure the analysis workflow. Software, data structures and methodology can be more easily reused. For example, the same machine learning algorithm can be applied to an expression matrix irrespective of whether the raw data were obtained on Affymetrix chips or on spotted cDNA arrays. A potential disadvantage of the stepwise approach is that each step is optimized for itself and that the results of subsequent steps have no influence on the previous ones. For example, the normalization procedure has to deal with whatever the preceding background correction procedure produced and has no chance to ask it to reconsider. This can and does lead to inefficiencies.

In contrast, *integrated* approaches try to gain sensitivity by doing as much as possible at once, and therefore using the available data more efficiently. For example, rather than calculating an expression matrix, one might fit an ANOVA-type linear model that includes both technical covariates, such as dye and sample effects, and biological covariates, such as treatment [22], to the raw data. In Ben Bolstad's affyPLM method [5], the weighting and summarization of the multiple probes per transcript on Affymetrix chips is integrated with the detection of differential expression. Another example is the vsn method [16], which integrates background subtraction and normalization.

Stepwise approaches are often presented as modular data-processing pipelines; integrated approaches as statistical models whose parameters are to be fitted to the data. In practice, data analysts will often choose to use a combination of both approaches, maybe starting with the stepwise approach, do a first round of high-level analyses and then turn back to the raw data to answer specific questions that arise. Good software tools allow us to use and explore both stepwise and integrated methods, and to freely adapt and combine them.

5.2 Measures of Differential Eexpression: The Variance Bias Trade-off

What is a good statistic to compare two (or several) measurements from the same probe on a microarray, taken from hybridizations with different biological targets?

Plausible choices include the difference, the ratio and the logarithm of the ratio. To understand the problem more systematically, we return to the notation of Section 3.2.2. Let z_1 and z_2 denote two measurements from the same probe, and assume that they are distributed according to Eq. (5) with the same parameters a, b, σ_a, and σ_b, but possibly with different values of x_1, x_2, corresponding to different levels of the target in the biological samples of interest. We want to find a function $h(z_1, z_2)$ that fulfills the following two conditions: *antisymmetry*, $h(z_1, z_2) = -h(z_2, z_1)$ for all x_1, x_2 and *homoskedasticity*, constant variance of $h(z_1, z_2)$ independent of x_1, x_2. An approximate solution is given by [17]:

$$h(z_1, z_2) = \operatorname{arsinh}\left(\frac{z_1 - a}{\beta}\right) - \operatorname{arsinh}\left(\frac{z_2 - a}{\beta}\right), \qquad (8)$$

with $\beta = \sigma_a b / \sigma_b$. If both z_1 and z_2 are large, this expression approaches the log-ratio:

$$q(z_1, z_2) = \log(z_1 - a) - \log(z_2 - a). \qquad (9)$$

However, for $z_i \to a$, the log-ratio $q(z_1, z_2)$ has a large, diverging variance, a singularity at $z_i = a$ and is not defined in the range of real numbers for $z_i < a$.

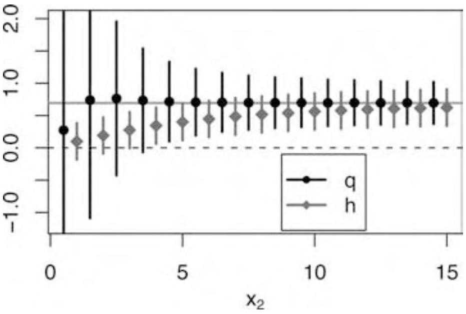

Figure 13 The shrinkage property of the generalized log-ratio h. Blue diamonds and error bars correspond to mean and standard deviation of $h(z_1, z_2)$, *cf.* Eq. (8); black dots and error bars to $q(z_1, z_2)$, cf. Eq. (9). Data were generated according to Eq. (5) with $x_2 = 0.5, \ldots, 15$, $x_1 = 2x_2$, $a = 0$, $\sigma_a = 1$, $b = 1$, $\sigma_b = 0.1$. The horizontal line corresponds to the true log-ratio $\log(2) \sim 0.693$. For intensities x_2 that are larger than about 10 times the additive noise level σ_a, h and q are approximately equal. For smaller intensities, we can see a *variance bias trade-off*: q has no bias but a huge variance, thus an estimate of the fold change based on a limited set of data can be arbitrarily off. In contrast, h keeps a constant variance – for the price of systematically underestimating the true fold change.

These unpleasant properties are important for applications: many genes are not expressed or only weakly expressed in some, but not all conditions of interest. That means we need to compare conditions in which, for example, x_1 is large and x_2 is small. The log-ratio (9) is not a useful quantity for this purpose, since the second term will wildly fluctuate and be sensitive to small errors in the estimation of the parameter a. In contrast, the statistic (8), which is called the *generalized log-ratio* [30], is well-defined everywhere and robust against small errors in a. It is always smaller in magnitude than the log-ratio (see also Figure 13):

$$\begin{aligned} &|h(z_1, z_2)| < |q(z_1, z_2)| \qquad \forall z_1, z_2, \\ &h(z_1, z_2) \approx q(z_1, z_2) \qquad \text{for } z_1, z_2 \gg a + \beta. \end{aligned} \tag{10}$$

The exponentiated value:

$$\widehat{FC} = \exp(h(z_1, z_2)), \tag{11}$$

can be interpreted as a shrinkage estimator for the *fold-change* x_1/x_2. It is more specific, i.e. leads to fewer false positives in the detection of differentially expressed genes, than the naive estimator $(z_1 - a)/(z_2 - a)$ [13,16].

5.3 Identifying Differentially Expressed Genes from Replicated Measurements

One of the main motivations for performing microarray studies is the need to identify genes whose patterns of expression differ according to phenotype or experimental condition. Gene expression is a well-coordinated system and, hence, measurements on different genes are in general not independent. Given more complete knowledge of the specific interactions and transcriptional controls it is conceivable that meaningful comparisons between samples can be made by considering the joint distribution of specific sets of genes. However, the high dimension of gene expression space prohibits a comprehensive exploration, while the fact that our understanding of biological systems is only in its infancy means that in many cases we do not know which relationships are important and should be studied. In current practice, differential expression analysis will therefore at least start with a gene-by-gene approach, ignoring the dependencies between genes.

A simple approach in the comparison of different conditions is to rank genes by the difference of means of appropriately transformed intensities in the sense of Section 5.2. This may be the only possibility in cases where no, or very few replicates, are available. An analysis solely based on a difference of means statistic, however, does not allow the assessment of significance of expression differences in the presence of biological and experimental variation, which may differ from gene to gene. This is the main reason for using statistical tests to assess differential expression. Generally, one might look at various properties of the distributions of a gene's expression levels under different conditions, though most often location parameters of these distributions, such as the mean or the median, are considered. One may distinguish between parametric tests, such as the t-test, and nonparametric tests, such as the Mann–Whitney test or permutation tests. Parametric tests usually have a higher power if the underlying model assumptions, such as normality in the case of the t-test, are at least approximately fulfilled. Nonparametric tests do have the advantage of making less stringent assumptions on the data-generating distribution. In many microarray studies however, a small sample size leads to insufficient power for nonparametric tests and, as discussed in Section 3.1, increasing the sample size might be uneconomical or unethical if parametric alternatives are feasible. A pragmatic approach in these situations is to employ parametric tests, but to use the resulting p-values cautiously to rank genes by their evidence for differential expression, rather than taking them for the truth.

A generalized log-transformation of intensity data as described in Section 5.2 can be beneficial not only when using a difference of means statistic, but also for parametric statistical tests. Typically it will make the distribution of replicated measurements per gene roughly symmetric and more or less close to normal. The variance stabilization achieved by the transformation can be advantageous for gene-wise statistical tests that rely on variance homogeneity, because it diminishes differences in variance between experimental conditions that are due to differences in the intensity level; however, of course differences in variance between conditions may also have gene-specific biological reasons, and these will remain untouched by the transformation.

One or two group t-test comparisons, multiple group ANOVAs and more general trend tests are all instances of linear models that are frequently used for assessing differential gene expression. As a parametric method, linear modeling is subject to the caveats discussed above, but the convenient interpretability of the model parameters often makes it the method of choice for microarray analysis. Due to the aforementioned lack of information regarding coregulation of genes, linear models are generally computed for each gene separately. When the genes of interest are identified, investigators can hopefully begin to study their coordinated regulation for more sophisticated modeling of their joint behavior.

The approach of conducting a statistical test for each gene is popular, largely because it is relatively straightforward and a standard repertoire of methods can be applied. However, the approach has a number of drawbacks – most important is the fact that a large number of hypothesis tests is carried out, potentially leading to a large number of falsely significant results. Multiple testing procedures allow us to assess the overall significance of the results of a family of hypothesis tests. They focus on specificity by controlling type I (false-positive) error rates such as the *familywise error rate* or the *false discovery rate* [10]. Still, multiple hypothesis testing remains a problem, because an increase in specificity, as provided by p-value adjustment methods, is coupled with a loss of sensitivity, i.e. a reduced chance of detecting true positives. Furthermore, the genes with the most drastic changes in expression are not necessarily the "key players" in the relevant biological processes [37]. This problem can only be addressed by incorporating prior biological knowledge into the analysis of microarray data, which may lead to focusing the analysis on a specific set of genes. Also if such a biologically motivated preselection is not feasible, the number of hypotheses to be tested can often be reasonably reduced by nonspecific filtering procedures, discarding, e.g. genes with consistently low intensity values or low variance across the samples. This is especially relevant in the case of genome-wide arrays, as often only a minority of all genes will be expressed at all in the cell type under consideration.

Many microarray experiments involve only few replicates per condition, which makes it difficult to estimate the gene-specific variances that are used, e.g. in the t-test. Different methods have been developed to exploit the variance information provided by the data of all genes [1, 20, 27, 36]. In Ref. [34], an empirical Bayes approach is implemented that employs a global variance estimator s_0^2 computed on the basis of all genes' variances. The resulting test statistic is a moderated t-statistic, where instead of the single-gene estimated variances s_g^2, a weighted average of s_g^2 and s_0^2 is used. Under certain distributional assumptions, this test statistic can be shown to follow a t-distribution under the null hypothesis with the degrees of freedom depending on the data.

6 Software

Many of the algorithms and visualizations discussed in this chapter are available through the Bioconductor project [14]. This project is an initiative for the collaborative creation of extensible software for computational biology and bioinformatics. Its goals include fostering development and widespread use of innovative software, reducing barriers to entry into interdisciplinary scientific research, and promoting the achievement of remote reproducibility of research results.

The software produced by the Bioconductor project is organized into packages, each of which is written and maintained relatively autonomously by its authors, who come from many different institutions around the world, and which are held together through a common language platform, R, a set of common data structures, a uniform structure of package organization and documentation, and a lively user community.

Results of this project are available on the website http://www.bioconductor.org. Among the packages that are most relevant for the subject of this chapter are affy (preprocessing of Affymetrix genechip data), vsn (affine-linear parametric normalization and variance stabilizing normalization), marray (two-color preprocessing) and limma (differential expression with linear models). Some further aspects are represented by arrayMagic (high-throughput quality control and preprocessing) and tilingArray (along chromosome plots and segmentation).

Acknowledgments

We thank Günther Sawitzki, Robert Gentleman, Dirk Buschmann and Andreas Buneß for fruitful discussions. We are grateful to all contributors to the R and Bioconductor projects for sharing their software. Holger Sültmann, Annemarie Poustka, Anke Schroth, Lars Steinmetz and Lior David are gratefully acknowledged for sharing experimental data.

26
Classification of Patients

Claudio Lottaz, Dennis Kostka and Rainer Spang

1 Introduction

In microarray gene expression studies tissue samples are examined using microarray chips covering as many as 50 000 transcripts. Automatic classification of patients is a powerful tool for molecular diagnosis as well as for the discovery of novel molecular disease subentities. Exploiting this potential in clinical research is of primary interest and holds great promise. Two early examples for clinical microarray studies are given below.

Roepman and coworkers [89] describe a study on head and neck squamous cell carcinomas. In this disease, treatment strongly depends on the presence of metastases in lymph nodes. However, near the neck, diagnosis of metastases is difficult. More than 50% of patients unnecessarily undergo surgery, while 23% remain under-treated. The authors show that treatment based on microarray prediction is significantly more accurate: in a validation cohort under-treatment was completely avoided, while the rate of unnecessary surgery dropped to 14%. By Alizadeh and coworkers [1] a clinical microarray study on diffuse large B cell lymphomas (DLBCLs) is described. Expression profiles from patients were complemented by profiles from cell lines of known differentiation stage and activation status. The authors were able to identify two different groups of DLBCL patients, characterized by expression profiles similar to germinal center B cells and *in vitro* activated peripheral blood B cells, respectively. Further on, significant differences in the survival rates of the two groups were detected.

From a statistical point of view, the major characteristic of microarray studies is that the number of genes is orders of magnitude larger than the number of patients. For classification as well as class discovery this leads to problems involving overfitting and saturated models. When blindly applying classification algorithms, a model rather adapts to noise in the data than to the molecular characteristics of investigated diseases. Thus, the challenge is to find molecular classification rules and novel disease subclasses that can be generalized from a study cohort to entire disease populations.

The most frequent clinical problems addressed by microarray analysis include molecular diagnosis of known disease entities, prognosis of disease outcome and prediction of treatment response. These are all supervised problems, relating expression profiles to additional clinical data. Additionally, the detection of previously unknown molecular subentities of a disease is of great interest. This task is an unsupervised problem, the objective is to detect structure inherent in the expression data without the help of additional clinical information. This chapter is structured accordingly. We start by discussing supervised analysis, covering the general setup of predictive classification and present a selection of classification algorithms. Further on, gene selection and issues of model selection as well as the validation of predictive performance are described. Then we proceed to unsupervised analysis including clustering algorithms, class finding, biclustering, semisupervised approaches and concepts related to the validation of unsupervised analysis results.

2 Molecular Diagnosis

Molecular diagnosis based on gene expression profiles is the most widely used approach in clinical microarray studies. The data consists of gene expression profiles of n patients. In addition, each patient has an attributed class label. The label reflects a clinical phenotype. Phenotypes can include previously defined disease entities, as in the leukemia study of Yeoh and coworkers [117], risk groups, like in the breast cancer studies of van't Veer and coworkers [110] or disease outcome, as in the breast cancer study of West and coworkers [116]. The challenge is to learn expression signatures that allow to predict the correct clinical phenotype for new patients.

It is important that the class labels must not be derived from the expression profiles themselves. This requirement embeds molecular diagnosis into the field of supervised machine learning and defines the difference to unsupervised class finding problems. The latter are discussed in Section 3. There are many more genes on the arrays than patients in the study and gene-to-sample ratios typically are in the hundreds. This is the main difficulty in the supervised approaches. A large number of machine-learning algorithms are available to overcome this problem and in the following we will summarize the basic ideas (see Table 1).

2.1 Problem Statement

We start by presenting a basic framework of supervised machine learning. This enables us to formulate the problem of molecular diagnosis in mathematical terms.

Table 1 Notation of key quantities used throughout the chapter (terms commonly used in the machine-learning literature as well as their counterparts in clinical applications are given).

Symbol	Theory	Application
$F(\boldsymbol{X}, Y)$	data generating distribution	disease population
$(\boldsymbol{X}, Y)$	random variable	new (future) patients
$\{\boldsymbol{x}^{(i)}\}_{i=1}^{n}$	profiles	microarrays from patients in the study
$\{y_i\}_{i=1}^{n}$	labels	clinical phenotypes
n	number of data points	number of patients in the study
p	dimension of input space	number of transcripts on the microarray
K	number of classes	number of phenotypes of interest in the study
$\mathcal{D}$	data set	microarrays hybridized in the study
$c(\boldsymbol{x})$	classifier	diagnostic signature
$c^{\star}(\boldsymbol{x})$	Bayes classifier	best possible signature
L	learning algorithm	method to infer a diagnostic signature
$\mathcal{C}$	function class	candidate signatures
$R[c]$	risk	performance of a signature on the disease population
$\hat{R}[c]$	empirical risk	performance of a signature on patients in the study
$E[c]$	conditional error rate	misclassification rate of a signature
$\bar{E}[L]$	unconditional error rate	misclassification rate of a learning algorithm

2.1.1 Notation

We measure p genes on n patients. The data from each microarray is represented by a *profile* $\boldsymbol{x}^{(i)} \in \mathbb{R}^p$. The corresponding *label*, that encodes one of K clinical phenotypes, is denoted by $y_i \in \mathcal{K} = \{k\}_{k=1}^{K}$.

The profiles are arranged as rows in a matrix $\underline{\mathbf{X}} \in \mathbb{R}^{n \times p}$. All labels together form a vector $\mathbf{y} \in \mathbb{R}^n$. The two quantities $(\underline{\mathbf{X}}, \mathbf{y})$ are called a data set $\mathcal{D}$. It holds all data of a study in pairs of observations $\{(\boldsymbol{x}^{(i)}, y_i)\}_{i=1}^{n}$. Study cases are always samples from a larger disease population. Such a population comprises all patients who had a certain disease, have it now or will have it in the future. Of course one has no access to this population. Nevertheless, it is convenient to make it part of the mathematical formalism. We assume that there is a data-generating distribution $F(\boldsymbol{X}, Y)$ on $\mathbb{R}^p \times \mathcal{K}$. $F(\boldsymbol{X}, Y)$ is the joint distribution of expression profiles and associated clinical phenotypes. The patients who enrolled for the study, as well as new patients who need to be diagnosed in clinical practice, can be modeled as independent samples $\{(\boldsymbol{x}^{(i)}, y_i)\}$ drawn from F. In general, capitalized quantities constitute random variables (population properties) (e.g. $\boldsymbol{X}$ and Y), whereas realizations (study properties) are in lower case (as in $\boldsymbol{x}^{(i)}$ and y_i). We aim for a diagnostic signature with good performance not only on the patients in the study, but also in future clinical practice. In mathematical terms this means that we aim for a well-generalizing *classification rule* $c : \mathbb{R}^p \to \mathcal{K}$.

2.1.2 Loss and Risk

We start with defining a mathematical framework for the performance of a diagnostic signature. In this context we need to distinguish between the performance on the samples in the study and the expected performance in clinical practice. We define a *loss function* l that quantifies the loss of diagnosing profile $\boldsymbol{x}$ to have phenotype $c(\boldsymbol{x})$, given the true phenotype is y:

$$l(\boldsymbol{x}, c(\boldsymbol{x}), y) : \mathbb{R}^p \times \mathcal{K} \times \mathcal{K} \to [0, \infty). \tag{1}$$

A simple loss function is the $0/1$ loss function, which assigns a loss of one to each misclassified sample. Loss functions play a role in signature construction as well as validation and vary from algorithm to algorithm. Let us now define the *risk* of a signature as:

$$R[c] = \mathbb{E}\, l(\boldsymbol{X}, c(\boldsymbol{X}), Y) = \int l(\boldsymbol{x}, c(\boldsymbol{x}), y)\, \mathrm{d}F(\boldsymbol{X}, Y), \tag{2}$$

which measures the expected loss of a diagnostic signature when applied to the entire disease population. It is the performance of the signature in clinical practice. Since we have no access to the population, we do not know F and cannot calculate the risk R explicitly. However, we have access to the patients in the study to approximate R. We define the *empirical risk*:

$$\hat{R}[c] = \int l(\boldsymbol{x}, c(\boldsymbol{x}), y)\, \mathrm{d}\hat{F}(\boldsymbol{X}, Y) = \frac{1}{n} \sum_{i}^{n} l(\boldsymbol{x}^{(i)}, c(\boldsymbol{x}^{(i)}), y_i), \tag{3}$$

where $\hat{F}$ is the empirical distribution function which puts weight $1/n$ on each observed data-point. In the context of a microarray study, the empirical risk for the $0/1$ loss function is the error rate of the signature on patients in the study. It can be easily calculated.

2.1.3 Bayes Classifier and Bayes Error

Before we explain how to build diagnostic signatures in practice we introduce a purely theoretical construct – the best thinkable signature, also called the *Bayes classifier*. While it cannot be built in practice, it is helpful for the development of the theory.

Assume we know what is called the *posterior densities* of F, i.e. $P(Y = k|\boldsymbol{X} = \boldsymbol{x})$. Then the Bayes classifier is defined as:

$$c^\star(\boldsymbol{x}) = \underset{k \in \mathcal{K}}{\operatorname{argmax}}\, P(Y = k|\boldsymbol{X} = \boldsymbol{x}). \tag{4}$$

Its error is called the *Bayes error*. The Bayes error can be different from zero, which means it is impossible to construct a molecular signature that never fails. This is not necessarily a matter of insufficient bioinformatics expertise, but can be an intrinsic property of the disease population F. If the same expression profiles can occur under different clinical phenotypes, it is obvious that false classifications cannot be ruled out entirely. The Bayes classifier can be derived theoretically from the risk defined in Eq. (2): Take the 0/1 loss, i.e. $l(\boldsymbol{x}, c(\boldsymbol{x}), y) = \mathbb{I}_{c(x)\neq y}$, where $\mathbb{I}$ denotes the indicator function. $\mathbb{I}_{c(x)\neq y} = 0$ if $c(\boldsymbol{x}) = y$ and 1 for wrong predictions. Minimizing the risk at some $\boldsymbol{x} \in \mathbb{R}^p$ is equivalent to minimizing the probability of future misclassifications at this point. This, in turn, is the same as always assigning the most probable class. That is precisely the statement of Eq. (4). The Bayes classifier is a purely theoretical construct. The challenge is to approximate it based on study data.

2.1.4 **Minimal Empirical Risk and Maximum Likelihood**

Here, we introduce a general principle for adjusting a signature to a given dataset. We assume a specific dependency structure f of Y on $\boldsymbol{X}$. Often f is a family of functions indexed by parameters. As an example, take the linear model. There one assumes $Y = \boldsymbol{X}^{\mathrm{T}}\beta + \varepsilon$, ε being a random variable. In this case Y depends on $\boldsymbol{X}$ linearly, $f(\boldsymbol{X}) = \boldsymbol{X}^{\mathrm{T}}\beta$ and the parameters are the components β. In general we model $F(Y|\boldsymbol{X}, f)$, i.e. $P(Y|f(\boldsymbol{X}))$, and define the *likelihood* of the observed y_i and $\boldsymbol{x}^{(i)}$ as:

$$P(\mathcal{D}|f) = \prod_{i}^{n} P(Y = y_i|\boldsymbol{X} = \boldsymbol{x}^{(i)}, f)P(\boldsymbol{X} = \boldsymbol{x}^{(i)}). \tag{5}$$

Maximization of the above quantity is the same as taking the log, dropping f-independent terms and minimizing

$$\mathcal{L}_l[f] = -\sum_{i}^{n} \log(P(Y = y_i|\boldsymbol{X} = \boldsymbol{x}^{(i)}, f)). \tag{6}$$

This is equivalent to minimizing the empirical risk defined in Eq. (3) taking the loss function to be $l = -\log P(Y|f(\boldsymbol{X}))$.

2.1.5 **Regularized Risk and Priors**

As mentioned before, the main challenge in microarray-based diagnosis is the large number of genes on the array compared to the few patients in the study. In this section we demonstrate mathematical implications of this situation.

In the previous section we have seen that minimizing the empirical risk can be equivalent to the maximum likelihood approach. This suggests that minimizing the empirical risk over a class of candidate signatures $\mathcal{C}$, i.e. $\hat{c} := \operatorname{argmin}_{c\in\mathcal{C}} \hat{R}[c]$, is a valid approach to molecular diagnosis. Unfortunately, the maximum likelihood approach can lead to ill-posed problems where the optimum is not uniquely determined [108]. For high-dimensional microarray data, this is the case even for simple signature classes. An example is *linear discriminant analysis* (LDA), which will be discussed in Section 2.2.

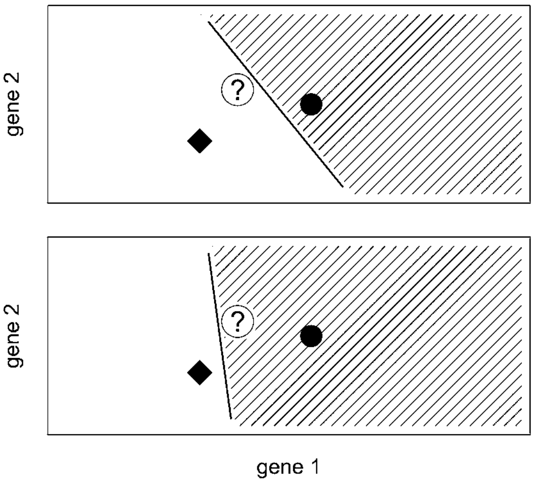

Figure 1 A toy situation with as many genes as patients. The solid diamond and circle represent patients from two different disease types. They can be separated linearly in several ways, two separating signatures are shown. The question mark represents a patient with unknown diagnosis. Both signatures yield conflicting predictions. The data alone does not suggest that one of the signature is better then the other – it does not suggest a unique diagnosis. This situation occurs if the number of genes is higher or equal then the number of patients, which is always the case in microarray studies.

As a simplified illustration imagine a study where two patients, each representative of a certain phenotype, are selected. Then the mRNA abundance of two genes is measured. Further on, we want to construct a linear signature that can discriminate between the two classes. This is the same problem as finding a straight line between two points (each representing a patient) in a plane. The candidate signatures in $\mathcal{C}$ now correspond to all possible straight lines. There is no unique solution (Figure 1). Next, think about a third point which incidentally does not lie on the line going through the first two points. Imagine it represents a new patient with unknown diagnosis. It is always possible to linearly separate the first two points such that the new one lies on the same side as either one of them. The two training patients do not contain sufficient information to diagnose the third patient uniquely. We are in this situation whenever there are more genes than patients. Due to the large number of genes on the chip this problem is inherent in microarray studies.

A way out of the dilemma is *regularization*, which artificially makes the minimizer of the empirical risk unique. In our example above this can correspond to finding the straight line which separates the two points *and* which has maximal distance to both of them. This strategy is implemented in *support vector machines* (SVMs), a classification algorithm discussed in the next section. Regularization results in the minimization of the *regularized risk functional*:

$$\hat{R}_{\text{reg}}[c] := \hat{R}[c] + \lambda\Omega[c], \tag{7}$$

where Ω is called the *regularization operator* and penalizes the complexity of signatures. The parameter λ determines a trade-off between performance on the study data ($\hat{R}$) and complexity of the classifier (Ω).

Introducing a regularization term seems natural from the following perspective. Recall the section about maximum likelihood. There we assumed a dependency f between the two random variables $\boldsymbol{X}$ and Y. If we start modeling prior belief about the dependency f and express them in a *prior distribution* $P(f)$, an application of Bayes rule leads to:

$$\underbrace{P(f|\mathcal{D})}_{\text{posterior}} = \underbrace{P(\mathcal{D}|f)}_{\text{likelihood}} \underbrace{P(f)}_{\text{prior}} \frac{1}{P(\mathcal{D})}, \tag{8}$$

where "posterior" represents the probability of a model f, given the data. Usually f corresponds to a certain diagnostic signature. The $f^\star$ that maximizes the posterior is a reasonable choice to yield a classifier, since it best explains the data at hand and matches prior beliefs. The classifier corresponding to $f^\star$ is called *maximum aposteriori* (MAP) estimate. Finding the MAP estimate is equivalent to minimizing a regularized risk. Recall that the posterior is proportional to the likelihood times the prior. The *likelihood* is, as discussed before, the probability of the data given the model. We have also seen that maximizing the likelihood can be viewed as minimizing a suitable empirical risk. The regularization now comes via the prior. It puts more weight onto models f that we deem more likely than others, without having seen the data. This can resolve ambiguities where the likelihood alone is undecided. More formally we can see the equivalence as follows. Ignore the last factor in Eq. (8), since it does not depend on f. Then recall Eq. (5), set $l = -\log P(Y|f(\boldsymbol{X}))$ and choose $\lambda\Omega[f] = -\log P(f)$ in Eq. (7).

2.2 Supervised Classification

Having introduced basic concepts and terminology of supervised machine learning, we now present a collection of classification algorithms commonly used with microarray data. It is important to distinguish between a diagnostic signature c and a learning algorithm L. A signature takes expression profiles as an input and returns class labels as an output. A learning algorithm is used to build signatures. It takes training data as an input and returns signatures as an output. To review notation, L is a set of rules how to generate a signature $\hat{c}$, given data $\mathcal{D}$ consisting of n independent samples from $F(X, Y)$, i.e. $L : \mathcal{D} \mapsto \hat{c}$. We will discuss gene selection-based methods, penalized logistic regression and SVMs as well as bagging and boosting. Several of these algorithms build linear signatures.

2.2.1 Discriminant Analysis and Feature Selection

We start by modeling the data-generating distribution F in a parametric way: $P(X, Y) = P(\boldsymbol{X} = \boldsymbol{x}|Y = k)P(Y = k)\colon = f_k(\boldsymbol{x})\pi_k$. We further assume that the f_k are Gaussian densities:

$$\begin{aligned} f_k(\boldsymbol{x}) &= |2\pi\boldsymbol{\Sigma}_k|^{-\frac{1}{2}} \exp\big[-\frac{1}{2}(\boldsymbol{x}-\mu_k)^{\mathrm{T}}\boldsymbol{\Sigma}_k^{-1}(\boldsymbol{x}-\mu_k)\big] \quad (9)\\ \log f_k\pi_k &= \log|2\pi\boldsymbol{\Sigma}_k|^{-\frac{1}{2}} - \frac{1}{2}\boldsymbol{x}^{\mathrm{T}}\boldsymbol{\Sigma}_k^{-1}\boldsymbol{x} \\ &\quad +\boldsymbol{x}^{\mathrm{T}}\boldsymbol{\Sigma}_k^{-1}\mu_k - \frac{1}{2}\mu_k^{\mathrm{T}}\boldsymbol{\Sigma}_k^{-1}\mu_k + \log\pi_k. \quad (10)\end{aligned}$$

For the unknown parameters, unbiased estimates for mean and covariance $(\hat{\mu}_k, \hat{\boldsymbol{\Sigma}}_k)$ can be employed. The priors π_k can be estimated by the relative class sizes $\hat{\pi}_k := n_k/n$. This yields estimates $\hat{f}_k$ and the Bayes classifier can be approximated via $\hat{c}(\boldsymbol{x}) = \operatorname{argmax}_{k\in\mathcal{K}} \hat{f}_k\hat{\pi}_k$. The classification boundary between any two classes i and j is defined in terms of the *log odds*:

$$\eta_{ij}(\boldsymbol{x}) = \log\frac{P(Y = i|\boldsymbol{X} = \boldsymbol{x})}{P(Y = j|\boldsymbol{X} = \boldsymbol{x})} \quad \text{for all } i, j \in \mathcal{K},$$

as the set $\{\boldsymbol{x}|\eta_{ij}(\boldsymbol{x}) = 0\}$ where the posterior probability to belong to either one of the two classes is the same. Assume equal covariance matrices in Equations (9) and (10). This is called the *homoskedastic* case. Then the first two terms in (10) are the same for all classes k and the classification boundaries are linear in $\boldsymbol{x}$. This is called LDA. If the $\boldsymbol{\Sigma}_k$ are assumed different in the two phenotypes (*heteroskedastic case*), the decision boundaries are quadratic. This is then called *quadratic discriminant analysis* (QDA). If the covariances are assumed to be diagonal, i.e. $\boldsymbol{\Sigma}_k = \operatorname{diag}(\sigma_{k1}, \ldots, \sigma_{kp}) =: \operatorname{diag}(\sigma_k)$, one talks about *diagonal discriminant analysis* (DDA). Consequently, the assumption of equal diagonal covariance matrices leads to *diagonal* LDA (DLDA).

Deriving the signature requires the inversion of the estimated covariance matrices. For QDA this leads to the constraints $n_i \geq p + 1$, where the n_i denote the class sizes, and for LDA to $n \geq p + K$. In other words, one needs more patients than genes on the chip, which in our setting is unrealistic. For DDA the estimates $\hat{\boldsymbol{\Sigma}}_k$ are always invertible and it can be applied to expression data directly. With the help of gene selection, LDA and QDA are also applicable to microarray data. Gene selection has to be done prior to the estimation of model parameters. From the entire set of genes only a small number of genes is selected and then discriminant analysis is applied using only the selected subset of genes. Also, the performance of DLDA can be improved using gene selection [30]. A popular method equipping a variant of DLDA with gene selection was proposed by Tibshirani and coworkers [107]. We will discuss it now in some detail.

In the case of LDA, diagnosis consists of classifying a new sample to the class k with the nearest group centroid μ_k (modulo the influence of the priors π_k). Distance is measured in terms of the *Mahalanobis distance* , i.e. $\hat{c}(\boldsymbol{x}) = \text{argmin}_{k\in\mathcal{K}}(\boldsymbol{x} - \hat{\mu}_k)^{\mathrm{T}}\hat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x} - \hat{\mu}_k)$. Tibshirani and coworkers [107] restrict Σ to be diagonal. Additionally it is pointed out, that the estimate of the mean might be obscured by noise present in the data. Therefore, Tibshirani and coworkers [107] advocate the use of a denoised or *shrunken* centroid for each group k in the distance calculation, i.e.:

$$\begin{aligned} \hat{c}(\boldsymbol{x}) = &\quad \underset{k\in\mathcal{K}}{\text{argmin}}(\boldsymbol{x} - \tilde{\mu}_k)^{\mathrm{T}}\hat{\boldsymbol{\Sigma}}^{-1}(\boldsymbol{x} - \tilde{\mu}_k) + \log \hat{\pi}_k \\ \tilde{\mu}_k = &\quad \hat{\mu} + \boldsymbol{\Delta}_k(\delta), \end{aligned} \tag{11}$$

where $\hat{\boldsymbol{\Sigma}} = \text{diag}(\hat{\sigma})$ and $\sqrt{\hat{\sigma}_i}$ is the pooled within-class standard deviation of class k for gene i plus a fudge factor s that reduces the effect of nearly constant genes. $\hat{\mu}$ is the usual estimate for the overall mean. The vector $\boldsymbol{\Delta}_k$ extracts only genes in which the mean of group k strongly differs from the overall mean, i.e.:

$$(\boldsymbol{\Delta}_k)_i = \text{sgn}(\hat{\mu}_k - \hat{\mu})_i \left| |(\hat{\mu}_k - \hat{\mu})_i| - m_k(s_i + s)\ \delta \right|_+,$$

where $m_k s_i$ estimates the standard error of $(\hat{\mu}_k - \hat{\mu})_i$ and $|x|_+ = x$ for $x > 0$ and 0 otherwise, i.e. each component of $\hat{\mu}_k$ is shrunken towards the overall mean in units of the standard error. Additionally to the classification function, this approach can yield an estimate of the posterior class probability $P(Y = k|\boldsymbol{X} = \boldsymbol{x})$ by the $\hat{f}_k(\boldsymbol{x})$ and an application of Bayes rule. The value for the gene selection parameter δ is obtained by *cross-validation*, which is discussed in Section 2.4. A link between this approach and classical linear models is discussed by Huang and coworkers [55]. Other flavors of discriminant analysis have been applied to gene expression data as well. For an overview as well as a comparison with other methods, see Refs. [30, 67].

2.2.2 Penalized Logistic Regression

In our discussion above we modeled the data-generating distribution explicitly via the class-conditional probabilities f_k. Here, we take a discriminative approach and model the posterior densities as follows:

$$P(Y = k|\boldsymbol{X} = \boldsymbol{x}) = \frac{\exp[\beta_k^{\mathrm{T}}\boldsymbol{x}]}{\sum_i^K \exp[\beta_i^{\mathrm{T}}\boldsymbol{x}]}, \tag{12}$$

with identifiability constraints. The classification rule corresponding to this model imitates the Bayes classifier: $\hat{c}(\boldsymbol{x}) = \text{argmax}_{k\in\mathcal{K}}\, P(Y = k|\boldsymbol{X} = \boldsymbol{x}, \hat{\beta})$. If we focus on the two-class problem with $y_i \in \{\pm 1\}$ this reduces to $\mathsf{p} := P(Y = 1|\boldsymbol{X} = \boldsymbol{x}) = 1/(1 + \exp(-\beta^{\mathrm{T}}\boldsymbol{x}))$ and $P(Y = -1|\boldsymbol{X} = \boldsymbol{x}) = 1 - \mathsf{p}$.

The likelihood of the class labels can be modeled via independent biased coin flips:

$$\mathcal{L} = \prod_{i=1}^{n} P(Y = y_i | X = \boldsymbol{x}^{(i)}, \beta) = \prod_{i=1}^{n} \mathsf{p}_i^{\frac{1}{2}|y_i+1|} (1 - \mathsf{p}_i)^{\frac{1}{2}|y_i-1|}, \tag{13}$$

and we can find $\hat{\beta}$ as the minimizer of the negative log-likelihood, i.e. $\hat{\beta} = \text{argmin}_{\beta} - \log \mathcal{L}$. The dependence of $\mathcal{L}$ on β is through p and the minimization can be done directly or via an iterated least-squares procedure. Note that this is equivalent to minimizing the empirical risk with a loss function chosen as $l = -\log[1 + \exp(y\beta^{\mathrm{T}}\boldsymbol{x})]$, the *logistic loss function*. Due to the high numbers of genes on the arrays the optimum of Eq. (13) is not unique. As a solution, a regularized risk (see Eq. (7)) can be minimized choosing an appropriate regularization term. Common choices are the L_1 and the L_2 penalty, where $\Omega[c] = \|\beta\|_1^2$ and $\Omega[c] = \|\beta\|_2^2$, respectively. The L_2 penalty is usually combined with gene selection techniques [34, 121], while the L_1 penalty automatically produces sparse solutions, i.e. only few genes contribute to the posterior [91, 95]. For the minimization Roth [91] utilizes an iterative least squares procedure extending an algorithm of Osborne and coworkers [80], while Shevade and coworkers [95] use a Gauss–Seidel method. Kim et al. [62] propose a gradient descent algorithm for problems of this form.

A related approach is that of West and coworkers [116] and Spang and coworkers [100], who model $P(Y = 1|X = \boldsymbol{x}) = \Phi(\boldsymbol{x}^{\mathrm{T}}\beta)$ via the *probit regression model* . Here, Φ denotes the cumulative density function of a standard normal distribution. However, in contrast to what corresponds to a maximum *a posteriori* estimate in the approaches before, a full Bayesian analysis is employed and the posterior distribution of all model parameters is sampled. Regularization is achieved via the introduction of hierarchical normal priors.

2.2.3 **Support Vector Classification**

For simplicity suppose a classification problem with only two possible clinical phenotypes, i.e. $y_i \in \{\pm 1\}$. Then, SVMs [93, 111, 112] fit a maximal (soft) margin hyperplane between the two classes. In high-dimensional problems there are always several perfectly separating hyperplanes (the maximum likelihood approach leads to an ill-posed problem). However, there is only one separating hyperplane with maximal distance to the nearest training points of either class.

This concept is typically combined with the *kernel trick* to allow for flexible nonlinear classification boundaries. The kernel trick is applicable to classification algorithms that can be expressed in terms of inner products of the inputs $\boldsymbol{x}^{(i)}$ who reside in what is called the *input space*. This is the case for the maximum margin hyperplane. The inner products are then substituted by a *kernel function* $k(\boldsymbol{x}, \boldsymbol{x}')$, which corresponds to a *feature map* Φ that maps the profiles from the input space into a *feature space* $\mathcal{H}$:

$$\begin{array}{llll}\Phi: & \mathbb{R}^p & \longrightarrow & \mathcal{H} \\ & x & \mapsto & \Phi(x). \end{array} \tag{14}$$

This results in the original algorithm being now carried out in $\mathcal{H}$ and leads to nonlinear decision boundaries in the input space.

After applying the kernel trick, a class of linear functions in feature space is given by $\mathcal{F} := \{f(x) = \sum_i^n \alpha_i k(x, x^{(i)}) + b \,|\, \alpha_i, b \in \mathbb{R}\}$. The associated diagnostic signatures read $c(x) = \operatorname{sgn} f(x)$. Finding the maximal margin hyperplane is the same as minimizing a regularized risk. The loss function employed is called *soft margin loss* and the regularization term is $\|f\|^2_{\mathcal{H}} := \alpha^{\mathrm{T}}\mathbf{K}\alpha$. Here, $\mathbf{K}$ is the *kernel matrix* and $\mathbf{K}_{ij} = k(x^{(i)}, x^{(j)})$. Regularization is essential to counter the additional flexibility acquired by the kernel trick. In summary:

$$\hat{f}(x) = \underset{f\in\mathcal{F}}{\operatorname{argmin}} \Big\{ \sum_i^n \max(0, 1 - y_i f(x^{(i)})) + \frac{\lambda}{2}\alpha^{\mathrm{T}}\mathbf{K}\alpha \Big\}. \tag{15}$$

In this formulation, separability of the two classes is not required and margin violations are allowed. The trade off between margin violations and margin size (measured as $\|f\|^{-2}_{\mathcal{H}}$) is reflected by the regularization parameter λ. Support vector classification, in combination with various gene selection methods, has been applied to microarray data [42,87] and compared favorably [16, 67, 72]. A SVM-specific *wrapper method* (see Section 2.3.2) for feature selection is presented by Guyon and coworkers [47]. The generalization to more than two classes is not straightforward and different methods are compared by Hsu and coworkers [54].

2.2.4 Bagging

Bagging [14] is a method of aggregating weak classifiers via bootstrapping the data at hand. Bagging stands for **b**ootstrap **agg**regat**ing** and roughly works as follows. M bootstrap samples are drawn from the data $\mathcal{D}$. A *bootstrap sample* from $\mathcal{D}$ is an *iid* sample $\{(x^{(i)*}, y_i^*)\}_{i=1}^{n_{\mathrm{B}}}$ of size n_{B} from the empirical distribution function of the data, which puts weight $1/n$ onto each observation. Then a simple learning algorithm is trained on each bootstrap sample minimizing the empirical risk. This results in a set of weak classifiers $\{\hat{c}_m\}_{m=1}^M$. In the end all weak classifiers $\hat{c}_m$ are averaged to obtain a final strong signature: $\hat{c}(x) = \operatorname{argmax}_k \sum_{m=1}^M \mathbb{I}_{\hat{c}_m(x)=k}$. The class k which most of the $\hat{c}_m$ agree on gets chosen. If the weak classifiers produce estimates of the class conditional probabilities, these can be averaged instead [52].

Random forests [15] constitute an application of this concept. There weak classifiers are derived using classification trees [13] grown using only a random subset of genes. The forest of trees (weak signatures) is then averaged over the bootstrap samples. Random forests are applied to gene expression data, for example, by Gunther and coworkers [46].

2.2.5 Boosting

Another method falling into the category of aggregated classifiers is *boosting*. The algorithm Adaboost was introduced by Freund and coworkers [39]. Several weak signatures c_m are combined to form an aggregate classifier. Hastie and coworkers [52] present Adaboost as an forward stagewise additive modeling approach. The empirical risk is minimized choosing the *exponential loss function* $l(\boldsymbol{x}, c(\boldsymbol{x}), y) = \exp(-yc(\boldsymbol{x}))$ for $y \in \{\pm 1\}$. Basically, the classifier $c(\boldsymbol{x})$ is viewed as an expansion in the weak c_m, i.e. $c(\boldsymbol{x}) = \text{sgn}[\sum_i^M \beta_m c_m(\boldsymbol{x})]$. However, in contrast to bagging, the different c_m are not independently fit to bootstrap samples. Rather, given coefficients $\{\hat{\beta}_i\}_{i=1}^{m-1}$ and classifiers $\{\hat{c}_i\}_{i=1}^{m-1}$, the next pair $(\hat{\beta}_m, \hat{c}_m)$ is determined to optimally supplement the previous ones in terms of minimizing the empirical risk. This results in an iterative optimization strategy. The complexity of the classifiers can be regulated by the number of iterations allowed, i.e. M.

Dettling and coworkers [24] apply this procedure to microarray data. As weak signatures *decision stumps* are used, i.e. classification trees with only two terminal nodes. They use the LogitBoost algorithm of Friedman and coworkers [40]. There, the exponential loss function of Adaboost is exchanged for the logistic loss function introduced earlier. As feature selection, a nonparametric filter method [81] is employed. A combination of bagging and boosting is presented in Dettling and coworkers [25] in the context of gene expression analysis. Both methods are discussed in Tan and coworkers [103]. Zhang and coworkers [119, 120] also apply classification trees in the context of gene expression.

2.3 Gene Selection

Combining classification algorithms with a gene selection procedure is common practice in microarray-based diagnosis. It is done for two reasons. First, and most importantly, gene selection reduces model complexity and in many cases impacts the predictive performance of the signature [30]. Here, model complexity refers to the flexibility of the decision boundaries. Methods like linear discriminant analysis are not applicable at all without gene selection. Other methods, like nearest shrunken centroids [106] or L_1-penalized regression techniques, implicitly reduce the number of genes involved in the signatures. Secondly, the reduction of genes leads to a smaller and hence cheaper design of diagnostic chips or marker panels [57].

Feature selection has a strong impact on the predictive performance of a signature. For this reason it cannot be considered to be a preprocessing step like data normalization discussed in the previous section. It is an essential part of the signature-building algorithm. There is an important difference between building a signature based on 10 genes and building a signature that depends on only 10 genes that, however, were chosen from a pool of 30 000 genes. The first is a low-dimensional model and can be specified by 10 parameters. The second still involves 30 000 parameters, although 29 990 of them were constrained to be zero. The important point is, that it was not agreed which of them should be zero *before* the data was looked at. The importance of not separating gene selection from the signature building process becomes apparent in Section 2.4.

2.3.1 **Filter Approaches**

When feature selection is performed independently of the learning algorithm one talks about a *filter approach* [59]. Straightforward implementations univariately screen for genes, optimizing a score reflecting correlation with the class labels. Popular choices are the t-statistic, the (nonparametric) Wilcoxon rank-sum statistic, the absolute difference of the group means divided by the sum of the estimated standard deviations [45] or the F-statistic in the multiclass case. More sophisticated are filter approaches (heuristically) searching for an optimal *subset* of informative genes [10,50]. Jäger and coworkers [58] and Ding and coworkers [27] also take into account and minimize the redundancy of the selected gene set.

2.3.2 **Wrapper Approaches**

If the learning algorithm is taken into account while looking for informative genes, this is called a *wrapper method* [59]; the feature selection procedure is "wrapped around" the learning algorithm. Either single features or subsets of features are sought that maximize a performance score of the learning algorithm, e.g. the estimated misclassification error. This is a generic procedure and independent of the learning algorithm considered. Looking for optimal feature subsets is a combinatorial problem, and heuristics like forward selection and backward elimination can be employed [59].

A prototypical example is *recursive feature elimination* (RFE) [47]. This approach has been put into the framework of assessing the sensitivity of generalization bounds [85]. This concept, in turn, has been applied to gene expression data by Cho and coworkers [21]. Another approach is to use the penalty term in the regularized risk to ensure sparse solutions (few genes contribute), as it is the case for L_1-penalized logistic regression. Shevade and coworkers [95] use this property together with cross validation (see next section) to simultaneously select and assess the relevance of genes. Such methods are also called *embedded methods* [48].

2.4 Adaptive Model Selection and Validation

This section covers two important steps in microarray-based diagnosis: adaptive model selection and the validation of the predictive performance of a molecular signature. While these are two different tasks, the methodology in use is similar.

2.4.1 Adaptive Model Selection

The algorithms discussed in the previous section can all be linked to minimizing the empirical or the regularized risk (with an appropriate choice of the loss function) over a class $\mathcal{C}$ of candidate signatures. For instance, in the case of penalized logistic regression the signatures take the parametric form of the right-hand side of Eq. (12) and are parameterized by the β_k. For kernel classifiers, $\mathcal{C}$ corresponds to signatures that can be written in the form $f(\boldsymbol{x}) = \text{sgn}[\sum_i^n \alpha_i k(\boldsymbol{x}, \boldsymbol{x}^{(i)}) + b]$ with α_i and $b \in \mathbb{R}$. Depending on how rich this class of signatures is, the learning algorithm is able to implement more or less flexible boundaries between the K phenotypes. For microarray data, the typical situation is that even simple signature classes, such as hyperplanes, are extremely rich due to the high dimensionality of the profiles $\boldsymbol{x}^{(i)}$. For simplicity, we will refer to the richness of the set of candidate signatures as the complexity of a *diagnostic model*.

2.4.1.1 **Bias-variance Trade-off** When dealing with complex diagnostic models not the empirical risk needs to be optimized, but the regularized risk in Eq. (7). This allows for controlling complexity. The regularization term introduces a complexity penalty, thus effectively restricting the complexity of the derived diagnostic signature $\hat{c}$. The regularization parameter λ quantifies the trade-off between model fit and model complexity. With little regularization the algorithm can fit very flexible decision boundaries to the data. This results in few misclassifications on the data from patients in the study. Nevertheless, it can have poor predictive performance in clinical practice. The reason is that the algorithm not only fits population properties (as desired), but also reflects noise resulting from patient sampling. We refer to this as *overfitting*. When the regularization term dominates Eq. (7), the resulting signatures might be too restricted. Then we have poor performance on both, the study patients and in future clinical practice. We refer to this situation as *underfitting*. The problem described above is also known as the *bias-variance trade-off*, since regularization introduces a bias into the estimation of model parameters, while at the same time reducing the sample variance. Sample variance here refers to $\hat{c}$ varying

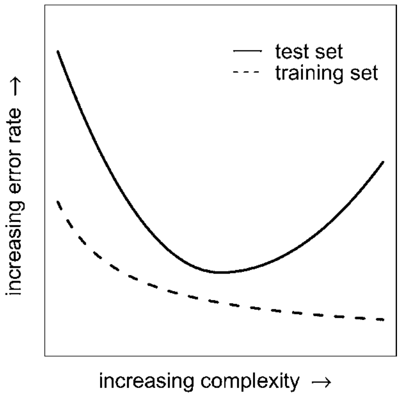

Figure 2 Schematic diagram to illustrate the *bias-variance trade-off* (see text). The x-axis codes for model complexity and the y-axis for error rates. The dashed line displays the training error, the solid line the test error. Low-complexity models produce high test errors (underfitting, low variance, high bias) and so do highly complex models (overfitting, high variance, low bias).

with different cohorts drawn from the same disease population. See also Figure 2.

2.4.1.2 **Choosing a Trade-off via the Hold Out** The regularized risk is a general example of how learning algorithms can implement a tuning parameter (in this case λ) that allows for balancing over- and underfitting. Further instances are the number of genes included after the variable selection process or the amount of shrinkage in the nearest shrunken centroid method.

Before we start explaining how these parameters can be tuned, we need some more notations: recall that we need to build signatures from a finite data set $\mathcal{D}$, drawn from F. Let us define the *empirical error rate* of a signature $\hat{c}$ built on $\mathcal{D}$ as:

$$\hat{e}_{\lambda}^{\text{emp}}\left[\,\hat{c}\,\right] := \frac{1}{n}\sum_{i}^{n}\mathbb{I}_{\hat{c}_{\lambda}(x^{(i)})\neq y_i}, \tag{16}$$

where we have made the dependency of the classification rule on the regularization parameter λ explicit and $\mathbb{I}$ denotes the indicator function. The empirical error rate is equivalent to the empirical risk $\hat{R}$ when using the $0/1$ loss function. The empirical error rate is a random variable since it depends on the random sampling of patients that were included into a study. When repeating the study with a second cohort of patients, one obtains a different empirical error rate.

We now split the data set into a *training* or *learning set* $\mathcal{D}_l$ and a *test set* $\mathcal{D}_t$. The training set constitutes a (smaller) study cohort, while the test set can be used like novel patients with unknown diagnosis. In this respect, we want little errors on the test set. To reduce test errors, we are even willing to pay a price in terms of some more errors on the training set. For a fixed value of the regularization parameter, one can learn a signature $\hat{c}_\lambda(\boldsymbol{x}) := L(\boldsymbol{x}; \mathcal{D}_l)$ by applying a learning algorithm only to the training data. Subsequently, its predictive performance can be evaluated by applying the generated signature to the independent test data and calculating the error on the test set only. The value of the regularization parameter can be varied, identifying a value such that the above estimate is minimal. That is, the learning algorithm then consists of minimizing $\hat{R}_{\text{reg}}$ and choosing the regularization parameter via assessment of generalization performance. This procedure is referred to as *adaptive model selection*, since by determining the regularization parameter one chooses a model with approximate optimal complexity. However, different clinical classification problems need different amounts of regularization. By using a hold out set, model selection is adapted to the data at hand.

2.4.1.3 **Using Data More Efficiently via Cross-Validation** Since microarray data is expensive and scarce, one can make use of the following procedure. The data set $\mathcal{D}$ is randomly partitioned into Q bins $\{\mathcal{D}_q\}_{q=1}^{Q}$. Each one of the $\mathcal{D}_q$ is then used as hold out set in turn. More formally: Let $\kappa : \{1, \ldots, n\} \rightarrow \{1, \ldots, Q\}$ be a partitioning, i.e. $\kappa(i) = q$ for all $i \in \mathcal{D}_q$, $i \in \{1, \ldots, n\}$ and $q \in \{1, \ldots, Q\}$. Further, let $\hat{c}_\lambda^{-\kappa(i)} := L(\boldsymbol{x}; \mathcal{D} \setminus \mathcal{D}_{\kappa(i)})$ be a classifier trained on $\mathcal{D} \setminus \mathcal{D}_{\kappa(i)}$ for a fixed value for λ. Then we estimate the misclassification rate via [43,102]:

$$\hat{e}_\lambda^{cvq}\,[\,\hat{c}\,] := \frac{1}{n} \sum_{i}^{n} \mathbb{I}_{\hat{c}_\lambda^{-\kappa(i)}(\boldsymbol{x}^{(i)}) \neq y_i}. \tag{17}$$

This quantity estimates the expected error rate on future data. Again, one can do this for a grid of values of the regularization parameter and an approximately optimal value can be identified. Adaptive model selection is a part of the learning algorithm, as it was the case with gene selection. This needs to be kept in mind when assessing the performance of a signature.

2.4.2 Validation of the Predictive Performance of a Molecular Signature

After having derived a diagnostic signature one needs to estimate its expected performance in future clinical practice. This validation step constitutes one of the most critical steps in the whole process of molecular diagnosis and several pitfalls are involved. Estimators can be overly optimistic (biased) or they might have high sample variances. It also makes a difference whether one is interested in estimating the performance of a fixed signature $\hat{c}$ (which is usually the case in clinical studies) or if one is interested in estimating the performance of the learning algorithm L that builds the signatures (which is usually the case in methodological projects). The performance of the fixed signature $\hat{c}$ varies due to the random sampling of the test set, while the performance of the algorithm L varies due to sampling of both the training and test set.

The two different situations correspond to two different theoretical error rates. The performance of a fixed signature $\hat{c}(\boldsymbol{x}) =: L(\boldsymbol{x};\mathcal{D})$, derived from a training set $\mathcal{D}$, is measured by the *conditional error rate(s)* or the *true error*:

$$\begin{aligned} E_{ij}[\,\hat{c}\,] &= \; P(L(\boldsymbol{X};\mathcal{D}) = j|Y = i,\mathcal{D}) \quad i \neq j \in \mathcal{K} \quad \text{and} \\ E[\,\hat{c}\,] &= \; P(L(\boldsymbol{X};\mathcal{D}) \neq Y|\mathcal{D}). \end{aligned} \tag{18}$$

The first quantity, E_{ij}, is the probability that the signature $\hat{c}$ will classify a patient from the disease population to belong to class j even though they actually belong to the phenotypical class i. The second quantity only asks for wrong classifications of $\hat{c}$, no matter which group is mistaken for what other group. These quantities are not obtainable in practice, since the probabilities need to be calculated with respect to the unknown population distribution $F(\boldsymbol{X},Y)$.

If, in contrast, one is interested in the performance of the learning algorithm L, the sampling variability of the training set has to be taken into account. This makes the conditional error rates random variables. Keeping the size of the training set fixed and taking expectations leads to the *(unconditional) error rate(s)* or the *expected error* :

$$\begin{aligned} \bar{E}_{ij}[\,L\,] &= \mathbb{E}_{\mathcal{D}}\,E_{ij} = P(L(\boldsymbol{X};\mathcal{D}) = i|Y = j) \quad i \neq j \in \mathcal{K} \quad \text{and} \\ \bar{E}[\,L\,] &= \mathbb{E}_{\mathcal{D}}\,E \;\; = P(L(\boldsymbol{X};\mathcal{D}) \neq Y). \end{aligned} \tag{19}$$

As it was the case for the conditional error rates, these quantities depend on F and are not accessible. Hence, both rates need to be estimated using the data at hand.

2.4.2.1 **Estimating Error Rates** One might assume the empirical error [Eq. (16)] can be employed to estimate the conditional error rate. The main problem with this approach is that it uses the *same* data in $\mathcal{D}$ to train the classifier and to evaluate it later on. This can result in highly biased error rates grossly underestimating the true error. This is practically relevant in gene expression data analysis, since the high dimensionality of the data makes algorithms without complexity control prone to overfitting [3,96].

A better approach is to use an independent test set. Only training data is used for gene selection, classifier learning and adaptive model selection. The final signature $\hat{c}$ is then evaluated on an independent test set. Unfortunately, this estimator can have a substantial sample variance, due to the random selection of patients in the test set. This is especially the case if the test set is small. It falls in this line of thought that good performance in small studies can be a chance artifact [79].

More effective use of the data at hand can be made via the cross-validation procedure introduced earlier. The leave-one-out version produces an estimator of the unconditional error rate with almost no bias. It is computationally more expensive than q-fold cross-validation and suffers from a very high sample variance. The latter is reduced for moderate q such as "somewhere between 5 and 10" [52, 64, 73]. Braga-Neto and coworkers [12] advise to average over many different partitionings. No unbiased estimator of the variance of the cross-validation estimate, i.e. valid for all distributions F, exists [7]. Cross-validation error rates naturally refer to the classification algorithm L. In each iteration a different classifier is learned, based on (somewhat) different training data. The cross-validation performance is the average of the performance of different signatures. Nevertheless, cross-validation performance can be also used as a bias-corrected estimator of the conditional error rate. In fact, in applied work it is often used to validate fixed signatures that were derived by the evaluated algorithm.

Efron and coworkers [33] apply *bootstrap smoothing* to the leave-one-out cross-validation estimate. The basic idea is to generate different *bootstrap replicates* $\{\mathcal{D}_b^*\}_{b=1}^{n_B}$, apply leave-one-out cross-validation to each and then to average the results. A result of this approach is the so called "0.632+ estimator". It takes into account the possibility of overfitting and reduces the variance compared to the regular cross-validation estimates. Ambroise and coworkers [3] have found it to work well with gene expression data.

2.4.2.2 **Selection Bias and Nested Loop Cross-validation** As we have discussed in the previous section, feature selection techniques are a central element in the analysis of microarray data. In filter approaches, special care has to be taken when using cross-validation: *the feature selection is part of the learning algorithm L*. For this reason feature selection has to be repeated again on each $\mathcal{D} \setminus \mathcal{D}_q$, i.e. Q times. Global gene selection before the cross-validation (which is also called *incomplete cross-validation* or *information leak*) can result in grossly over-optimistic (biased) estimates of the error rates [3]. For example, Simon and coworkers [96] describe a case, where the incomplete cross-validation method and the fully cross-validated method result in estimated error rates of 27% and 41%, respectively. Similarly, assume the algorithm L contains an adaptive model selection procedure. To get reasonable error rate estimates via cross-validation, the selection procedure has to be applied to every $\mathcal{D} \setminus \mathcal{D}_q$ separately. This leads to a cross-validation step inside a cross-validation, i.e. to a *nested loop* cross-validation [43, 92]. Applying the selection procedure to the complete data can lead to biased estimation of the error and over optimistic results. Ruschaupt and coworkers [92] and Wessels and coworkers [115] realize such a *complete validation procedure* and compare various methods.

Ntzani and coworkers [79] and Michiels and coworkers [75] report that, at least in studies up to 2003, many of 84 considered studies lacked appropriate validation of derived signatures. In fact, many of the shortcomings could have been avoided keeping in mind the two points above.

2.5 Discussion

In the previous sections we introduced basic concepts and methods used in classification problems. Whenever possible, we tried to point out aspects specific to the classification of microarray data. General literature about machine learning includes Refs. [26, 29, 52, 88, 93], where a more thorough treatment of the theoretical concepts can be found. More focused on the analysis of microarray data are Refs. [73, 101].

The methodology above was presented in the classification context only. One might be tempted to interpret the genes driving the models, but this is dangerous. First, it is unclear how the regularization term biases the selection of signature genes. While a bias is a blessing from the diagnostic perspective, this is not the case from the biological perspective. Second, signatures are generally not unique: While outcome prediction for breast cancer patients has been successful in various studies, e.g. [86, 99, 109], the respective signatures do not overlap at all. Further on, Ein-Dor and coworkers [35] derived a large number of almost equally performing signatures in a single dataset. This is not too surprising considering the following: the molecular cause of a clinical phenotype might involve only a small set of genes. This primary event has secondary influences on other genes, which in turn deregulate more genes and so on. In clinical microarray analysis we typically observe an avalanche of secondary or later effects, often involving thousands of differentially expressed genes. While complicating biological interpretation of signatures, such an effect does not compromise the clinical usefulness of predictors. On the contrary, it is conceivable that only signals enhanced through propagation lead to a well-generalizing signature.

3 Finding Molecular Disease Entities

In the previous section we were concerned with reconstructing phenotypically defined disease entities based on expression profiles. This is a supervised learning problem and results in diagnostic signatures with obvious clinical relevance. In this section we go beyond the level of already established clinical phenotypes and aim to define novel disease entities exclusively based on the molecular properties that are reflected in expression profiles. This is an unsupervised learning problem and results in novel patient stratifications. The clinical relevance of such results must always be proved in subsequent analysis. For instance, clinical follow-up studies may confirm that patients belonging to different molecular entities respond differently to treatment. If this is the case, treatment can be adjusted according to this novel molecular diagnosis.

In various microarray studies researchers have applied unsupervised machine-learning techniques to discover molecular disease subgroups, and subsequently validated the clinical impact of the stratification. For instance, patient subgroups with particular outcome probabilities were characterized in Ref. [8], and so far unclear disease mechanisms have been uncovered in Refs. [1,76].

3.1 Clustering

The most widely used approach to molecular disease characterization is via clustering algorithms. Although this approach suffers from several limitations, which we will point out below, we cover the most frequently used methods here. Clustering algorithms are discussed in detail in Chapter 27 in the context of clustering genes. In this section, we focus on specific issues when applying the same algorithms to the clustering of patients.

3.1.1 Clustering Algorithms

Hierarchical clustering is a well-studied and established method in the statistical community, and is by far the most widely used method for clustering patients. It was first applied to microarray data in 1998 by Eisen and coworkers [36]. Since then it has been applied in many clinical microarray studies to support distinctions between patient groups, which are claimed to be coherent from a molecular point of view. Clinical fields of these studies include lung cancer [8], lymphomas [1,76], leukemia [20,45,117], breast cancer [82], ovarian cancer [114], cutaneous melanoma [9], colon cancer [2], glioma [38, 41] and parathyroid tumors [53]. The result of hierarchical clustering is typically illustrated using dendrograms (Figure 3), where similar samples are depicted close to each other. Cutting dendrograms at any level naturally defines a set of clusters, but is subject to arbitrary decisions on where to cut.

Other clustering methods also based on distances between samples directly aim to separate the set of samples into a given number of clusters. Examples of such methods are *k*-means clustering [51], partitioning around medoids [60] and self-organizing maps [65]. These methods, however, are restricted to detect a predefined number of clusters. The FOREL method, otherwise very similar to *k*-means, overcomes this limitation by determining one cluster at a

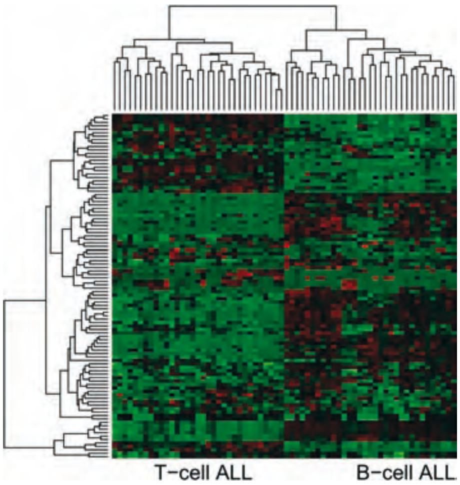

Figure 3 Dendrograms illustrate results of hierarchical clustering. The cluster plot shown is generated from microarray data on acute lymphocytic leukemia (ALL) partially published in Ref. [20]. Half of the samples chosen are from T cell ALL, the other half from B cell ALL. The dendrogram at the top of the image shows that hierarchical clustering clearly separates these two classes.

time, removing its samples and then restarting to find the next cluster [83]. Alternatively, methods for automatic determination of the most adequate number of clusters are suggested in Refs. [31, 66, 105].

In Ref. [19], probabilistic clustering based on a mixture model is suggested. The authors present an algorithm to determine model parameters by Bayesian inference. A similar approach is implemented in mclust [37], a freely available add-on package for the statistical computing environment R [56, 84]. It was applied to microarray data in Ref. [118]. Probabilistic model-based clustering is discussed in further detail in Ref. [98] together with a suggestion of how to choose model parameters in a cross-validation setting.

3.1.2 **The Problem of Distances**

All of the clustering methods described above compute distances between objects, which are in this case patients. Typical choices are the Euclidean distance or a distance based on Pearson's correlation coefficient. Each patient is described by a long list of gene expression values, but not all of them can be assumed to carry information on disease states. Hence, it makes no sense to include all genes in the distance function. Instead, clusters are computed based on a subset of the genes measured in the expression profiles. Including different sets of genes into a Euclidean metric, leads to different distances between patients and consequently influences the results of clusterings. Nevertheless, there is no such thing as a justifiable best choice of features.

The most straightforward selection method is simple selection for maximal variance or maximal bandwidth of expression values within a gene (e.g. Ref. [18]). The motivation for this is to avoid measurement noise expected to be dominant in the many low variance genes. Bhattacharjee and coworkers [8] as well as Monti and coworkers [76] suggest to select reproducibly variable genes. In order to do so they extract two samples from a number of tumors and determine a robust *F*-statistic to capture the reproducibility of genes together with their corresponding variance. Genes are then selected for low variance between replicates and high variance between patients.

3.2 Searching for Partitionings

3.2.1 Overlapping Partitionings

Clustering of patients returns the dominating structure of the patient space. However, from a clinical perspective we expect that different sets of genes uncover different structures on patients, which can all be relevant in their own right. In the context of oncology we can think of one set of genes that partitions the patients with respect to the regulation of the apoptosis pathway, while a second set of genes classifies patients according to the proliferation rate of tumor cells.

Systematically combining clustering with variable selection is one feasible approach to uncover multiple structures in the patient space. For instance, Dougas and coworkers [32] suggest an iterative exclusion of cluster supporting genes in order to find new clusterings in each iteration. In each step, 2-means clustering determines one clustering of the data and the most differential gene with respect to this clustering is removed. During this procedure, various differing clusterings are discovered.

3.2.2 Search and Find

The common aspect of algorithms discussed here is that they search in the space of all partitionings for interesting splits. Different criteria to characterize interesting partitionings are suggested and local or global search algorithms to find them are applied. When searching for homogeneous groups in patients, a desirable property is good separability. This property inspires a group of unsupervised methods, which search in the space of possible partitionings by optimizing a score for separability.

3.2.3 ISIS – Identifying Splits with Clear Separation

The ISIS method [113] is restricted to detecting bipartitions or splits of the data. To this end it uses the diagonal linear discriminant score (DLD) to measure separability of the two classes in a split. For computing the DLD scores, all samples are projected on one dimension as in DLD analysis (DLDA) to discriminate between the two candidate classes. The DLD score is then the two-sample *t*-statistic for the projected values. ISIS detects multiple structures by searching for splits with local minima of the DLD score. Figure 4 illustrates the result obtained from a single call to this method. In Ref. [61], the ISIS method is applied to patients with congenital heart defects. The authors of this study were able to confirm and further characterize molecular subclasses of this disease.

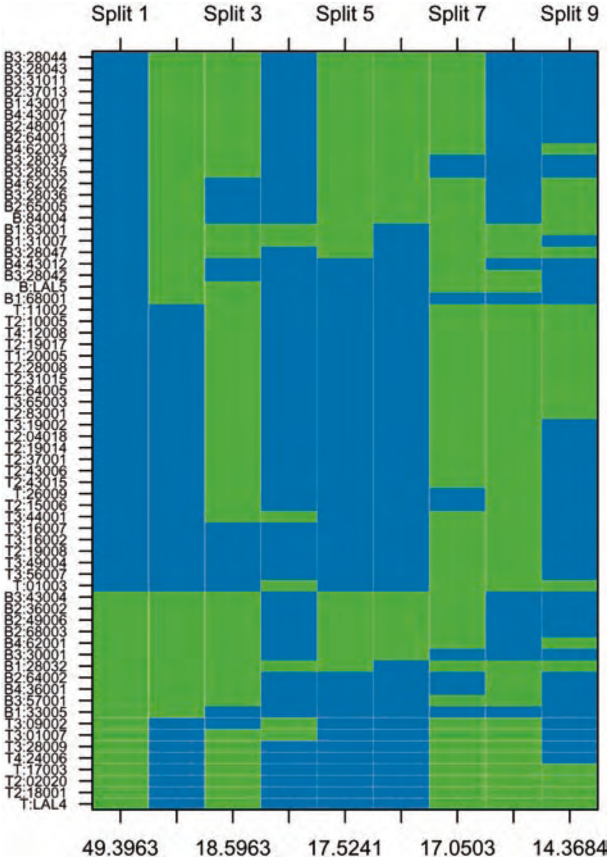

Figure 4 The ISIS method reports a set of locally optimal bipartitionings. Here, it was applied on a subset of samples from the leukemia dataset in Ref. [20] including B cell and T cell ALL cases. The 500 most variable genes are used to compute the results shown here. Each row in the figure corresponds to one of the samples, each column to a split suggested by ISIS. The colors indicate the partition of the cases and the scores on the bottom are DLD scores. Split 2 in the figure corresponds to the separation of T and B cell ALL.

3.2.4 Overabundance of Differential Genes

An alternative approach to class finding is described in Ref. [6]. The authors define a figure of merit measuring the overabundance of genes supporting one split compared to a null model for random splits. This provides a notion of significance for candidate splits. Splits with optimal figure of merit are searched using simulated annealing. This probabilistic process is iterated to yield several alternative splits. An extension from bipartitions to multiple partitions is described in Ref. [68].

3.2.5 Best-fitting Gaussian Model

The two methods described above are heuristics. A full statistical model for class discovery has been described in Ref. [90]. A two-class Gaussian mixture model is used for finding patient splits. In addition, the authors modify the well-known expectation-maximization (EM) algorithm to incorporate feature selection in the M-step using L_1 regularization. Finally, a stability criterion using artificial noisy versions of the data is used to test the robustness of partitionings. The method reports only partitionings which prove stable in the resampling step.

3.3 Biclustering

Methods discussed so far mostly insist on partitioning the entire set of patients or samples. In contrast, biclustering algorithms directly search for homogeneous subgroups of patients which may be based on a subsample of genes. Thus, there are opportunities to search more freely for homogeneous groups of patients, while leaving out the samples which are difficult to associate with others. An overview on suggested algorithms is given in Ref. [71].

Researchers have suggested various versions of biclustering algorithms with differing applications in mind. Getz and coworkers [44] rediscovered the distinction between lymphocytic and myeloid leukemia in the dataset in Ref. [45] in a completely unsupervised manner. In the same analysis, the authors report the rediscovery of the distinction between T and B cell ALL as well as the detection whether patients underwent treatment. For each of these distinctions supporting genes are determined. In a dataset on colon cancer by Alon and coworkers [2], biclustering detected a change in protocol for the data acquisition. Similar proofs of principle are reported in Refs. [63,78,94,104] on data from lymphoma, leukemia, breast cancer, multiple sclerosis and central nervous system embryonal tumors.

3.4 Semisupervised Methods

So far we have discussed both supervised and unsupervised analysis of patient profiles. Recently, several papers have described analysis strategies, which carry characteristics of both fields in parallel. We will call them semisupervised methods.

A major problem with unsupervised methods is that they detect any structure among patients. Novel stratifications can be of clinical relevance, but in many cases they just reflect trivial differences like age and gender. Even worse, clusterings may be detected due to experimental artifacts or noise. The idea of semisupervised methods is to direct class discovery towards clinically relevant partitionings through additional phenotypical information on the patients.

3.4.1 Molecular Symptoms

From the hypothesis that known clinical phenotypes may be caused through different molecular causes, Lottaz and coworkers [70] have derived a semisupervised approach called structured analysis of microarray data (StAM). As input the method needs both expression profiles and class labels reflecting a relevant clinical phenotype, typically a disease group versus a control group. Unlike purely supervised methods StAM does not aim to find a single molecular signature, but searches for hidden subentities (the unsupervised aspect), which need to be subsets of the predefined disease group (the supervised aspect). Then it searches for molecular characteristics, which distinguish the newly found subgroup of disease patients from all other patients. These characteristics are called molecular symptoms in contrast to the molecular signatures derived from purely supervised analysis. They are similar to clinical symptoms, since these as well are not necessarily present in all patients, but almost never occur in healthy people. The method searches for molecular symptoms using classifiers based on biologically focused sets of genes. Candidate sets are deduced from functional annotations collected in the Gene Ontology (GO) [4]. Figure 5 shows the structured analyses concerned with mixed lineage leukemias from the leukemia dataset by Yeoh and coworkers [117].

3.4.2 Survival-driven Class-finding

Outcome prediction is a particularly important issue in clinical studies. Most methods described in the literature combine cluster analysis and classification methods. In this respect, they can be considered semisupervised.

One approach to find classes related to survival is described in Bullinger and coworkers [17]. In a first step, a cox proportional-hazards model is

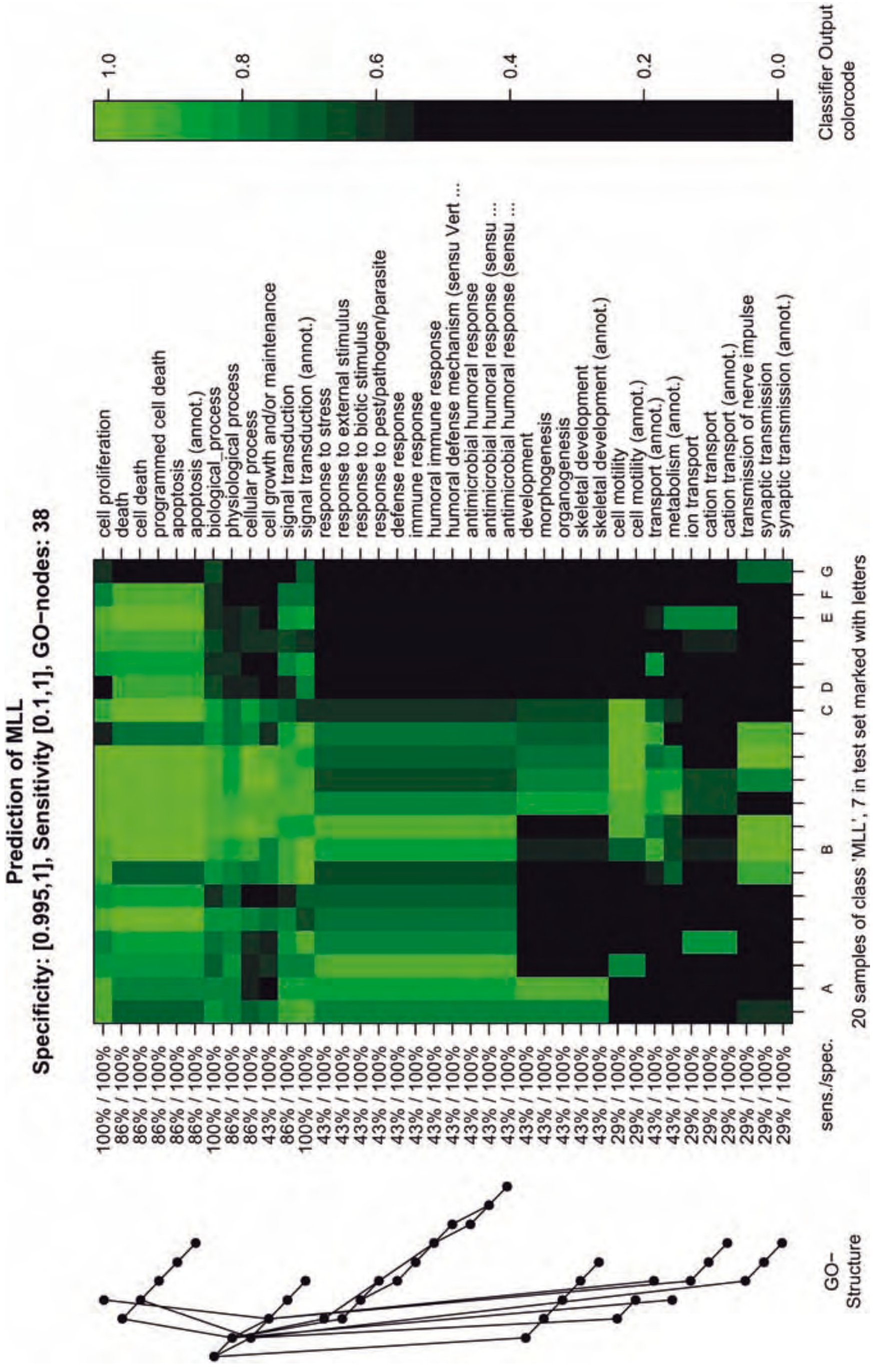

Figure 5 Molecular symptoms stratify patients. Rows correspond to GO-node-based classifiers, columns represent patients with mixed-lineage leukemia. Colors in the image encode classifier results. Bright regions represent presence and dark regions represent absence of molecular symptoms. Presence/absence patterns of molecular symptoms provide a molecular patient stratification.

used together with a permutation test to find genes, which are significantly correlated to outcome. k-means clustering is used on the expression data restricted to these outcome-related genes to separate patients into two groups. Finally, Bullinger and coworkers use the nearest shrunken centroid classification to confirm the separability of the two groups in a cross-validation scheme. The authors have evaluated their method on data from a clinical study on acute myelogenous leukemia in adults where they molecularly characterize a separation into good- and poor-outcome patient groups.

3.4.3 Towards Survival Prediction

Dave and coworkers [22] suggest to determine survival correlated genes similar to Ref. [17], but organize them into signatures associated with poor prognosis and signatures associated with good prognosis by hierarchical clustering on genes. A linear combination of these signatures was used to compute survival scores used to separate patients into four different classes of expected survival. The authors validate their approach on data from a clinical study on follicular lymphoma. A similar approach more focused to determine a small, clinically practical signature for survival prediction of diffuse large B cell lymphoma patients is described in Ref. [69]. Its validity is confirmed on data from independent clinical studies.

3.5 Validating Unsupervised Analysis

Compared to supervised analysis, the validation of clustering and class-finding results is notoriously difficult, since predictive performance cannot be assessed. Researchers have developed various quality indices based on significance of structure, stability of clusters and over-representation of pathways in the genes defining the classes.

3.5.1 Statistical Significance

In order to estimate statistical significance of a clustering, Monte Carlo methods are suggested to estimate the density distributions of indices under the null hypothesis of random and unstructured data [49, 74]. Bolshakova and coworkers [11] provide a tool to evaluate clusterings and quality indices interactively.

3.5.2 Stability

Lange and coworkers [66] suggest to measure cluster stability computed as follows. The data at hand is split many times into training and test set. For each split, the clustering algorithm is applied to both data sets, yielding labels for all samples. The training sets are then used to train a classifier, the corresponding test sets are used to determine misclassification rates compared to the labels given by the clustering algorithm. Lange and coworkers suggest to use average misclassification rates to measure stability of clusterings, expecting low values for stable clusterings.

3.5.3 **Detect Consensus by Subsampling**

Consensus matrices computed on subsampled data are suggested in Ref. [77] to validate cluster stability. These are computed as follows. N random equal size subsets of samples are generated. For each of them the same clustering algorithm is applied to compute N perturbed partitioning. Each column and each row of a consensus matrix represent one patient, rows and columns are in the same order, such that elements from the same cluster in the partitioning of the complete data are adjacent. The element in row i and column j of the consensus matrix contains the relative frequency that patients i and j fall in the same cluster. For a stable clustering, the consensus matrix holds values close to zero and close to one. In this case, the consensus matrix holds square blocks along the diagonal. Figure 6 shows a consensus matrix from the leukemia data in Ref. [20] with two stable clusters (upper panel) and a consensus matrix computed from the same data, but restricted to only B cell samples, which displays a less apparent structure (lower panel). Monti and coworkers [77] suggest to use average consensus values per cluster to identify stable clusters as clusters with consensus value close to 1. Similarly, they use average consensus values per sample to estimate if it is clearly attributed to its cluster. Consensus clustering revealed three stable clusters in more than 200 diffuse large B cell lymphoma patients [76].

3.5.4 **Adding Simulated Noise**

An alternative to subsampling in order to perturb the clusterings is to add noise from a Gaussian distribution to all expression levels and evaluate the stability of clusters with respect to this noise. This is suggested in Ref. [74].

3.5.5 **Over-represented Pathways**

Evidence for the biological relevance of a molecular patient entity is given when the list of driving genes has a clear biological focus. Therefore, biologists often investigate functional annotations of these genes, e.g. using the GO. Statistically significant over-representation of certain pathways or biological processes in the list of genes that define a molecular partitioning of patients can be used as validation for the partitioning itself. Over-representation analysis is described in Refs. [5, 23, 28]. It is used as argument for cluster validity in Ref. [76].

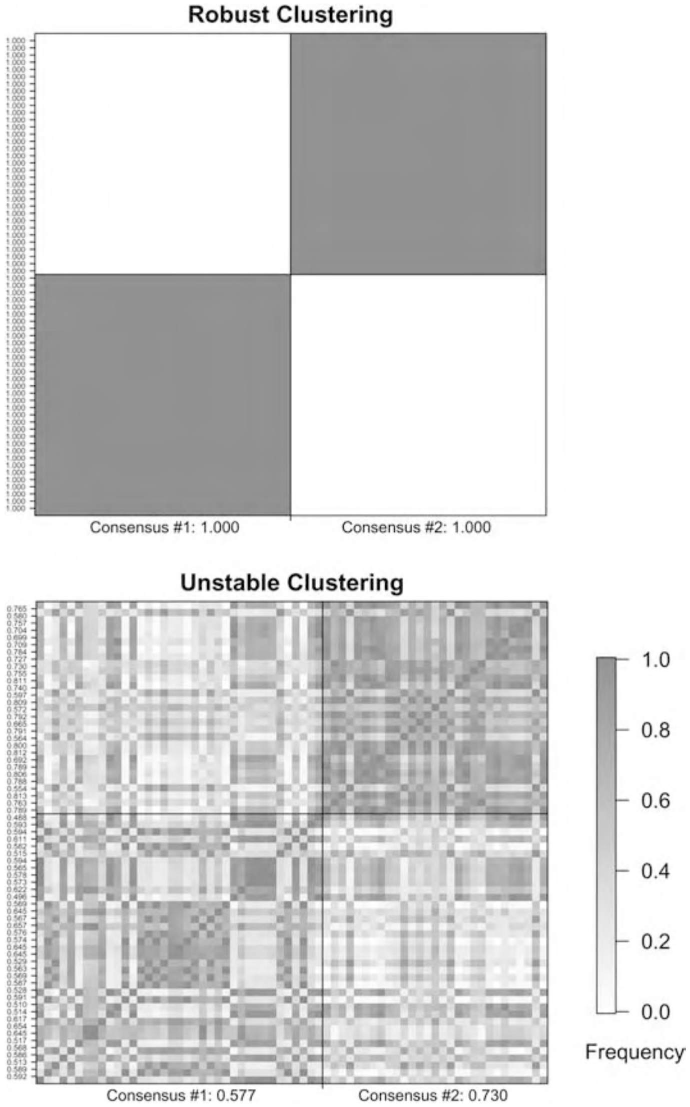

Figure 6 Consensus matrices for subsets of leukemia patients from Ref. [20]. The set of patients used to generate the upper consensus matrix contains T and B cell leukemias. Expression profiles of these differ strongly and yield a clear consensus matrix. To generate the consensus matrix in the lower panel, only B cell leukemias were used and no obvious separation was found.

4 Conclusions

Both computational diagnostics and clinical class discovery using microarray gene expression profiling are established fields in clinical research. Currently, however, the importance of microarray studies is limited to basic research, while there is little impact on therapeutical decision making. Some reasons for this are discussed in Ref. [97].

Important obstacles for large enough and sufficiently focused microarray studies include stringent planning of unified protocols and procedures, acquisition and selection of patient material, appropriate logistics as well as financial support. The need for many patients to conduct a decent clinical study often implies that material from several hospitals must be used. Such complex collaborations, however, enforce meticulous planning to ensure homogeneous procedures as well as efficient logistics to make sure that probes are handled quickly and reliably. Finally, such studies are expensive in labor and material, given that several hundreds of patients are to be enrolled to provide clinically relevant conclusions.

Furthermore, findings based on gene expression profiling need, as any other clinical procedures do, external validation. With increasing commercial interest, however, the technology is likely to find its way into medical routine.

Classification of Genes

Jörg Rahnenführer and Thomas Lengauer

1 Introduction

Microarray experiments provide simultaneous measurements of transcript levels of a large number of genes in a certain tissue and cellular condition. The potential impact of this technology on our health is twofold. It has been demonstrated repeatedly that expression patterns of samples belonging to different patients can be used for classifying these samples into distinguishable groups. This process can generate disease-specific expression profiles that potentially provide improved molecular diagnosis (see Chapter 26 for a detailed description).

The second option is to draw from a set of microarray experiments the expression patterns of single genes across different samples, and analyze and classify the resulting expression level trajectories. The goal then is to elucidate the role of specific genes in the disease process. The two main objectives of this approach are (i) to assign a function to previously unannotated genes and (ii) to group genes into functionally related groups – a concept that generalizes the notion of a molecular pathway or network. Grouping genes is much more difficult than grouping samples since, typically, the number of genes is considerably larger than the number of samples which result from different experiments. In many cases, assigning molecular function to genes just on the basis of expression data is hopeless since learning about the differences between a large number of genes based on very few experiments is an ill-conditioned problem.

In addition, prediction of gene function based on expression profiles is challenging from a biological point of view. The function of a gene is not entirely encoded in expression patterns at the mRNA level, but is also influenced by translation efficiency, post-translational modifications, and other cellular mechanisms. Therefore, sophisticated mathematical models are rarely suitable and typically not worthwhile computing.

Nevertheless, it is accepted that similar expression patterns of two genes across a sizeable number of experiments can be a clue to their functional

Bioinformatics - From Genomes to Therapies Vol. 2. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

relatedness. Increasing the diversity of the set of experiments can enhance the explanatory power of gene comparisons based on coregulation. In early studies, clustering algorithms were used to group genes based on their expression trajectories, following the approach presented in a seminal paper by Eisen and coworkers [19].

Soon the limitations of this approach became evident [32]. Also, the even more challenging goal of inferring genetic networks from expression data alone turned out to be too ambitious [26]. Instead, a more promising idea was increasingly adopted: in order to construct more complex and reliable functional models, gene expression data were supplemented with additional biological information, such as chromosomal location data [55] and shared motifs in the promoters of similarly regulated genes [42,48,67,69,74]. Coexpressed genes that share functional sites in their upstream regulatory regions are expected to be under similar regulatory regimes and thus to share a functional relationship. Subsequently, explicit models of the involved regulators have been developed [57,58] (see also Chapter 21).

Another procedure which is different, in principle, but also effective, is to use the supplementary biological data as a starting point and pursue a more hypothesis-driven approach. Given predefined sets of genes that are already known to share the same functional context, one compares a list of genes identified from a microarray study with these *a priori* groups. As functional gene sets, Gene Ontology (GO) terms [1,4,16,17], metabolic pathways [50,53, 76], and protein interaction data [29,56] have been used, for example. In this setup, single unannotated genes can be tested against the predefined functional groups, transforming the unsupervised into a supervised classification problem.

In general, the difference between unsupervised and supervised learning is that in unsupervised learning there is no *a priori* output available, whereas in supervised learning, training data are labeled with outputs that are supposed to be learned. In Section 2, we give an introduction to gene classification against the background of this important discrimination. In Section 3, unsupervised methods for grouping genes from expression data are discussed in detail. In Section 4, the supervised approach is presented, giving a detailed description of methods for predicting gene function from expression data.

2 Overview of Gene Classification Tasks

From a methodical viewpoint, classifying gene probes can be divided into two major tasks, i.e. class discovery and class prediction. Class discovery makes use of unsupervised learning methods like clustering. Class prediction is applied in a supervised setting, where certain gene groups, whose functional context is known or presumed, are given in advance and single genes have to be classified to one or several of these groups. The knowledge of functional class labels for a considerable number of genes enables the assignment of unknown cDNA sequences to one of the labeled classes. We briefly describe the ideas of both approaches.

2.1 Grouping Genes without Additional Information

To date, the function of the majority of the genes on a microarray with genome-wide measurements is not known yet. Thus, addressing the unsupervised learning problem, in which one lacks gene class labels, will continue to be a relevant task for some time to come. One major objective is to partition a set of genes into new, previously unknown functional classes on the basis of their expression patterns across a number of samples. In this context, it is important to understand and account for the difference between supervised learning and unsupervised learning. If class labels are unknown, it is difficult to ascertain the validity of inferences drawn from the obtained results – a major characteristic of unsupervised learning. Cluster analysis as the most prominent approach in this situation attempts to find regions that contain modes of the underlying data distribution. The aim is to group the genes into subsets such that those within a cluster are more closely related, in some sense derived from the expression patterns, than those belonging to different clusters. When generating the clustering, one has to deliberately make two choices, i.e. which notion of similarity to use when scoring a pair of genes and which clustering algorithm to apply for grouping genes according to this similarity measure.

The analysis of expression data has not reached maturity yet. No commonly accepted stochastic data models for gene expression measurements exist. Therefore, in general, simple interpretable methods are preferred over more complex algorithms. Unsupervised methods can be used for generating new hypotheses from expression data that afterwards can be verified with other methods from molecular biology.

2.2 Functional Predictions

The major principle of unsupervised learning is to first cluster genes into groups and then assume that genes belonging to the same cluster share some biological function, e.g. in a disease process. However, researchers are often explicitly interested in inferring the function of specific unannotated genes. In this case a more promising approach is to incorporate *a priori* knowledge about the function of already annotated genes in the analysis. A disadvantage of this supervised learning approach is that the quality of the annotations is often low, such that class labels referring to biological functions are not always reliable.

The prospects can be improved by integrating other biological data into the models and predictions. Various additional sources of information have been used. The most prominent examples are shared motifs in the promoters of genes, joint membership to a metabolic or regulatory pathway, and known interactions between the corresponding proteins.

The idea to combine different data types was further established in another approach with a different philosophy. Here, a set of genes known to be in a functional context is treated as a unit. By analyzing the expression levels of such a group of genes in concert, statistical models can be introduced. Based on this model, the statistical significance of a gene group is an indication that the function common to the genes plays some role in the underlying experiment, e.g. in the analyzed disease process. Moreover, in a second step the statistical model can be used to quantify the probability of other genes to belong to this gene group.

3 Grouping Genes on the Basis of Expression Data

3.1 Cluster Analysis

Many existing clustering algorithms have been proposed and new methods have been developed specifically for grouping genes based on expression values. For a general introduction to cluster analysis, an established statistical discipline, see Ref. [33]. A recent extensive review on clustering algorithms applied to gene expression data has been presented in Ref. [3]. For grouping genes into classes, one first has to define a measure for the similarity or distance, respectively, of two genes. Then a clustering algorithm has to be chosen. Different combinations of similarity measure and clustering scheme can lead to substantially different results. Thus the analysis has to be performed with care. In the following the basics of the most widely used methods as well as a few clustering algorithms specifically developed for the analysis of expression data are described.

3.1.1 Similarity Measures

In microarray research, the most popular measures for comparing gene expression trajectories are the Pearson correlation coefficient and the Euclidean distance. Given two genes with corresponding expression vectors x and y

over p different samples, the correlation distance is defined as:

$$\mathrm{d}(x,y) = 1 - \rho_{xy} = 1 - \frac{\sum_{i=1}^{p}(x_i - \bar{x})\,(y_i - \bar{y})}{\left(\sum_{i=1}^{p}(x_i - \bar{x})^2\right)^{1/2}\,\left(\sum_{i=1}^{p}(y_i - \bar{y})^2\right)^{1/2}}.$$

Correlation measures the linear dependence between two vectors, here the vector of expression levels for two genes. The measure assigns high similarity values if the two genes exhibit a joint trend across the samples. Thus gene pairs with different means and variances can also receive small distances – an often desired feature in the analysis of gene expression data. Sometimes it is plausible that pairs of genes with opposite trends also belong to the same biological process, e.g. if upregulation of one gene causes the simultaneous downregulation of the other gene. In this case the correlation distance can be modified to $d(x,y) = 1 - |\rho_{xy}|$. In contrast, when using the Euclidean distance:

$$\mathrm{d}(x,y) = \sqrt{\sum_{i=1}^{p}(x_i - y_i)^2},$$

two genes are only close if they have similar values for all samples. Note that after standardizing genes with respect to mean and variance across samples, correlation and Euclidean distance coincide up to a constant factor. It has been demonstrated that the choice of the similarity measure has a substantial influence on the final results [53, 54]. Various measures developed in other research fields could be reasonable alternatives, but have been rarely explored in microarray re search. The Manhattan distance:

$$\mathrm{d}(x,y) = \sum_{i=1}^{p}|x_i - y_i|,$$

for example, is the sum of absolute differences of expression values and can be used as a robust version of the Euclidean distance. This measure is less sensitive to outliers in the data.

3.1.2 Hierarchical Clustering Algorithms

The initial influential paper on analyzing results obtained from expression experiments describes the application of a hierarchical clustering algorithm for grouping genes in the budding yeast *Saccharomyces cerevisiae* [19]. In this paper, for the first time, it was demonstrated that gene clusters obtained from expression data contain genes with known similar function. Hierarchical clustering immediately became popular in the field due to two major advantages. First, the large number of genes can pose a runtime problem to more complicated clustering algorithms. Second, hierarchical clustering provides a convenient visualization – a so-called *dendrogram*.

The basic idea of hierarchical clustering is the generation of a hierarchy of nested clusterings, with the number of clusters ranging from one to the number of genes. Both agglomerative and divisive hierarchical clustering exist. In divisive clustering, iteratively best possible ways of splitting a cluster into two clusters are calculated. In the more popular agglomerative clustering, initially, each gene is assigned to its own cluster. Then, iteratively the two most similar clusters are joined until only a single cluster remains. Two clusters that are joined represent a new node of the dendrogram, and new dissimilarities between this node and the remaining clusters are calculated. In average linkage hierarchical clustering, the distance between two clusters is defined as the average distance between genes in the two clusters; in single linkage, as the smallest pairwise distance; in complete linkage, as the largest pairwise distance.

The dendrogram is an intuitive visualization of the hierarchical clustering process. It depicts the level of similarity at which two clusters are merged. A line connects clusters when they are joined. The height of this line denotes the distance between the clusters. Typically, the cluster with smaller variation, e.g. measured by within-cluster variance, is plotted on the left side, but other procedures exist (see Section 4.5 in Ref. [62]).

Figure 1 shows a dendrogram calculated from gene expression measurements for patients with acute lymphoblastic leukemia (ALL) [11]. For the 20 genes with largest variance across samples and for replicates of these genes on the array, the plot shows the result of average linkage hierarchical clustering using Euclidean distance.

It turns out that even replicates of the same gene are not always put in the same cluster, e.g. the three copies of the gene *HLA-DQB1*. The third (rightmost) replicate is joined with the other two replicates only in a late step of the (agglomerative) algorithm, although a calculation shows that its closest gene with respect to Euclidean distance actually is one of the other two copies. The reason for this discrepancy is the local iterative nature of the algorithm that can lead to low-quality clustering results on a global level.

In the list of genes arranged corresponding to the order in the dendrogram, the three replicates of *HLA-DQB1* are neighbors, which can be misleading as the three genes do not belong to the same cluster. This underlines the need for a careful interpretation and evaluation of the results. An important disadvantage of hierarchical clustering is the information loss due to the enforcement of a tree structure. However, despite all these pitfalls, due to the large number of genes, subgroups of genes with a high degree of coregulation often exist. Hierarchical clustering can be particularly useful for identifying such compact subgroups.

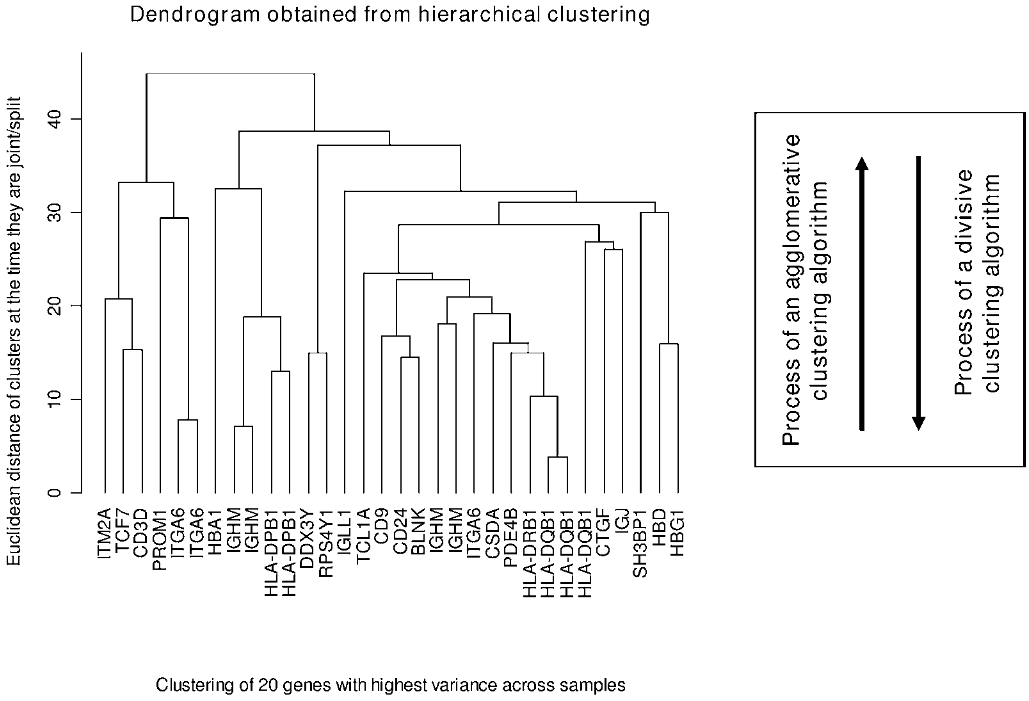

Figure 1 Average linkage hierarchical clustering of 20 high-variance genes and their replicates using Euclidean distance. Gene expression measurements are obtained from 128 patients with ALL [11].

Figure 2 shows a heatmap of the above analyzed ALL data set. A heatmap is a popular visualization for microarray data, providing a false color image of the expression values with a dendrogram added to the left side and to the top. Typically, rows correspond to genes and columns to samples.

3.1.3 **Partitioning Clustering Algorithms**

Partitioning algorithms seek to minimize the within-group dissimilarity and/or to maximize the between-group dissimilarity for a fixed number k of clusters. Often small heterogeneity within clusters is associated implicitly with a clear separation between clusters. In contrast to hierarchical clustering, the resulting clusters for different numbers of k are typically not nested.

The most popular and widely used partitioning method is k-means. This algorithm aims at minimizing the sum of within-cluster variances:

$$WSS = \sum_{i=1}^{n} \min_{j=1\ldots k} d(x_i, m_k). \tag{1}$$

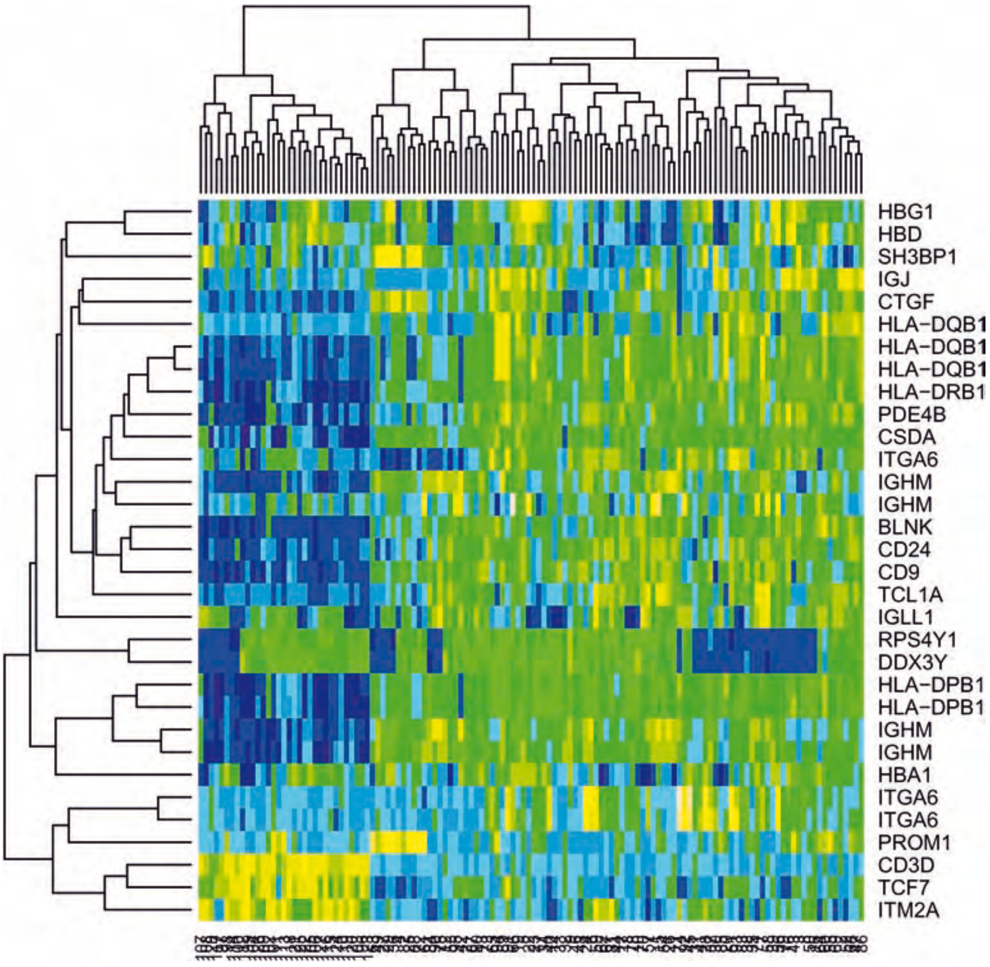

Figure 2 Heatmap for gene expression measurements from 128 patients with ALL [11].

Here, the first sum is taken over all genes, $m_1, \ldots, m_k$ are k cluster midpoints and $d(\cdot, \cdot)$ is the squared Euclidean distance. k-means starts with a random sample of k different objects as initial midpoints. Then it alternates between assigning all objects to the closest of the k midpoints with respect to Euclidean distance and calculating k new midpoints as averages of the newly assigned clusters. The midpoints are also called centroids. It is guaranteed that the algorithm converges to a local optimum. Since different starting solutions lead to different final solutions, it is advisable to run the algorithm several times and to memorize the result with minimal sum of within-cluster variances.

Several clustering algorithms can be regarded as generalizations or modifications of *k*-means. For gene expression data, especially Partitioning Around Medoids (PAM [34]) and self organizing maps (SOMs [37,64]) have been used.

PAM [34] has the advantage that it allows for an arbitrary dissimilarity matrix as input and thus is not restricted to Euclidean distance. Another important difference to *k*-means is that data points themselves serve as so-called cluster prototypes. Given pairwise dissimilarities, PAM also aims at minimizing an objective function, i.e. the sum (over all genes) of distances to the closest of *k* prototypes, see Eq. (1). In the BUILD phase, initial prototypes are chosen. Then, in the SWAP phase, iteratively the objective function is locally optimized by replacing one of the prototypes with another data point such that the objective function is decreased most. The usefulness for clustering microarray data is due to the combination of the optimization principle of *k*-means and the flexibility of hierarchical clustering algorithms regarding the choice of the gene similarity measure. A disadvantage compared to k-means can be the increased running time.

In a SOM [37] data are represented by *k* cluster prototypes that are subject to some topological restriction. The prototypes are arranged in a low-dimensional structure, typically a one- or two-dimensional array, such that every prototype has a set of neighbors. Again, a random starting solution is improved iteratively. Per iteration, one data point is picked at random and all prototypes are moved into the direction of this data point. The amount of change depends on the initial neighborhood structure of the prototypes. The prototype that is closest to the selected data point is the winner and is moved by the largest distance. The further a prototype is from the winner in the neighborhood topology, the smaller is its movement. The amount of change decreases with the number of iteration steps.

SOMs were successfully applied to group genes into biologically relevant clusters suggesting novel hypotheses about hematopoietic differentiation [64]. They are especially appealing for analyzing gene expression data since the topological structure between the prototypes provides information about relationships between neighboring clusters. On the other hand, an interpretation based on the assumption of a meaningful topology between cluster prototypes can easily be misleading. Another disadvantage of SOMs is the large number of parameters characteristic for neural networks, such that sensible parameter tuning requires some previous experience.

3.1.4 **Model-based Clustering**

Model-based clustering is based on probability models. It is assumed that the data are generated by a mixture of distributions. The most popular model is a Gaussian mixture model, in which the underlying distributions are multivariate normal distributions. The task of selecting a clustering algorithm is then reduced to fitting parameters or, more general, to a model selection problem. For the Gaussian mixture model, an Expectation-Maximization (EM) algorithm is used to estimate the means and the covariance matrices of the distributions that represent the clusters. The classical EM algorithm for learning Gaussian mixture models can be regarded as a soft version of *k*-means [24]. *k*-means assigns each sample to exactly one of the *k* clusters, whereas in the EM algorithm samples can be assigned to more than one model component. The probability of a sample to belong to a specific component is called responsibility – for a given sample all responsibilities thus add up to one. Both on real and on simulated gene expression data, model-based clustering was compared with competing clustering approaches [71]. The algorithm based on the mixture model turned out to have superior performance on selected synthetic data sets and to be competitive on real gene expression data.

The assumption that cluster analysis applied to gene expression data produces biologically related gene groups was tested in a comparative study using various clustering algorithms and gene expression data sets of different sizes [73]. The quality was measured by the fraction of gene pairs from the same clusters that share at least one known common transcription factor, making use of various transcription factor databases. On yeast data it was shown that at least 50–100 experiments are needed for identifying coregulated genes and even then gene pairs that do not share a common transcription factor are often more likely to be clustered together than coregulated genes. In this study the model-based clustering algorithm outperformed the other algorithms in terms of assigning coregulated genes to the same clusters.

In the presence of experimental replicates of genes on a microarray, the probabilistic framework of mixture models can be used for modeling between-replicates variability [44]. It was shown that for the identification of coexpressed genes improvements in precision can be achieved with as few as two replicates when the between-replicates variability is high.

3.1.5 **Biclustering Algorithms**

It is often a reasonable assumption that functionally related genes are not coexpressed in all samples of a study, but only in a subset of the analyzed samples. *Vice versa*, it is not advisable either to consider all genes when discriminating samples via expression measurements (see Chapter 26). This insight stimulated the development of so-called two-way clustering algorithms, sometimes also called *biclustering* algorithms, referring to the simultaneous clustering of genes and selection of samples. For a recent overview over biclustering algorithms see [47]. The first algorithm developed for gene expression data based on this principle was an efficient node-deletion algorithm for finding submatrices in the gene expression data with low mean-squared residue scores [10]. Another advantage of this method is that genes can belong to several clusters and thus represent multiple functions.

Progressing along this road, a graph-theoretic algorithm coupled with statistical modeling was introduced [65]. Here, both genes and samples are represented as nodes of a bipartite graph. This means that every gene is connected with every sample. Gene–sample pairs are associated with weights depending on the expression level of the respective gene in the respective sample. The algorithm determines the heaviest induced subgraph (measured in terms of the sum of edge weights) in polynomial time. It was shown that within the presented probabilistic framework it is guaranteed that the most significant biclusters are found. Moreover, using cross-validation techniques (see Chapter 26) it was demonstrated that in comparison to classical one-way clustering methods, specificity is increased when assigning gene function based on expression data.

A statistical framework for the simultaneous clustering of genes and samples was proposed [52] in which classical properties of clustering methods, such as consistency, can be analyzed. For a two-way clustering algorithm, a so-called simultaneous clustering parameter is defined. For example, this parameter can be the set of all cluster labels for genes and samples, respectively, that are obtained by a biclustering algorithm. The parameter can therefore be defined as a function of the true data generating distribution. An estimate for the parameter is obtained by applying the same function to the empirical distribution function, i.e. to the data set under investigation. Methods for estimating the distribution of the simultaneous clustering parameter are introduced. It is shown that a large number of clustering algorithms including hierarchical clustering fit this framework.

3.2 Heuristic Gene Grouping of Expression Data

The number of clustering algorithms that were developed in a variety of research areas is enormous. Still the specific structure of microarray data provoked the development of yet additional algorithms. Since the identification of gene groups with similar expression patterns in a typically small number of samples is of particular interest, a central idea is to only search for gene groups with notably low heterogeneity.

3.2.1 **CLICK Algorithm**

The CLICK algorithm (CLuster Identification via Connectivity Kernels) [59] combines probabilistic and graph-theoretic aspects. The goal is to identify groups of genes that have a high likelihood to belong to the same cluster. The input of the algorithm consists of pairwise similarities of genes. The data are represented as a graph where genes are vertices and edge weights are derived from the gene similarities. The CLICK algorithm consists of two steps. First, initial groups of genes with large pairwise similarities are identified. The algorithm recursively splits subgraphs until a stopping criterion regarding minimal gene similarity is reached or the subgraph is a singleton. In the second step, the identified gene groups are expanded to final clusters. The output comprises potential clusters with high gene similarity as well as singletons.

In a comparative study the CLICK algorithm outperformed *k*-means, hierarchical clustering and SOMs on a variety of gene expression data sets with respect to several cluster validity measures. Furthermore, it was shown that common regulatory motifs occurring in the upstream regions of coregulated genes could be identified for the resulting clusters. The suitability of the CLICK algorithm is due to its stringent criterion of within-cluster similarity, which is shown to be crucial for the relevance of inferred gene function.

3.2.2 **CAST**

CAST (Cluster Affinity Search Technique) [5] is targeted to the use on large data sets and, therefore, is also suitable for clustering gene expression data. The input of CAST consists of a gene similarity matrix and a threshold parameter. The clusters are generated iteratively. Genes are added to a cluster as long as the average similarity in the cluster exceeds the predefined threshold. If no more genes fulfill this criterion, a new cluster is opened. Afterwards, genes can still be added or re moved from clusters in order to further increase the average similarity. The algorithm is similar to hierarchical clustering in spirit, resulting in a short runtime, but the reassignment step provides additional flexibility.

3.2.3 **Gene shaving**

In a similar sense, *gene shaving* [25] aims at the identification of several small and possibly overlapping groups of genes with small between-gene variance and large between-sample variance. Principal components are orthogonal directions calculated from a data set. The first principal component is the direction in which the data have their highest variance, the second principal component indicates highest variance among all directions orthogonal to the first component and so on. In gene shaving, iteratively, clusters are generated using principal components and discarding a fraction of genes whose expression vectors have low similarity with the principal component. Both an unsupervised and a supervised version of gene shaving exist. In the supervised version, known properties of the genes are included in the process.

4 Predicting Gene Function from Expression Data

In order to produce high-quality functional predictions for genes from expression data, at least two types of information are required. First, a vocabulary of functional attributes is needed. There have been several efforts to provide meaningful directories, the most popular currently being the Gene Ontology (GO) [2] (see Chapter 29 for a detailed description). GO is a controlled vocabulary that provides structured networks of defined terms for describing attributes of gene products. Second, given such a vocabulary, one needs a considerable number of genes with annotations from that vocabulary. If both requirements are met, the supervised learning problem of assigning function to unannotated genes can be tackled by a multitude of statistical and algorithmic classification methods. If the expression pattern of a specific gene is similar to the patterns of a group of genes that are annotated with the same function, one can expect the gene to be associated with this function, as well. Another extensive source for annotations is MIPS [45] – a collection of automatically generated and manually annotated genome-specific databases and systematic classification schemes for the functional annotation of protein sequences.

The difficulties in predicting gene function from expression data have been pointed out repeatedly [35, 70]. One problem is the influence of events that happen after transcription, e.g. post-translational modifications. However, additional annotation information can help to improve the reliability of predictions. By combining the results of clustering algorithms applied to yeast genes with predefined functional annotations, useful hypotheses about protein function could be generated [70]. A variety of clustering algorithms with different parameter settings were compared regarding their ability to group coexpressed genes. Among others, hierarchical clustering, *k*-means and SOMs were applied, resulting in a large number of possibly overlapping clusters. Then, annotations and confidence values were assigned to each cluster using the hypergeometric distribution. Clusters with significant confidence values are expected to be biologically relevant. Using this procedure, potential new members of many existing functional categories involved in transcription, processing and transport of noncoding RNA molecules were found.

Even in the metabolic networks of well-studied organisms, for some reactions the corresponding enzymes have not been identified yet. In an effort to identify genes encoding such enzymes, coexpression of genes representing enzymes in close topological neighborhood within the metabolic network was used to generate predictions from expression data [35]. The method was tested by predicting metabolic enzyme-encoding genes in *S. cerevisiae* for known cases. The limitations of the approach became manifest by the negligible number of correct predictions. Only 20% of all known genes scored within the top 50 out of 5594 candidates for their respective enzymatic function. However, this number increased to 70% for those genes whose expression level had been significantly perturbed across samples. This underlines the need for considerable variation between samples.

4.1 Classification methods

For the supervised classification problem of assigning gene function in the presence of functional labels for a large training set of genes, many statistical and data-mining techniques are available. We present prototypic cases in which genes with common function could be identified.

4.1.1 Support Vector Machines (SVMs)

SVMs provide a supervised learning method that has been applied successfully to both classification and regression problems in many research areas. The basic classification SVM creates a maximum-margin hyperplane that lies in a transformed input space. Given training data points with binary labels, the maximum-margin hyperplane splits the positive and negative training points, such that the margin, i.e. the distance of the closest data point to the hyperplane, is maximized (see Chapter 26 for a more detailed introduction to SVMs).

SVMs have achieved high prediction accuracy in classifying samples based on expression data, partly due to their effective dimensionality reduction. When classifying genes, the small number of samples is typically a handicap. However, other classification methods also suffer from this dimensionality problem. The first study on gene classification that compared SVMs with other supervised learning methods, including decision trees, Parzen windows and Fisher’s linear discriminant analysis [9], was based on gene expression data from 79 samples and 2467 yeast genes with MIPS [45] annotations. Several SVMs using different similarity metrics were tested. In the study it was demonstrated that SVMs outperform the competitors with respect to correctly classifying genes to gene sets with common annotated function.

4.1.2 Rule-based Models

In order to increase interpretability, predictive rule models have been introduced for the functional classification of genes [27, 28]. The trained model defines relationships between gene expression profiles and the involvement of genes in biological processes. For example, if–then rules are used to define minimal expression profile properties needed to classify a gene to a specific biological process. The approach is supervised since functional classes of unclassified genes are learned using GO [2] annotations of classified genes.

First, biologically meaningful features are extracted from the expression data, e.g. expression increase or decrease over time in a time series experiment. Then, a rule model described in terms of these features is induced from the expression data. Before classifying unknown genes, the model is fine-turned using cross-validation on subsets of classified genes. On human fibroblast serum response expression data [32], both the predictive quality of the model and the interpretability of the extracted rules have been demonstrated.

This method provided high-precision GO biological process classifications for 211 of the 213 uncharacterized genes in the data set [38]. An advantage of the model is its capability of assigning genes to multiple biological processes. The model is flexible as it allows genes in the same functional class to exhibit a variety of expression profiles including inverse coregulation. Also, for characterized genes, new roles in biological processes were hypothesized by the algorithm and confirmed by literature search. For many previously uncharacterized genes the predicted biological processes were in agreement with homology information.

Another data-mining algorithm for predicting gene function from expression data is based on PolyFARM (Poly-machine First-order Association Rule Mining) – a program that finds first-order associations [12]. For the 40% of uncharacterized genes in the yeast *S. cerevisiae*, MIPS [45] annotations have been predicted. Again, an advantage is the informativeness of the induced rules. For many cases, agreement with biological knowledge can be observed.

4.2 Supplementing Expression Data with Additional Biological Information

In all classification methods described above the same principle is used to incorporate *a priori* biological knowledge in gene function prediction. A set of functional classes containing characterized genes is used to predict the membership of uncharacterized genes. In this sense additional biological knowledge enters only into the classification algorithm, but the unannotated genes are not augmented with other biological data. In Chapter 35, information integration for protein function prediction is described in more detail. Here, we focus on methods in which gene expression data play an important role.

One has to deliberately differentiate between two ideas for more efficiently supplementing expression data with additional biological information. In a more comprehensive classification approach, uncharacterized genes are not only associated with labeled genes, but also with other data like sequence or pathway information. The second idea is different in philosophy. The goal is to relate biological terms or functions to the underlying microarray experiments instead of characterizing single genes. For groups of genes that are associated with the same function a joint score is calculated from the expression data. If this score is significant in a statistical sense, the biological function is assumed to be relevant for the underlying experiment. In this way more subtle signals can be detected by combining small coordinated expression changes on the single-gene level to a significant change on the gene-set level.

Both ideas are different from the aim of inferring gene function by elucidating new pathways or parts thereof directly from expression data [15, 23, 29, 51, 66] (see also Chapter 21 on inferring gene regulation networks). Prominent examples are reverse engineering of genetic networks using discrete Boolean networks [15], Bayesian networks [23, 51], a model of a cellular pathway using expression data, quantitative proteomics, databases of known physical interactions [29], and a framework supporting the incorporation of biologically motivated network constraints and rules [66]. Due to the dimensionality problem with many genes and few experiments, the network reconstruction from expression data is almost infeasible [26]. In simulation experiments with dynamic Bayesian networks only local structures of the network could be recovered, but the inferred global network was meaningless. The number of spurious interactions substantially outweighed the number of true interactions.

An extension is an algorithm that identifies modules of coregulated genes, their regulators and the conditions under which regulation occurs, generating testable hypotheses [57, 58]. Also, systematic transcriptional perturbations can be used to construct better models of regulatory interactions in small networks with just few genes. The major regulatory genes in a nine-gene subnetwork of the SOS pathway in *Escherichia coli* were correctly identified with this approach [21].

A general framework for integrating external data sources with expression data is the Signature Algorithm [30, 31]. This approach can be viewed as a biclustering algorithm that is enhanced by additional biological knowledge. The standard algorithm [30] requires as input a set of genes that are expected to be coregulated in a set of experimental conditions, e.g. due to common functional annotation. First, the conditions that induce the highest average expression changes in the input group of genes are selected. Then, all genes highly expressed in these conditions are identified. The output set of genes contains a coregulated subset of the input genes, as well as correponding experimental conditions and additional genes with consistent profiles. The Iterative Signature Algorithm [31] is an extension that does not require a biologically motivated gene set. The two steps of the basic algorithm are applied iteratively until convergence. This procedure yields a self-consistent module, i.e. the resulting genes are most coherently coexpressed over the resulting conditions and the resulting conditions induce the most coherent expression of the resulting genes.

4.2.1 **Adding Sequence Data**

The most important and well-studied source for understanding gene function is sequence data. Combining chromosomal location and gene expression data, binding of gene-specific transcription activators in yeast was monitored [55]. Here, genes were identified whose expression is directly controlled by the transcription factors Gal4 and Ste12, as cells respond to changes in carbon source and mating pheromone. The identified pathways were jointly regulated by each of the two activators, and previously unknown functions for Gal4 and Ste12 were revealed. Using SVMs, gene expression profiles and phylogenetic whole-genome sequence comparisons were combined in an algorithm for function prediction [50] (see Chapter 35 for details).

Another relevant source is provided by the promoters of the investigated genes. Many studies have been dedicated to the goal of finding putative transcription factor binding sites in the upstream sequences of similarly expressed genes [48]. Correlations between known binding site motifs in the upstream regions of all genes in *S. cerevisiae* and gene expression changes in various gene-disruption experiments were uncovered. Several of these correlations turned out to be consistent with existing biological knowledge. Even without significant sequence similarity of the involved genes, on the basis of their common promoter structures gene expression data are capable of elucidating functional features of genes [69].

An ambitious task is to identify transcriptional modules, sets of genes that are coregulated in a set of experiments, through a common motif profile [58]. The motif profile specifies the relevance of different sequence motifs to the module. After an initial gene-clustering step, a sophisticated application of an EM algorithm was used to iteratively refine both the assignment of genes to the modules and the motif profile itself, in order to best explain the expression data as a function of transcriptional motifs. An evaluation of this method on two *S. cerevisiae* expression data sets demonstrated the ability to recover known motifs and to generate biologically coherent modules.

4.2.2 **Adding Gene Ontology Data**

GO [2] provides a vocabulary of gene product attributes, together with annotations of a large number of genes to these attributes. For every annotation of a gene product with a GO term, the source of this annotation and an evidence code are provided. The source may be a literature reference, another database or a computational analysis. The evidence is a categorical variable that indicates what kind of evidence is found in the cited source to support the corresponding annotation. However, for a specific gene and attribute, the crucial information is whether the gene is associated with this attribute. This information is binary and no quantitative values can be obtained. Thus, the kind of data provided by GO annotations is particularly suitable for the hypotheses-based approach in which functional gene sets are analyzed as a unity.

The approach applied most frequently in this field uses enrichment methods. In this approach the enrichment of members of a functional gene set among the top-ranking genes in a gene expression study is evaluated. Onto-Express [17] constructs functional profiles based on GO terms for the following categories: biochemical function, biological process, cellular role, cellular component, molecular function, and chromosome location. The starting point is a list of differentially expressed genes in a cellular condition under study. For a given set of functionally related genes, the significance of the number of genes contained in this list is calculated using the hypergeometric distribution or χ^2-type tests. Similar implementations of the same idea include FatiGO [1], GOstat [4], GoMiner [75] and a set of Perl modules called GO-TermFinder [6]; for an overview of current tools, see Ref. [36]. Most of these methods use Fisher's exact test for the significance calculation. We briefly describe the underlying probabilistic framework.

The statistical principle common to all scoring methods is based on the analysis of a 2×2 contingency table. Let $sigGenes$ be the set of genes identified in a microarray experiment, e.g. differentially expressed genes, and let $\overline{sigGenes}$ be all other genes on the microarray. Let $funcGenes$ be a set of genes G with a known common function and $\overline{funcGenes}$ the complement with respect to the set of all genes, denoted by $allGenes$. Table 1 counts numbers of genes according to their membership to $sigGenes$ and to $funcGenes$.

Table 1 Contingency table of genes grouped according to significance in an expression study and to membership to a functional group G.

	Significant genes	Not significant genes	Sum
Genes in G	$\lvert sigGenes \cap funcGenes\rvert$	$\lvert\overline{sigGenes} \cap funcGenes\rvert$	$\lvert funcGenes\rvert$
Genes in $\overline{G}$	$\lvert sigGenes \cap \overline{funcGenes}\rvert$	$\lvert\overline{sigGenes} \cap \overline{funcGenes}\rvert$	$\lvert\overline{funcGenes}\rvert$
Sum	$\lvert sigGenes\rvert$	$\lvert\overline{sigGenes}\rvert$	$\lvert allGenes\rvert$

Assume that a particular gene is known to have the function attributed to the gene group G. Such a gene is a member of $funcGenes$. The question then is if this gene has an increased likelihood of being a significant gene, e.g. with respect to differential expression. The significance of the dependence between the groups $funcGenes$ and $sigGenes$ can be quantified using Fisher's exact test. This test computes a p-value based on the contingency table shown in Table 1. The p-value denotes the probability of obtaining by chance at least the same amount of enrichment with significant genes as observed in the data. Lower p-values thus indicate stronger dependencies. Other tests based on the contingency table have been proposed [16]. After calculating the percentages of significant genes in *allGenes* and in *G*, respectively, *z*-scores are used to determine the significance of enrichment. From a statistical viewpoint, all these tests implicitly use random gene label assignments as the null hypothesis.

An extension of this idea is the iterative Group Analysis (iGA) that also scores functional groups like GO classes [8]. First, an ordered list of genes is obtained from the expression data. In contrast to the methods described above, no fixed cutoff in this list is predetermined for dividing the genes into interesting and uninteresting ones. Instead the algorithm moves along the list, taking into account all possible cutoffs, and calculates a *p*-value of enrichment for every cutoff. Then, the cutoff that yields the minimal *p*-value is determined and assigned to the GO group. Due to the adaptive selection of the cutoff, the minimal *p*-value itself is not valid in a statistical sense. Thus, the significance of enrichment is determined by comparing the observed minimal *p*-value with values obtained by applying the same algorithm to random gene groups *G*. The method has been extended to a graph-based group analysis [7]. For functional evidence represented in the form of graphs, e.g. metabolic or signaling pathways, subgraphs showing the most significant patterns of gene expression are identified.

The same cutoff optimization principle has been used to test a gene set for association with disease phenotype [46]. All genes are ranked according to gene expression differences in the phenotypes. The optimal cutoff in this list with respect to gene enrichment of a functional group *G* is obtained by maximizing a Kolmogorov–Smirnov running sum statistic. The significance is determined by permuting the labels for the diagnostic assignments.

GO provides a graph structure containing parent–child relationships between functional classes. If a specific functional attribute is a generalization of another attribute, then the genes in the more specific GO class form a subset of the genes in the other GO class. Efforts have been made to also integrate the topology of the GO graph into the significance calculation [41]. A graph-theoretic algorithm extracts common biological attributes of a set of interesting genes *G* in order to find the representative biological meanings. The biological significance of the group *G* then is assessed by defining a distance function on the GO graph. If the biological attributes associated with the genes in *G* are closer in GO distance, the biological interpretation is more reliable.

4.2.3 Integrating Pathway Information

Metabolic pathways are sequences of metabolic reactions that are represented by enzymes. In an initial attempt to score genes with respect to metabolic pathways based on expression data, the glycolysis pathway was analyzed

[76]. It turned out that it is not possible, in general, to assign single genes to this pathway using only gene expression measurements. However, scoring the set of genes associated to the pathway as a whole, in order to relate the pathway to the underlying microarray experiment, turned out to be a promising alternative. Using time series data, the average correlation between pairs of genes associated to the glycolysis pathway was shown to be significantly large. This approach was extended by developing scoring functions based both on coexpression and on estimated functional distance [22, 61].

In a general context, three different scores for the significance of gene groups defined by existing annotation schemes have been introduced [49]. The first score is based on the average correlation of the expression profiles in the gene group, as in previous work [76]. The second score exploits the learnability of a given classification of samples, i.e. the ability to discriminate given classes of samples using only members of the gene group. The third score compares single-gene t-test type of scores between gene class members and randomly selected genes. The latter method thus can be interpreted as an enrichment method. All methods were particularly applied to score metabolic pathways (see Chapter 35 for more details).

A sound statistical framework for calculating the significance of coregulation of genes has been presented in Ref. [53]. The ScorePAGE algorithm scores changes in pathway activity from gene expression data with a nonparametric permutation test. The algorithm was validated on two yeast gene expression data sets with time series measurements. It was shown that the specific measure for calculating coregulation, e.g. correlation or covariance, drastically influences the significance value. However, it is possible to adaptively identify a suitable measure. In addition, two extensions targeted to metabolic pathways were presented. To overcome the ambiguity of enzyme-to-gene mappings for a fixed pathway, different algorithms to select the best-fitting gene for a specific enzyme in a specific condition were introduced. It was shown that these algorithms improve the coherence of gene clusters predefined by metabolic pathways. Including information about pathway topology in the significance score further improved the sensitivity of the method. A comparison with the classical enrichment approach showed that ScorePAGE detects more relevant pathways.

4.2.4 Combination of Multiple Data Types

When combining expression data with other biological data it is reasonable not to restrict oneself to one additional data source. The main challenge for methods that use multiple sources is to combine the information from different data types in a balanced manner. In the following we describe methods that include expression data in such an analysis. A more comprehensive and detailed description of this kind of data integration is presented in Chapter 35.

In an initial attempt proteins were grouped by correlated expression patterns, correlated evolution based on phylogenetic profiles and patterns of domain fusion in order to determine functional relationships in *S. cerevisiae* [43]. For more than half of the 2557 (at that time) uncharacterized yeast proteins, a function could be assigned through a link with a characterized protein. This work represented initial evidence that general biochemical functions of proteins can be inferred by associating proteins on the basis of properties other than sequence homology.

It has been discussed how diverse large-scale data sets can be integrated to generate complex probabilistic gene networks, with a focus on exploring how these gene networks can contribute to an understanding of developmental pathways [20]. A master network was described as the total set of possible pairwise interactions between proteins encoded in a genome. Subsets of the master network are, for example, physical interaction networks of different cell types. Only a small subset of the interactions of the master network is present in any cell or tissue at any time. Thus, the idea is to first analyze the subnetworks that are important at different stages in development and to deal with the master network only at a later stage.

Another example for merging several data sources is the generation of a map of the transcriptional regulatory network in *S. cerevisiae* [74]. The presented map comprised 7419 interactions that connect 180 transcription factors with their target genes. Networks from transcription factor-binding experiments were correlated with findings from expression data. It turned out that the degree of coexpression between genes targeted by the same transcription factors increases with the number of transcription factors. Moreover, genes targeted by the same transcription factor often have similar cellular functions. A plausible insight was that, in general, correlation is not the best measure for coexpression between a transcription factor and its target, since the regulatory response of the target gene is typically delayed.

The most advanced regulatory network model generated from expression data identifies modules of coregulated genes, their regulators and the conditions under which regulation occurs [57]. The method fits in a probabilistic framework. With an EM algorithm genes are iteratively assigned to modules and the regulation model is updated for the sets of genes assigned to the modules. The result of the EM algorithm consists of testable hypotheses on which regulators regulate which models under which conditions. Functionally coherent modules and their correct regulators were identified on yeast data. The same idea was applied to identifying modules from expression data and protein interaction data [56]. Here, a module is a pathway with the two properties that genes are coregulated and the respective protein products interact. Again, using an EM algorithm, both coherent functional groups and entire protein complexes were discovered. For an overview of the combination of expression data with protein interaction data, see also Chapter 31.

The most comprehensive approach that combined multiple data types for predicting yeast protein functional classifications was based on SVMs [39, 40] (see also Chapter 35). For each data type separately, a similarity function between pairs of genes is defined. An advantage of the SVM framework is that single similarities can be combined to one function in a straightforward way. The optimal combination minimizing a statistical loss function can be computed efficiently. The method was applied to yeast genome-wide measurements of amino acid sequences, hydropathy profiles, expression data and known protein–protein interactions. In particular, the new method outperformed any of the SVMs trained on one of the single data types, which provides evidence that combining multiple data sources enhances gene function prediction.

5 Evaluation

The result of a method that classifies genes based on expression data is either a set of gene groups or a list of annotations of single genes to such groups. In both cases the results must be evaluated carefully due to inherent biological noise in expression measurements. Every algorithmic or statistical estimation process that does not account for the dependence of the estimating procedure on the data introduces too much optimism in the estimated model [24]. This effect is also called *overfitting*. Overfitting is a statistical property of estimation methods that is independent of the underlying biological truth.

In general, two kinds of evaluation procedures are available. First, other biological data or further biological experiments can be used to verify the results. However, the use of *a priori* biological knowledge for the evaluation also has disadvantages. In particular, the additional information could help in the estimation process itself (see Section 4.2 about supplementing expression data with other biological knowledge). On the other hand, the alternative approach to carry out additional experiments after the estimation process can be costly and time consuming.

The second option for the evaluation is to account for the optimism in the estimation with the help of statistical methods (see Chapter 26 for details). The most frequently applied method for eliminating optimism is cross-validation. In cross-validation, a data set is randomly partitioned into several subsets. Each of the subsets is used in turn as a test set, while the remaining subsets are aggregated and used for the estimation process. On the test set, the quality of the method can then be evaluated. An alternative is to correct for optimism by applying model selection criteria. Here, a penalty for model complexity punishes models with large parameter spaces. Due to their flexibility, more complex models would otherwise suffer from overfitting.

5.1 Assessing the Biological Relevance of Gene Groups

The biological relevance of gene groups obtained from clustering algorithms has to be checked carefully. Any clustering procedure imposes some structure on the data and groups objects into clusters, no matter whether such a structure is available in the data or not. Even if the clustering algorithm maximizes an objective function, the significance of the resulting value is *a priori* not clear. In general, one can analyze the relevance of gene groups by comparing the results with those obtained in a controlled scenario, e.g. by applying the method to data sets generated from models without the imposed structure.

5.1.1 **Validation of Clustering Results**

For validating the results obtained from clustering algorithms, one can follow three directions, using either external, internal or relative criteria. External cluster indices provide measures for the comparison with an independently drawn structure, for example based on other biological data. If such independent class labels are available, the number of misclassifications of a clustering algorithm, for example, can be computed by minimizing the number of different assignments to classes and clusters, respectively, when considering all possible matchings of class labels with cluster labels. Internal criteria assess the quality of a clustering algorithm based on the clustering itself. An example for an internal cluster index is the value of an objective function that is maximized by a clustering algorithm, like the sum of within-cluster variances (Eq. 1) for *k*-means. Relative criteria compare the clustering result with clusterings from the application of the same algorithm, but with different parameter values, or with clusterings obtained with other algorithms.

For hierarchical clustering, the coherence of the clustering result can be measured via the cophenetic distance. The *cophenetic distance* is induced by the dendrogram and assigns to a pair of genes the distance at which the respective clusters containing the two genes are merged for the first time. For validation, the cophenetic distance matrix is compared to the original distance matrix that was the basis of the hierarchical clustering. If both distance matrices are similar, the clustering captures the true structure of the data.

The importance of a careful evaluation can be discussed in the context of cell cycle genes identified by clustering expression measurements in *S. cerevisiae*. In the original publication, periodicity and correlation algorithms were applied to identify 800 genes that meet an objective minimum criterion for cell cycle regulation [63]. The gene clusters were validated by analyzing genes for known and new promoter elements that turned out to contain information predictive of cell cycle regulation. Subsequently, explicit criteria for synchronization and precise criteria for identifying gene expression patterns during the cell cycle were proposed [13]. Problems both in synchronization and statistical methodology were pointed out, causing doubt about the validity of the previous results. For identifying the correct set of periodically expressed genes, a thorough benchmark of identification methods has been provided [14], revealing that most new advanced methods perform worse than the original approach. A simple permutation-based method is proposed that performs better than most existing methods.

An initial validation algorithm for assessing the quality of clustering algorithms applied to expression data was based on cross-validation [72]. In a leave-one-out scenario the clustering algorithm is applied to the expression data with one sample left out. The predictive power of the resulting clusters is then assessed on the left-out sample. It was also shown that the quantitative measures of cluster quality obtained with this approach are positively correlated with external measures for cluster quality.

5.1.2 Estimating the Number of Clusters in a Data Set

A difficult and unsolved task is the estimation of a suitable number of clusters that is needed as input for many clustering algorithms. Two resampling methods have been proposed for estimating this number. The prediction-based method Clest [18] proves to be competitive to other estimators with respect to both accuracy and robustness. Cluster stability scores for microarray data based on a subsampling technique have been developed in the context of cancer studies [60]. Here, scores both for known and unknown clusters have been introduced. The *gap statistic* [68] compares the change in within-cluster variation with the variation that is expected under an appropriate reference null distribution. Limited applicability of the method on high-dimensional data has been discussed.

The silhouette value of an observation [34] compares the average distance of an object to members of the same cluster with the average distance to members of the closest of the other clusters. The number of clusters with minimal average silhouette width over all observations best captures the structure in the data and thus can be used as an estimate for the true number of clusters. This method can be applied in the context of any clustering algorithm. Furthermore, the silhouette value of a single observation can be used to evaluate this observation on its own. Objects with lower silhouette values are more likely to be misclassified, as they lie closer to a boundary separating two clusters, whereas a silhouette value close to 1 indicates that an object lies well in the center of the respective cluster.

5.2 Assessing Function Prediction Accuracy

The evaluation of supervised gene function prediction methods has not drawn much attention in the literature. For the classification of samples based on high-dimensional expression measurements, the need of evaluation schemes is evident. The problem of classifying samples, often to well-defined disease subtypes, is much more prevalent. Classical approaches to assess prediction accuracy, e.g. cross-validation, are described in detail in Chapter 26. These techniques have been further refined and adapted to efficiently deal with the dimensionality problem, since a meaningful gene selection is required to cope with the large number of genes compared to the small number of samples.

The classical approaches for assessing prediction accuracy can also be applied for the supervised classification of genes. However, for this task, the opposite problem emerges. The number of samples is too small compared to the number of genes. In addition, the annotation schemes are often not reliable. Thus, more importance should be attached to the biological annotations and to the number of samples. For a reliable classification, a sizeable number of samples with considerable variability in the conditions under which the expression experiments are performed is required.

6 Conclusions

Microarrays have become standard tools for gene expression profiling and their potential impact on clinical research is beyond controversy. However, different research tasks addressed with microarray technology are associated with different levels of expected clinical relevance. For the classification of patients based on expression profiles, sophisticated and suitable methods exist (see Chapter 26). In this area, the most important requirements for meaningful conclusions are studies with considerably large numbers of patients as well as careful experimental design.

Classification of genes using microarray gene expression profiles is a more difficult task due to the mostly small number of patients opposed to the huge number of genes on a standard microarray. The unsupervised task of finding coregulated gene groups depends on the choice of a distance measure between expression profiles and a clustering algorithm for grouping genes into coherent clusters. These choices can be guided by knowledge on properties of the respective measures and algorithms, but arbitrariness always remains. The supervised task of predicting gene function from gene expression data is even more difficult, mostly due to the dimensionality problem and the low quality of annotation schemes. Therefore, integrative approaches that combine expression data with other types of biological information are expected to have higher potential for reliable function prediction.

Proteomics: Beyond cDNA

Patricia M. Palagi, Yannick Brunner, Jean-Charles Sanchez and Ron D. Appel

1 Introduction and Principles

The term *proteome* had its first use in 1994 to picture the *prote*in complement of a gen*ome* [89]. It describes the ensemble of protein forms expressed in a biological sample at a given point in time and in a given situation. Two years later, the term *proteomics* was first used to define the study of proteomes, in a very simplified way. A broader definition advocates that proteomics is the science that deals with the global analysis of proteins, and this includes their identification, the measure of their level of expression and their partial characterization. Other definitions state that proteomics is the large-scale study of proteins; in particular, their structures, their functions and their interactions. Whatever the definition adopted, proteomics is in constant evolution, and relies on efficient protein separation techniques, mass spectrometry (MS), bioinformatics as well as gene and protein databases.

There are numerous proteomes for a single genome and proteomes are much more complex than genomes. DNA chip technology allows for the simultaneous analysis of the expression of thousands of genes at the mRNA level and can unravel biological processes. However, the correlation between the expression of mRNA and protein is low [2]. For instance, the dynamic range between transcription factors and albumin can be 10^{12} or higher. Moreover, the complete sequences of active proteins can only be partially deduced from their corresponding gene sequence. In fact, during and after the transcription and the translation processes leading to an active gene product, alterations often occur, such as alternative splicing, N-terminal truncation and post-translational modification (PTM). In addition, single genes can be expressed in more than 20 protein forms in a single tissue, e.g. at least 22 different protein forms matching α_1-antitrypsin have been described in human plasma. Proteomics involves also the description of the events generating the modifications that these proteins carry as functional entities. Besides, one single organism will have radically different protein expressions in different stages of its life cycle and in different cells, tissues and

fluids. Therefore, the analysis and the understanding of the suspected 0.5–1 million proteins in human, expressed by a number of genes that is currently estimated to be around 25 000, represent a real challenge in proteomics from the technological, analytical and bioinformatics points of view. Methods involving high-resolution protein separation, parallelization of sample preparation, automation of experimental processes and database comparison, as well as powerful and specific visualization tools had to be developed and integrated.

The development of new diagnostic tests and the discovery of new drug therapies both depend on the capacity to analyze complex systems. Proteomics offers the possibility to identify disease markers, to discover drug targets or to observe the global influence of a drug in a complex mixture of proteins. This will be possible only if one can describe the identity, the occurrence and the interaction of each individual component of this mixture.

Proteomics was a real revolution to biochemistry and molecular biology, essentially due to advances in experimental technology and the combination with bioinformatics. Due to the chemical and physical complexity of proteomes, various methodological approaches have been considered so far. Nevertheless, a representative workflow of a proteome analysis can be described as the one given in Figure 1. This pathway includes most of the wet-lab (*analytical*) and dry-lab (*bioinformatics*) steps required for the complete analysis of a proteome.

The first crucial step is the sample choice. It can be a raw biological fluid, a cell extract, a fraction of a sample, etc. Above all, the choice is also strongly dependent on the separation method to be applied since it has to be compatible with the dynamic range that the separation can handle. The proteins contained in this sample have then to be separated. In proteomics,

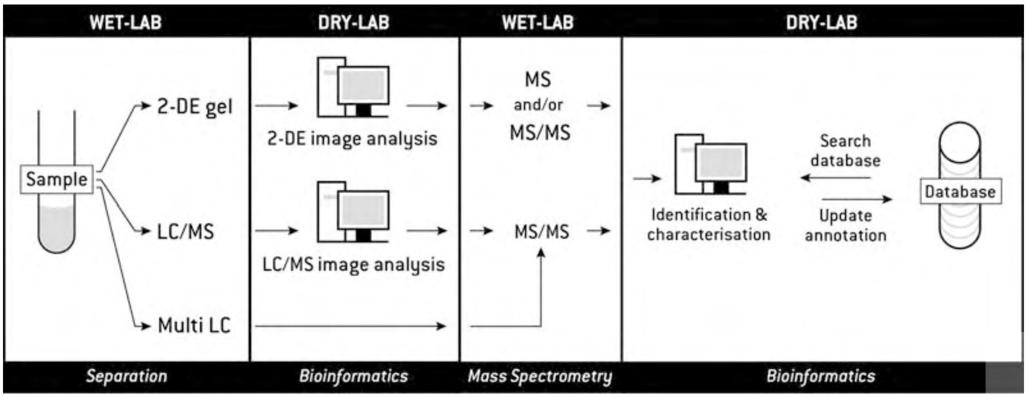

Figure 1 A schematic proteomics workflow. Digestion of proteins may occur either before the sample separation or before the MS.

one-dimensional, two-dimensional or capillary electrophoresis (respectively, 1-DE, 2-DE and CE), or liquid chromatography (LC), or a combination of them, are the preferred methods.

Once a separation method has been chosen, the next step is the analysis of the result and the selection of the proteins to be identified. In the case of a separation by 2-DE gels, the analysis is made with image analysis software. This kind of software allows for visualizing images, for comparing images and for performing a number of comparative analyses that enable tracking statistically significant changes in protein expression between populations of gels/samples. It helps to highlight the proteins of interest. Computer analysis of proteomics images is discussed in Section 3.

To proceed further, proteins separated with LC or those selected from a gel analysis are submitted to post-separation analysis. This experimental step determines highly specific protein attributes, such as peptide mass fingerprints or amino acid sequence information, when preceded by endoproteolytic cleavage. In endoproteolytic cleavage the proteins are typically incubated with an enzyme that recognizes particular amino acids and cuts the polypeptide chains at specific cleavage sites. The reaction produces shorter peptides that are fragments of the so-called digested proteins. Today's standard procedure most often involves a protein digestion step with trypsin and the analysis of the generated fragments with a crucial tool in proteomics, i.e. MS. Separation and post-separation techniques are briefly described in Section 2.

The intensive use of LC and MS in proteomics analysis has opened a new domain in proteomics imaging. The representation of LC-MS datasets as 2-D plots highlights the redundancy of data not necessarily observable when displayed in 1-D. Even though the analysis of this kind of images is still in its infancy, their potential and advantages can already be anticipated. Computer analysis of proteomics images is also discussed in Section 3.

Once in possession of the protein attributes acquired through the previous experimental steps, we can then move to database search. This search identifies a protein by looking at the best match between experimental data and data obtained by *in silico* processing and "digestion" of proteins in a sequence database. The identification (determining the name or sequence of the known proteins) and characterization (obtaining information about their function, cellular localization, PTMs, etc.) procedures using bioinformatics tools are the topic of Section 4.

Comprehensive sequence databases are a prerequisite for successful protein identification, and data from the identified proteins and samples are in turn used to populate specific proteomics databases. Section 5 browses some of the necessary databases for current proteomics projects.

The representation of a proteome analysis pathway such as the one given in Figure 1 assembles the different steps required to perform the identification of proteins from a crude biological sample. This pathway can, for instance, generate a systematic description of a complete proteome observable in a 2-DE gel. The result of such an analysis can be made concrete by the creation of an annotated database such as SWISS-2DPAGE [43] or other 2-DE databases. In addition, the information in such databases, e.g. annotated 2-DE gels, can be compared to an unannotated image to correlate positions and intensities of protein spots. From all the spots in the unannotated image, only those representing a real interest are further analyzed with identification methods. A widely used method to search for biological markers of specific diseases is the comparison of a statistically significant number of 2-DE images from samples of healthy and diseased patients or samples treated and not treated with target drugs. The images are compared, clustered and searched for protein spots that appear to be differently expressed. These become the spots of interest to be further identified. In this approach most of the efforts are concentrated in the generation of the 2-DE gels and in the comparison of the generated images. Section 3 describes the possibilities of undergoing such an analysis using dedicated software.

In addition, beyond the identification efforts, it is of great interest to describe and understand the modifications carried by the active gene products. This implies the search for splicing variants, amino acid mutations or PTMs that characterize a protein. Often, MS is used in a so-called MS/MS mode to decipher the spectra generated by this process, and to reveal structural information on the amino acid sequence and the description of PTMs attached to the studied peptides.

2 Proteomics Analytical Methods

2.1 Electrophoresis Gels

2-DE is currently one of the fundamental tools to display and evaluate the proteome complexity of any organism. It enables the separation of heterogeneous mixtures of proteins on a single polyacrylamide gel according to isoelectric point and molecular weight. The introduction of 2-DE in 1975 by O'Farrell and coworkers [48, 62, 75] allowed for separating between 2000 and 3000 proteins in a single gel. Isoelectric focusing (IEF) is the electrophoretic technique in which the proteins are separated according to their isoelectric point (pI) through a pH gradient. The pI of each protein corresponds to the pH at which the net charge of the protein is equal to zero. Under an electric field the proteins migrate until they reach their pI. Two methods are available for IEF. In the first one, the pH gradient is created and maintained by passing an electric current through a solution containing amphoretic compounds. These compounds are molecules with particular p*K*s. By mixing them in the polyacrylamide gel, it is possible to form a mixture, which establishes a pH gradient. In the second IEF technique, an immobilized pH gradient (IPG) is used [36]. In this process, the pH gradient, which exists prior to the IEF, is copolymerized within the fibers of the polyacrylamide matrix. This type of pH gradient is achieved through the use of a set of weak acids and bases named immobilines. Different types of IPG strips can be used with different ranges of pH. Most of the laboratories running 2-DE gels are currently using strips with a pH range from 3.5 to 10 to display a wide range of proteins. However, IPG strips with a narrow pH range can also be used to create a biochemical zoom on a part of the gradient range (like 4–7 IPG or 2–5 IPG). This provides higher protein concentration loading and the investigation of more proteins on a proteome "window".

After the first dimension of separation (IEF), the IPG gel containing proteins needs to be equilibrated in a solution containing sodium dodecylsulfate (SDS). It is an anionic detergent that binds to the majority of proteins in a constant mass ratio (1.4 g of SDS per gram of proteins). SDS allows the proteins to acquire a net charge per mass unit that is approximately constant. During this equilibration step, proteins are first reduced using dithiothreitol and then alkylated by incubation with iodoacetamide. Once the equilibrium is achieved, the IPG strip is loaded on the top of a polyacrylamide gel. In this second dimension of the 2-DE technique, the polypeptides enter into the polyacrylamide gel under an electric field and migrate through the porosity strictly according to their size (the molecular weight, M_r).

After the second dimension, the polypeptides must be detected either by staining, radiation (for radiolabeled proteins) or immunologic assays. Silver staining is one of the most popular methods of detection due to its very high sensitivity (below 1 ng). The main drawback of this method is the incompatibility with MS because of the presence of glutaraldehyde, which cross-links proteins. To overcome this problem, a silver staining method without glutaraldehyde has been introduced (about 10 times less sensitive) [91]. Coomassie blue staining is also very popular. It is a very simple method, although 50 times less sensitive than standard silver staining. Other methods are also used such as fluorescence or negative staining with zinc. After staining, the 2-DE gels can be scanned, and are ready to be analyzed through informatics software developed to perform quantitative protein analysis and automatic comparison of gels.

Even though 2-DE gels are considered the gold standard of proteomics, some issues remain uncertain. Due to analytical problems, between-gel variations (up to 30% coefficient of variation) lead to the problematic detection and quantification of differences in protein expression, resulting in difficulties in distinguishing biological from experimental variations. The 2-D difference gel electrophoresis (DIGE [83]) partially circumvents these problems. The DIGE method labels each sample with a spectrally resolvable fluorescent dye (Cy2, Cy3 or Cy5) prior to electrophoresis. The labeled samples are then mixed before IEF and resolved on the same 2-DE gel. Different images are acquired using different wavelengths and are compared with image analysis software. Variation in spot intensities due to gel-specific experimental factors is the same for each sample within a single DIGE gel. Consequently, the relative amount of a protein in a gel in one sample compared to another is unaffected.

Other issues remain unsolved in the 2-DE technique. This approach does not allow for identifying and characterizing all proteins present in a biological sample. Some proteins will not appear on the gel because of their extreme physicochemical properties, such as exceedingly high or low molecular weight, exceedingly high pI, extreme hydrophobicity, or insufficient abundance. Other techniques must therefore be applied to complete the picture, such as 1-DE (which separates samples only by molecular weight), pretreatment of the starting material, prefractionation and early digestion of the protein mixture followed by LC.

2.2 LC

The first chromatographic experiments were carried out in 1906 by the Russian botanist Mikhaïl Tswett, when he succeeded in separating various vegetal pigments. Chromatography is an analytical method for separating the different components of a mixture of molecules. It relies on differential affinities of these molecules for a mobile phase, the medium that carries the molecules, and for a stationary adsorbing medium, through which they pass. The stationary phase is either a solid or a liquid and the mobile phase is either a gas or a liquid. The separation is achieved through the different rates of migration of each component of a complex mixture, depending on their affinity for the stationary phase. Three types of chromatography have been developed: thin-layer (TLC), gas (GC) and liquid (LC) [27,49,52,70].

In LC the mobile phase is a liquid and the stationary phase can be either a liquid or a solid. The role of the liquid mobile phase is first to solubilize the protein sample and second to carry the proteins along the column. Various types of LC have been developed, depending on the type of stationary phase. The separation can be based on partitioning, adsorption, ion exchange, size exclusion or affinity.

In partitioning LC, the stationary phase is composed of an organic liquid covalently fixed on an inert solid support (such as silica) or embedded in a porous inert support. The principle of separation is based on the partitioning coefficient of the proteins between the nonmiscible stationary and mobile phases. The higher the partitioning coefficient, the higher the number of soluble proteins in the organic stationary phase and the higher the retention time for these proteins [10].

In adsorption LC, the stationary phase is composed of a solid adsorbent. The proteins are separated due to their varying degree of adsorption onto the solid surfaces. Different types of adsorbent can be used. In normal phase absorption, the stationary phase is composed of a polar compound (such as an amine or carboxyl) linked to silica beads. In contrast, in reverse-phase LC the stationary phase is composed of a nonpolar hydrophobic compound. In general, the hydrophobic compounds are aliphatic chains such as C_8 or C_{18} bound to silica beads. When the proteins are loaded to the top of the column they bind to aliphatic compounds through hydrophobic interactions. The proteins are eluted with increasing concentration of a hydrophobic solvent such as acetonitrile. The low-hydrophobic proteins are eluted first by low concentration of solvent and the high-hydrophobic proteins are eluted only by a high concentration of solvent [61].

Ion-exchange LC is used to separate proteins on the basis of their electric charge. In this method, ionic groups are covalently bound to the matrix column. These groups can be either positively or negatively charged and are compensated for by small concentrations of counterions that are present in the buffer. When a sample is added to the column, an exchange with the weakly bound counterions takes place. With a cationic exchange column the matrix is negatively charged. The higher the positive charges of proteins, the higher are their ionic interactions with the matrix. Increasing concentrations of salt solution are then used to elute the bound peptides. The principle is the same with anionic exchange, except that the matrix will be positively charged and the most negatively charged proteins have higher retention times [78].

Size-exclusion LC is used to separate proteins by their size and shape. Its principle is to use a porous polymer composed of beads with very small holes. As the protein solution is poured on the column, small molecules enter the pores in the beads. The small molecules are eluted last because they have a longer path to go through, as they get stuck over and over again in the maze of pores running from bead to bead [9].

Finally, affinity chromatography relies on the biological ability of a protein to bind to a column. The most common type involves a ligand, a specific small biomolecule. This small molecule is immobilized and attached to a column matrix, such as cellulose or polyacrylamide. The target protein is then passed through the column and binds to it by its ligand, while other proteins elute out. This is a very efficient purification method since it relies on the biological specificity of the target protein, such as the affinity of an enzyme for its substrate [50].

Currently, a large number of proteomics projects couple LC with MS, which is described in the following section.

2.3 MS

MS is an analytical technique that is commonly used to identify unknown compounds, quantify known materials, and elucidate the structural and physical properties of ions. It is a technique associated with very high levels of specificity and sensitivity. Analyses can often be accomplished with tiny quantities, sometimes requiring less than picogram amounts of material. Sir J. J. Thomson developed the first mass spectrometer in the first decade of the 20th Century, even before the determination of mass-to-charge ratios (m/z) of ions. The goal of all mass spectrometers is the exact determination and analysis of the m/z ratio of ions. A mass spectrometer is formed of three fundamental parts, i.e. the ionization source, the analyzer and the detector. The first step in a mass spectrometric process is to generate ions from the analyte. Nowadays, the two ionization methods used most frequently for biochemical analyses are electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). However, other methods also exist such as chemical ionization (CI), electronic ionization (EI) or fast atom bombardment (FAB).

ESI, developed by Fenn and colleagues [30], is one of the atmospheric pressure ionization (API) techniques and is well suited for the analysis of polar molecules ranging from less than 100 to more than 10^6 Da in molecular weight. In ESI, the sample is introduced into a capillary and then submitted to a high voltage (around 4000 V). The high voltage causes the formation of a cloud of charged droplets. Evaporation of the solvent from the initially formed droplet as it traverses a pressure gradient toward the analyzer leads to a reduction in diameter and an increase in surface field until the Rayleigh limit is reached. The latter corresponds to the point where the surface tension can no longer sustain the charge. At this point, an explosion occurs and the droplet is ripped apart. This produces smaller droplets that can repeat the process until obtaining singly or multiply charged ions.

The Nobel Laureate, Koichi Tanaka [80], developed the MALDI method in 1987. It is based on the bombardment of molecules with a laser light to provoke sample ionization. Most commercially available MALDI mass spectrometers now have a pulsed nitrogen laser of 337 nm wavelength. In MALDI, the sample is first mixed with a highly absorbing matrix compound. The matrix cocrystallizes with the sample on the metal support. The matrix minimizes the degradation of the sample caused by the energy absorption of the incidental laser beam. The exact mechanism by which the MALDI ionization occurs is not precisely understood. It is supposed that the matrix absorbs the energy transmitted by the laser and this contribution of energy causes its expansion in gas phase by involving the molecules of the sample. The sample is mainly ionized by transfer of protons, either before desorption in the solid phase or by collision after desorption with the excited matrix to form singly charged ions.

Once obtained, ions must be analyzed. The analyzer uses dispersion or filtering to sort out ions according to their m/z ratios. Several types of analyzers have been developed such as the quadrupole, the ion trap or the time of flight (TOF). The Quadrupole mass filter consists in four parallel rods to which an electric field is applied. The resultant magnetic field allows for selecting ions according to their m/z ratio. Indeed, at one particular magnetic field strength, only ions with a particular m/z will pass trough the quadrupole filter and all other ions are thrown out of their original path. The ion trap mass analyzer consists of three hyperbolic electrodes: the ring electrode, the entrance end-cap electrode and the exit end-cap electrode. These electrodes form a cavity in which it is possible to trap and analyze ions. Both end-cap electrodes have a small hole in their center through which the ions can travel. Ions produced from the source enter the trap through the inlet focusing system and the entrance end-cap electrode. Various voltages can be applied to the electrodes to trap and eject ions according to their m/z ratios.

TOF mass analyzers separate ions by virtue of their different flight times over a known distance. A brief burst of ions is emitted from a source. These ions are accelerated so that those with the same charge have an equal kinetic energy and then are directed into a flight tube. Since kinetic energy is equal to $1/2mv^2$ (where m is the mass of the ion and v is the ion velocity), the lower the mass ion, the greater is the velocity and the shorter is the flying time. The travel time from the ion source through the flight tube to the detector, measured in microseconds, can be transformed onto an m/z value through the relationships described above. As all ion masses are measured for each ion burst, TOF mass spectrometers offer high sensitivity as well as rapid scanning. They can also provide mass data for very-high-mass biomolecules [79].

Two analyzers can be combined to perform tandem MS (MS/MS). The first analyzer selects a first ion, which is called the "parent ion". After fragmentation of the parent ion by collision-induced dissociation (CID – a fragmentation obtained by the collision of a molecule with neutral gas molecules), a second analyzer measures the m/z ratio of the ions resulting from this fragmentation. As fragmentation occurs mainly in the peptide bond of the amino acid backbone, a ladder of sequence ions is generated. The resulting peptide fragmentation masses differ by the mass of amino acid residues, thus allowing stretches of the peptide sequence to be deduced, which can be very useful to identify compounds in complex mixtures [1]. Fragments will only be detected if they carry at least one charge. According to Roepstorff's nomenclature [74],

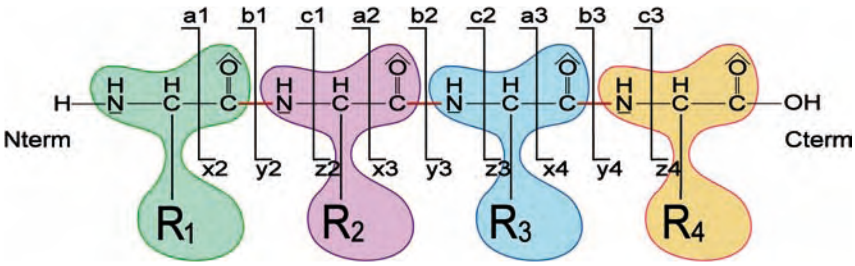

Figure 2 Fragmentation schema of a peptide with four amino acids. Fragments that carry the charge on the N-terminal side are denoted a, b and c, while those carry the charge on the C-terminal are denoted x, y and z.

the product ions are denoted as a, b and c, when the charge is retained on the N-terminal side of the fragmented peptide, and x, y and z when the charge is retained on the C-terminal side. As shown in Figure 2, ion types differ by the position of the fragmentation in respect with the peptide bond.

Once the ion passes through the mass analyzer, the ion detector (the final element of the mass spectrometer) then detects it. The detector allows a mass spectrometer to generate an electric current signal from incident ions by generating secondary electrons, which are further amplified. Alternatively, some detectors operate by inducing an electric current generated by a moving charge. Among the described detectors, the electron multiplier and scintillation counter are the most commonly used and convert the kinetic energy of incident ions into a cascade of secondary electrons.

Ideally, the MS and MS/MS processes should generate a list of m/z values of all peptides (respectively, fragmented ions) present in the analyzed sample. In reality, due to physicochemical properties of some peptides or ions, not all m/z values are detected making the data interpretation much harder.

Finally, MS can be used in combination with analytical separation methods such as LC (LC-MS) or GC (GC-MS). In these cases MS is used as a detector after chromatographic separation. Nowadays, this configuration is often used in many laboratories because it allows for combining high separation and detection capacities [22]. Shotgun proteomics has evolved from the combination of some of these techniques, MS and multidimensional chromatography, and bioinformatics. In a typical shotgun proteomics approach, a complex protein mixture is digested with proteases to produce an even more complex peptide mixture. The peptides are loaded directly onto an LC/LC column placed in-line with an MS/MS spectrometer. The spectra are acquired "on the fly" as peptides are eluted from the column, ionized, and emitted into the mass spectrometer. Using elaborated algorithms, respective peptide sequences generated from MS/MS are automatically identified by comparison against protein databases, avoiding any manual interpretation. One such approach is the multidimensional protein identification technology (MudPIT [86]), which has been applied to the proteome study of various species such as yeast, *Escherichia coli* [72], human extracts [14], *Toxoplasma gondii* [93], etc.

2.4 Protein Chips

The necessity to miniaturize and to automate high-throughput analysis systems led to the development of microarray (biochips) technology. It is based on immobilizing small molecules, oligonucleotides or proteins onto surfaces for various high-throughput screening studies. Microarrays were initially developed for large-scale gene expression studies, e.g. to compare gene expressions between different tissue types, treatments, disease models and human samples (see Chapters 24–27). Today, DNA microarrays are well established for studying the transcriptional state of a biological sample [69]. However, the level of expression of a transcribed mRNA does not always correlate with the protein expression level [39]. Protein microarrays were thus developed to analyze the expression level of a large number of proteins simultaneously and to study the interaction of proteins with a variety of molecules. It is already a successful method for the identification, quantitation and functional analysis of proteins in proteome research [55].

There are two main types of protein microarrays used: (i) to measure the abundance of a protein (abundance-based microarray) by the use of a specific reagent, and (ii) to study protein function. Abundance-based microarrays are divided in two types: capture microarrays and reverse-phase microarrays. In capture microarrays, a molecule (such as antibodies, peptide, RNA or DNA aptamers, or chemical molecules) is spotted on the surface of the microarray to catch and assay their target from a complex mixture. The relative amounts of the targeted proteins are then determined by comparison with a reference sample [40]. In this technique, the most popular capture molecules are antibodies because of their sensitivity and selectivity. However, it is estimated that only 30% of the commercially available antibodies can be used qualitatively and only 20% quantitatively. Contrary to capture microarray, reverse-phase microarrays [76] consist of spotting an unknown mixture sample on the array and probing it with an antibody or another specific reagent.

In function-based microarrays, the protein of interest is spotted on the microarray surface to study its biochemical properties and/or activities. This type of microarray can be used to examine protein interaction with other proteins, nucleic acids, lipids and other biomolecules. Furthermore, function-based microarrays can be used to study enzyme activity and substrate specificity [94, 95]. However, there are several limitations to this type of microarrays. First, proteins are often produced *in vitro* and do not possess their native conformation and their usual PTMs. Furthermore, the methods used to attach proteins to the surface array can change the behavior of the proteins. Finally, all tests are realized *in vitro* and must be confirmed *in vivo*.

Whilst there is tremendous excitement about the potential of protein arrays to further our understanding about protein function, protein–protein interactions and biological activities, there are also concerns over frustrating technical limitations. Robustness, sensitivity and automation of protein microarrays still need to be improved in order to increase its use in proteomics. The bioinformatics issues of protein microarrays are similar to those of cDNA microarrays (see Chapters 24–27) and they are deliberately not dealt with in this chapter. Several other proteomics approaches and combinations of methods exist to separate, analyze and quantify complex protein mixtures. They are not treated in this chapter either. We have intentionally decided to focus on a few proteomics techniques that touch especially challenging bioinformatics issues, which are detailed in the following sessions.

3 Computer Analysis of Proteomics Images

For each analytical method (2-DE, LC, MS and MS/MS) described in the previous session, there is a corresponding bioinformatics tool to analyze and interpret the resulting data. These tools allow for detecting differentially expressed proteins in different proteomics samples, on the one hand, and for identifying and characterizing the most pertinent proteins, on the other hand.

3.1 Analysis of 2-DE Gels

2-DE gel patterns, once digitized, provide an important basis for quantitative analysis and comparative proteomics. The possibility of detecting protein expression changes associated with diseases and treatments or finding therapeutic molecular targets opens up new frontiers for biological and biomedical research. These applications have been a major incentive to the development of specialized software systems for 2-DE gel image analysis [3, 5, 34, 51, 84]. Currently, a number of dedicated software packages are commercialized, the main ones being listed in Table 1. Although each of the 2-DE gel image analysis systems has its own philosophy and approach [85], most of them provide the same basic operations and functionalities necessary to carry out a complete gel study. These operations are usually based on state-of-the-art image processing algorithms that have been adapted to this specific biological need. In this section, the key issues and steps of 2-DE gel image analysis are discussed and illustrated using the ImageMaster^{TM} 2D Platinum release 6 (powered by Melanie, which is developed by the Proteome Informatics Group at the Swiss Institute of Bioinformatics). Note that a free viewer of this software is available at www.expasy.org/melanie. It has the usual visualization operations of the full version and most of the analysis procedures as well, even though the analysis is restricted to a small number of proteins and only from gels that have already been analyzed by a full version.

3.1.1 Data Analysis and Validation

The first operation of a 2-DE gel analysis is the scanning of the gels. In most cases, this is achieved by the use of flatbed document scanners, camera systems, densitometers, phosphor imagers or fluorescence scanners. These equipments produce images of typically around 2000 × 2000 pixels or more and a depth of 12 or 16 bits, thus providing a dynamic range of 4096 or 65 536 gray levels, respectively.

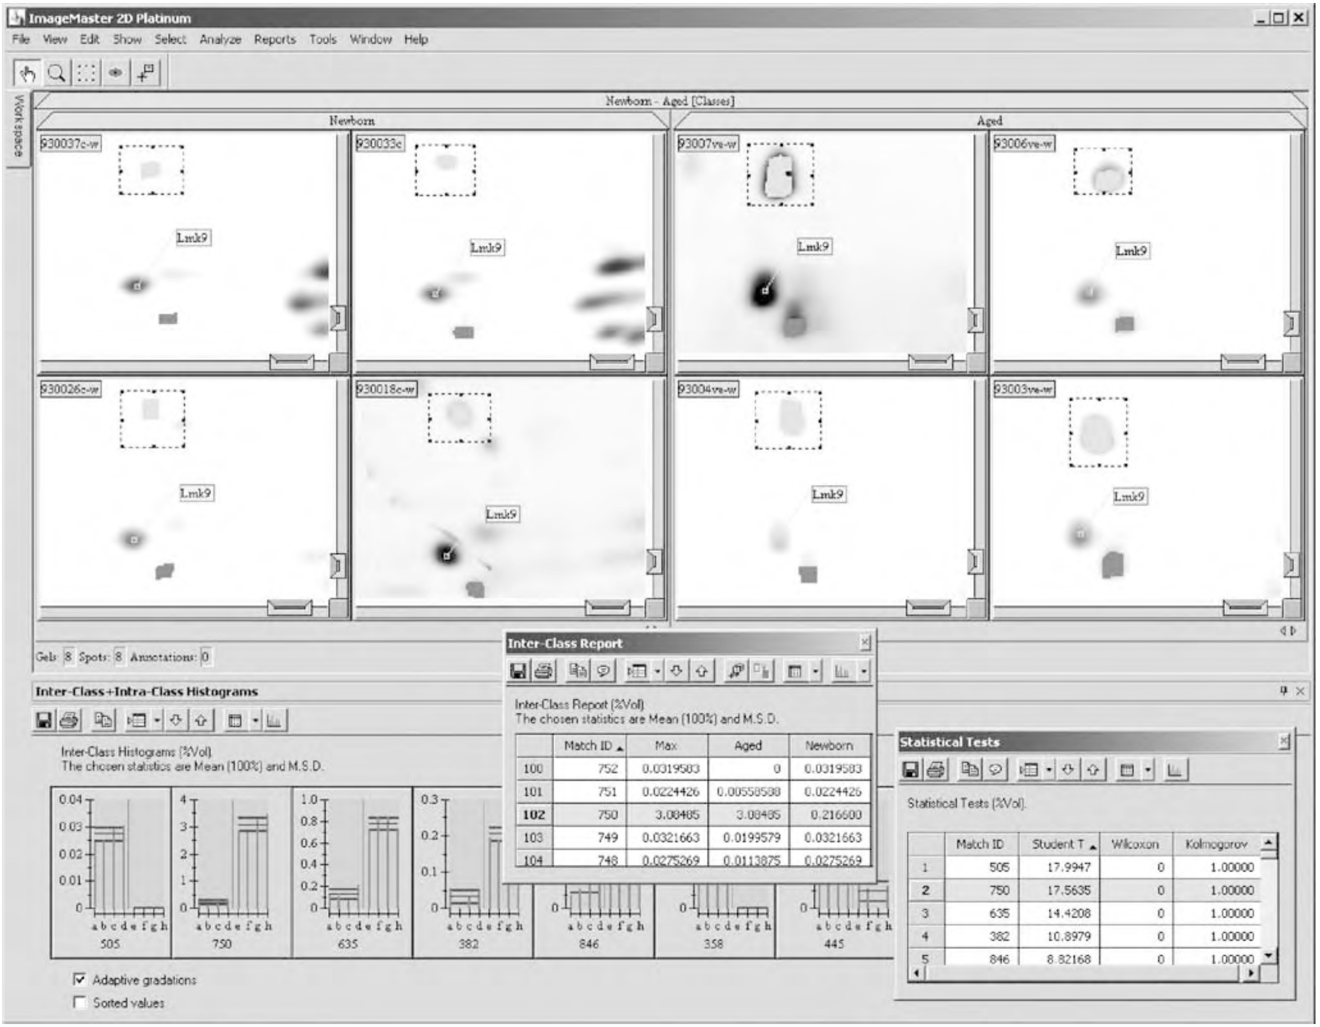
One of the basic properties of 2-DE analysis software is image visualization. ImageMaster provides several means of manipulating and displaying the gels, such as gel stacking, various zoom modes, customizable grids, "flicking" back and forth between gels or a transparency mode to visually inspect the result of matching. This makes it easy to browse through the data extracted from the 2-DE images.

Apart from the basic visualization properties, the major functions of software systems for 2-DE image analysis are (i) to detect and quantify the protein spots on the gels, (ii) to match corresponding spots across gels and (iii) to locate significant protein expression changes. To achieve (iii), both (i) and (ii) must have been successfully carried out. The optimal and reproducible definition of spot borders depends mostly on gel running issues, uneven focusing and polymerization problems. Very often proteins are not resolved as discrete spots, particularly in regions with high spot density. Numerous dim spots may be missed because they are confused with the background, whilst others might be wrongly detected. In order to overcome these issues, detection algorithms often include filtering steps to automatically remove streak artifacts and noise spikes [6] or a segmentation process based on the analysis of the gray levels [23]. Spot detection algorithms produce a repository of all protein spots contained in the 2-DE images, as well as related quantitative data, such as the spots' optical densities, area and volume (integration of the optical density over the area). Relative measures of these values are also given, e.g. the relative volume calculated as the absolute volume divided by the total volume of protein in the whole 2-DE gel. Relative values allow for partially compensating for variations in sample load or staining. Using such relative quantitative values provides better reproducibility of data.

Finding corresponding pairs of spots in gel images is also a critical task, whether it is based on the detection of spots first [68] or based on the intensities of the regions before the detection of spots [77]. Pair matching relies on the similarity of the spatial distribution of spots, which then may vary according to experimental gel running conditions and gel scanning. Quantitative differential protein expression can be erroneous when spots representing the same protein are not correctly matched or when spots representing different proteins are mistakenly matched together.

After matching, the statistical data analysis is carried out to find interesting proteins, i.e. those that have been suppressed or are upregulated. Descriptive statistics summarize the values of matched spots that may indicate significant characteristic spots of gel populations. Usually, 2-DE analysis software offers common statistical tests such as Student's *t*-test, or the Mann–Whitney or Kolmogorov test, but they also propose multivariate analysis, clustering tools or neural networks [26] to locate variations in protein expression profiles. The results can then be visualized through histograms, scatter plots, reports or different views of the gels such as gel transparency, overlapping spot contours or 3-D view.

Figure 3 illustrates the analysis reasoning with eight 2-DE images. These are eight gels from smooth muscle cells of rat samples, out of which four are from newborn and four from aged rats [21]. All images have been matched to gel 930018c-w (upper left in Figure 3). Two classes have been defined, each containing four images (marked "Newborn" and "Aged", respectively, in Figure 3). We first select all groups of spots in each of the two classes and then produce an Inter-Class Report (detail of Figure 3) that shows the Maximum value of each class computed on the spots' normalized volumes (%VOL). A group is a set of spots that have been matched across all gel images, thus representing the same protein. A Statistical Tests report will then show various statistics about the groups in the two classes, such as Student's *t*-test, or the Wilcoxon or Kolmogorov–Smirnov test. This lets the user select and highlight protein spots that are differentially expressed between the two classes. Figure 3 shows the result of one of these tests, highlighting the group of spots that were ranked highest in term of separability between the two



Inter-Class Histograms (%Vol)

classes. In Figure 3, the same group of spots has been highlighted on the Inter-Class Report, the Inter-Class + Intra-Class Histograms and in the gels.

Once specific proteins of interest have been selected via careful data analysis, such as illustrated in Figure 3, further analysis may be carried out to identify or partially characterize those proteins.

3.1.2 **Annotation and Databases**

After extensive analysis of the protein spots has been carried out, including protein identification as detailed in Section 4, 2-DE images may be annotated. The annotations have mainly two functions: linking gels and external databases, and adding information on the gels for later reference. ImageMaster provides broad annotation capabilities in order to include into the gel image all related data and information that has been acquired. Annotations can be added either manually, or they may be imported from an external database, for example through a Laboratory Information Management System (LIMS). Any kind of annotations may be attached to a spot or a pixel, as for example the protein ID, a SWISS-2DPAGE ID (or any other protein database ID), a landmark, calibration values (pI, M_r, intensities) or comments, as well as links to external files such as text files or MS spectra, and also Internet links. By double clicking on the various labels that mark annotated objects, the corresponding piece of information is displayed. In the case of an accession number of a SWISS-2DPAGE entry (e.g. P02990), it launches the default web browser and downloads the corresponding database entry from the local or external user-specified database.

3.2 Analysis of LC-MS Images

So far, we have seen examples from a proteomics workflow in which samples are separated via 2-DE gels. Another possible workflow in proteomics combines separation of proteins and peptides by LC followed by direct analysis by MS (Figure 1). In this case, data may also be represented in two dimensions, the elution time and m/z, and they can be visualized and analyzed as images. LC-MS image analysis systems are still in their infancy. Some prototypes have been presented so far, such as Decyder-MS, MapQuant, SpectroArray, MSD-Viewer and MarkerView, but almost no literature is available describing their performance and characteristics. Pep3D is a tool for producing LC-MS images that is also capable of representing the score values of protein identifications of precursor ions using different color hues [53]. Its simple interface permits the visualization of one experiment at a time and only a single view of the image. The Proteome Informatics Group at the Swiss Institute of Bioinformatics has developed a software tool, MSight [65], for the 2-D representation, visual analysis and comparison of LC-MS datasets. MSight features (i) display and browsing, as an image, of any portion of the collected mass spectra, with a smooth transition from a global overview of all spectra to selected isotopic peaks, (ii) user-friendly navigation through large volumes of data, and (iii) visualization tools to discriminate peptide or protein from noise or to perform differential analysis. This software tool is available free of charge through the ExPASy web server [35] at http://www.expasy.org/MSight. Future versions of this tool will allow for semiautomatic analysis of LC-MS datasets, including quantitative differential proteome analysis.

The images displayed in Figure 4 were obtained from a 42- to 59-kDa fraction of an extract of the human BJAB B cell line. The sample was digested with trypsin and separated by reverse-phase capillary LC coupled to a SCIEX/Applied Biosystems QSTAR quadrupole-TOF mass spectrometer equipped with an ESI source. Spectra were acquired in the m/z range 400–1200, and the image was created using a 0.025 m/z sampling rate and thus contains 55 million measures. The top-right image in Figure 4 displays a 2-D view of the sample described above and the bottom-left image highlights part of this sample in a 3-D view. The bottom right image in Figure 4 shows one single spectrum of the sample.

Image processing of LC-MS datasets can be extremely useful for the monitoring and quality control of experiments as well as knowledge extraction. Software tools specifically developed for the representation of mass spectra along with data from the separation step (such as LC-MS or SDS-MS) provide simple ways to navigate through very large volumes of data. Assessment of the data quality and of the experimental design is simplified by providing a direct means of verifying the quality of the separation and detecting the presence of artifacts and contaminants or mass calibration problems. The redundancy in successive mass spectra may even be used to enhance the signal-to-noise ratio, thereby improving the reliability of MS analysis. Such visual representation of experimental data also helps to understand features such as PTMs of peptides. Most importantly, it allows for automatic or semiautomatic differential proteome analysis by comparing several sets of data, as well as providing fast and intuitive detection of significant qualitative and quantitative differences.

4 Identification and Characterization of Proteins after Separation

Pinpointing differentially expressed protein spots on gels or analyzing mass spectra profiles in LC-MS runs using imaging tools is only the first step in the computer analysis of proteomics data. An important challenge consists of the interpretation of MS and/or MS/MS data to identify (determining the name or sequence of the proteins) as well as to characterize (obtaining information

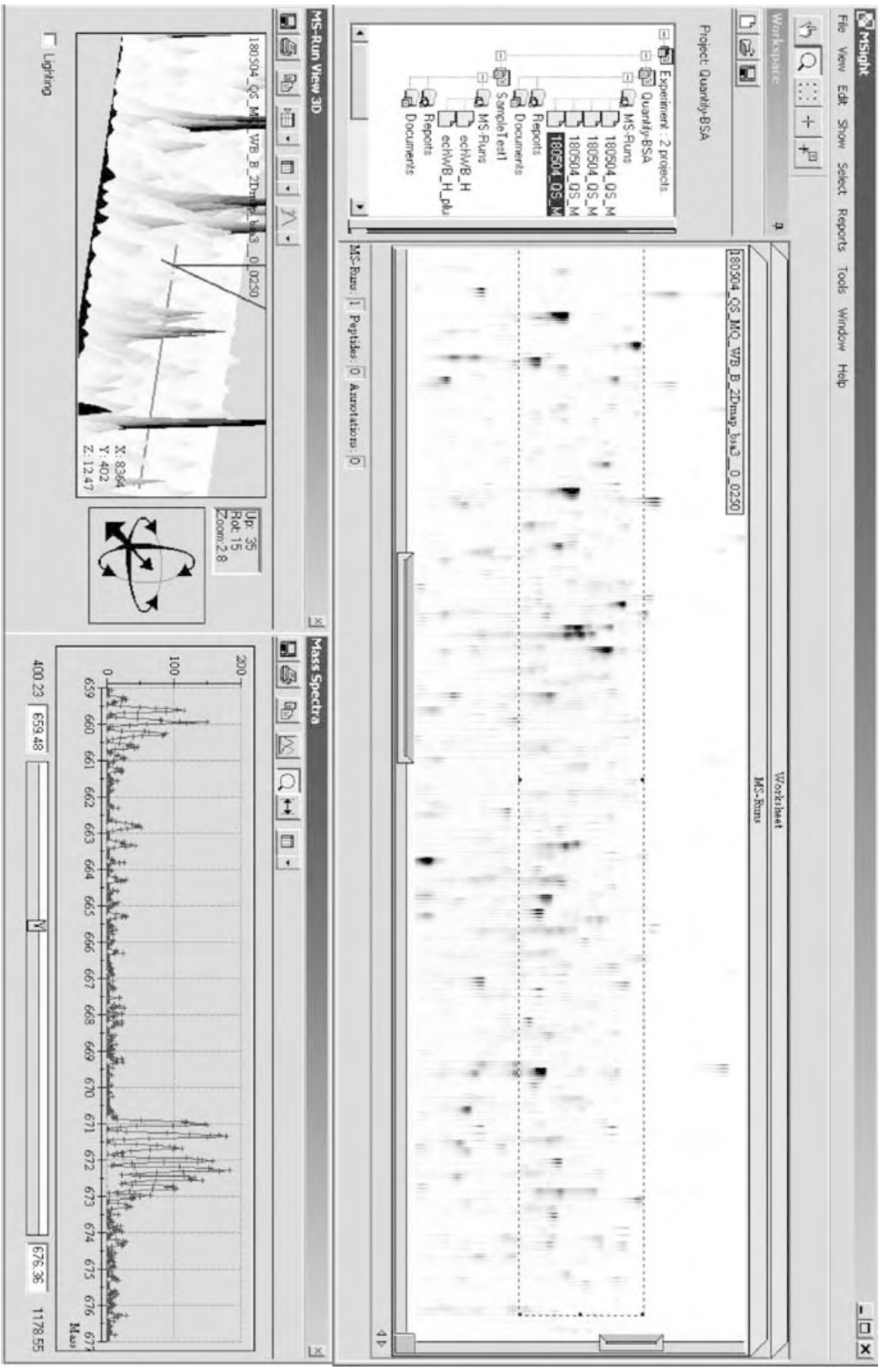

Figure 4 The MSight software showing three different views of the same LC-MS sample: 2-D, 3-D and 1-D (one spectrum) views.

about their function, cellular localization, PTMs, etc.) the concealed proteins. Developing identification and characterization tools from MS data has therefore represented for bioinformatics research a major effort in the last 10 years.

Typically, identification tools identify one or several proteins by matching experimentally obtained protein-related properties against the corresponding theoretical values computed from sequences in a protein sequence database. Once the sequence is known, characterization tools attempt to predict functional and structural features, such as PTMs, splice variants or any other modification or polymorphism.

This section presents the general mechanism of identification and characterization tools from mass spectrometric data, as well as the major tools that are available on the Internet. Most of them are listed on the ExPASy tools page at http://www.expasy.org/tools.

4.1 Identification with MS

MS is typically used to measure the mass of peptides obtained by proteolytic cleavage of one or a mixture of proteins [the peptide mass fingerprinting (PMF) approach] and/or the mass of fragment ions obtained by subsequent fragmentation of one or several peptides [the peptide fragment fingerprinting (PFF) approach]. In PMF, experimental peptide masses are compared to theoretical mass values obtained by applying a proteolytic cleavage rule to the entries in a sequence database. By analogy, PFF compares experimental MS/MS fragmentation mass values of a peptide to theoretical MS/MS spectra computed from the database. In both methods the matches between experimental and theoretical spectra are scored such as to provide a measure of similarity between the two spectra, a higher score indicating a higher likelihood that the corresponding protein or peptide is the target protein or a peptide, respectively, from the target protein.

Software tools to identify proteins using the PMF or PFF approaches share common characteristics:

- A database (typically Swiss-Prot/TrEMBL [12] or NCBI [87]) is searched for the protein, whose theoretical MS (respectively MS/MS spectrum) is most similar to the experimental one.
- A score function measures the similarity between experimental and theoretical spectra; the result is presented as a list of candidate proteins or peptides, sorted by decreasing score values. In PFF, the result shows either candidate peptides or candidate proteins after peptides have been combined to proteins.
- Experimental mass values may be entered manually or copy-pasted. Alternatively, a file with mass values for one or several spectra may be uploaded.

- Experimental parameters may be specified which include the enzyme used for proteolytic digestion as well as the user's confidence in it (maximum number of missed cleavage sites to be considered), the peptide mass tolerance (respectively, precursor ion mass and fragment ion mass tolerances) and various fixed or variable modifications that can affect the protein or peptide sequence, e.g. acetylation, carbamylation or oxidation of residues.
- To increase the specificity and speed of the database search, restrictions may be added. For example, the search may be limited to one species or taxonomic category, or to given p*I* or M_r intervals; resulting protein or peptides may also by filtered out by various other criteria such as the minimum number of matching peaks, minimum score value, etc.

Although PMF can produce excellent results in given situations, particularly when searching databases for species of small and fully sequenced genomes, PFF is a more specific and sensitive identification method and is better adapted when searching in larger databases or when working with complex mixtures of peptides. The sequence information given by the amino acids fragmentation, that are then analyzed using PFF programs, increases the chances of finding true positive hits in database searches. It is possible that even a single peptide (a single MS/MS spectrum) will correctly identify a protein, but this depends on the number of amino acids in its sequence (and as a consequence the peptide coverage on the identified protein). PFF identification is not a perfect method either. Many MS/MS spectra collected during an experiment may not be assigned to any peptide. Possible reasons for these nonmatches can be the presence of contaminants, the poor-quality spectra with noise and unusual fragmentation, spectra derived from proteins not present in the database or with an alternative splicing not annotated in the database, etc. In general, more and more current experimental settings use both PMF and PFF methods in a complementary approach to increase the number of confidently identified proteins.

PMF and PFF are very similar approaches; both correlate experimental spectra with theoretical spectra (respectively, MS and MS/MS spectra). The main difference among the substantial number of existing tools for PMF and PFF lies in their scoring scheme and thus in their ability to identify the correct protein or peptide amongst all candidates, i.e. to distinguish true-positive from false-positive matches. A scoring function must take into account many factors to produce a robust score, like dissimilarities in the peak positions due to internal or calibration errors, peak intensities, noise, contaminants or missing peaks, presence of PTMs, and so on. A variety of different scoring functions have been implemented in various algorithms and programs for PMF and PFF identification [42] such as:

- Aldente [82] (http://www.expasy.org/tools/aldente) is a PMF identification software developed at the Swiss Institute of Bioinformatics. It implements rules, empirical observations and user knowledge in various steps of the identification procedure, and automatically determines the mass deviation of the mass spectrometer by searching for the best mass alignment within the estimated instrument internal precision using a robust method, the Hough transform [73]. Aldente eliminates the need to provide calibrated data, as the alignment procedure considers relative mass variations and thus automatically recalibrates all mass values. The alignment procedure also eliminates outliers thus making the identification much more robust than usual PMF identification programs. Similarly to most other tools on the ExPASy proteomics server (http://www.expasy.org), Aldente takes into account the annotations available in the Swiss-Prot database, particularly PTMs and alternative splicing information. Aldente compares the score of candidate peptides or proteins to the score obtained by matching the spectra to a randomized database in order to statistically compute the likelihood that the candidate proteins or peptides are true positive matches (p-value). Also in line with the other tools on ExPASy, resulting proteins in Aldente may directly be submitted to other ExPASy proteomics tools such as Findpept (that explains peptides that result from unspecific cleavage), PeptideMass (that theoretically cleaves proteins), BioGraph (that graphically represents matched and unmatched peaks in spectra) or FindMod and GlycoMod (see below for details).

- Mascot [66] (http://www.matrixscience.com) includes both a PMF as well as a PFF search tool. Mascot uses a probability-based scoring system that considers matches as random events dependent on the number of entries in the database. Mascot may be obtained from Matrix Science. A free public Internet version is accessible from the above-mentioned URL.

- The ProteinProspector Server [16] (http://prospector.ucsf.edu) from the University of California San Francisco MS facility has a suite of programs that mine sequence databases using MS experiments. Among their tools are MS-Fit for PMF analysis, MS-Tag for PFF, and MS-Seq for a combination of PFF and peptide sequence tag analysis. MS-Seq assumes that short sequence tags are usually easily determined in MS/MS spectra and that their combination with the mass values of the prefix and suffix fragments creating a sequence composed of mass + Tag + mass) increases the discrimination. MS-Seq program is based on the PeptideSearch tool (http://www.narrador.embl-heidelberg.de/GroupPages/Homepage.html) from EMBL [57].

- The PROWL environment [92] (http://prowl.rockefeller.edu) at Rockefeller University comprises ProFound, a PMF identification program which can also be configured to identify components from a mixture of up to four proteins, and PepFrag, an identification tool for PFF. It uses a Bayesian probabilistic score that considers the deviation between theoretical and experimental masses.

- Phenyx (http://www.phenyx-ms.com), developed at Geneva Bioinformatics (GeneBio) in collaboration with the Swiss Institute of Bioinformatics, is a second-generation MS analysis platform that includes both a PMF algorithm using the Aldente alignment algorithm and a PFF identification tool that implements the OLAV true probabilistic scoring scheme [17]. This scoring function, based on a likelihood ratio, takes into account a significant amount of physicochemical parameters of the fragment ions such agmentation pattern probabilities, the presence of different ion series (*a*, *b*, *y*, etc), peak intensities and residue modifications (as annotated in the Swiss-Prot/TrEMBL database). This gives Phenyx the ability to efficiently discriminate between true- and false-positive matches. In addition, the score can be optimized for specific mass spectrometers using a training set of validated identified proteins. Finally, Phenyx also provides a combined PMF and PFF identification mode that makes the identification process more robust. Phenyx, available from GeneBio (http://www.genebio.com), can also be accessed freely at the above-mentioned URL.
- Sequest [28] (http://fields.scripps.edu/sequest/index.html) was the first PFF program to be developed. It compares a simplified experimental spectrum to theoretical spectra built from the databases and ranks candidate peptides using a simple correlation measure. Sequest is available from Thermo Electron Corporation. Examples of tools employing heuristic algorithms include Spectrum Mill, X!Tandem and Sonar [32].

Other tools exist that perform PMF and PFF; however, their intrinsic algorithms are similar to those already cited here. The performances of the above-mentioned tools depend not only on their algorithms, but also on the parameter values and on the content and size of the searched databases. For example, the correct proteins and peptides (the true positives that should be ranked first) would appear at the bottom of the resulting list when the number of sequences in the searched database is very high or when many missed cleavages are allowed. On the other hand, true positives have better chances to appear in the top of the ranked list when restricting the search to the taxonomy of the studied species or group of species. Two metrics are used to compare the performances of MS and MS/MS algorithms and to give some hints on how to determine the confidence level of an identification result. The sensitivity of a tool indicates the ability to make a correct identification regardless of the quality of the data and is calculated by:

Sensitivity = TP/(TP + FN),

where TP stands for true positives and FN for false negatives. The specificity of the tools indicates the ability to calculate low-ranking scores for random (or incorrect) matches and is calculated by:

Specificity = TN/(TN + FN),

where TN stands for true negatives and FP for false positives. In both cases, a certain empirical threshold has to be determined to indicate the correctness of a match. Some of the above-mentioned tools were compared considering these two metrics [15,46]. Regarding the compared PMF tools, ProFound was considered more sensitive and specific than MS-Fit. For the compared PFF tools, Sequest and Spectrum Mill had good sensitivity values, while Mascot, Sonar and X!Tandem had good specificity. It is important to note that these results have to be taken with caution, since the comparisons are made with very specific parameters and databases. In real life, end users submit their MS and MS/MS data to one or two of these tools, and heuristically interpret the different results based on their own biological knowledge, experience and judgment.

Finally, when no matches are found with PMF or PFF, a third alternative approach can be used to obtain protein information from MS/MS data. It is called *de novo* sequencing and consists of inferring the amino acid sequence of the source peptide from an MS/MS spectrum without searching any database. This approach can be useful for determining parts (peptide tags) or all of the sequence of unknown proteins, especially in the case of a proteome from an incompletely sequenced genome, or of mutated or modified proteins that failed to be identified by identification software. Since *de novo* sequencing algorithms do not use database information during spectrum interpretation, they work in a search space composed of the set of all possible sequences that can be represented by the spectrum without any other restriction than the peak patterns. However, these peak patterns can be of very low quality due to fragmentation errors, such as the presence of contaminants and noise, and to missing peptide fragments (noncontinuous signal). Due to these two issues, the size of the search space and the complexity of MS/MS spectra, *de novo* sequencing methods are difficult to automate and current *de novo* software tools often fail to extract correct sequence data.

Despite these issues, some tools are available for *de novo* sequencing. PEAKS [54] is one of them. It uses a dynamic programming algorithm to perform the computation and a mathematical model based on the abundance of ions in the spectra. PEAKS is distributed by Bioinformatics Solutions. Most other software for *de novo* sequencing (such as Spectrum Mill, SeqMS [31], Sherenga [24] or Luthefisk [81]) use a graph theory approach. The spectrum is first translated into a "spectrum graph" where nodes in the graph correspond to peaks in the spectrum and two nodes are connected by an edge if the mass difference between the two corresponding peaks is equal to the mass of an amino acid within a given mass tolerance. The software then attempts to find a path that connects the N- and C-termini, and to connect all the nodes corresponding to the *y* ions (or *b* ions, see Section 2.3 for ion explanations).

Popitam [41], also developed at the Swiss Institute of Bioinformatics, uses a hybrid approach. Similarly to *de novo* sequencing programs, it builds a spectrum graph, but only searches for paths or partial paths (tags) in the graph that match the sequence of candidate peptides from the database. The algorithm specifically allows for identifying modified and/or mutated peptides without any *a priori* knowledge about the expected type of modifications.

4.2 Characterization with MS

Even though the analysis of MS and MS/MS mass spectra can lead to the reliable identification of a protein, a considerable portion of the spectra often remains unmatched and could potentially represent PTMs. Bioinformatics plays an important role in this specific proteomics area with the development of software to help understanding these modifications.

The FindMod tool (http://www.expasy.org/tools/findmod) can be used for *de novo* prediction of PTMs in proteins and potential single-amino-acid substitutions in peptides [88]. It is typically used after PMF identification, and examines mass differences between theoretical peptide masses of a specified known sequence and empirical mass values. If such a mass difference corresponds to a mass difference known to be induced by a PTM, but not yet annotated in the Swiss-Prot entry, FindMod uses a set of rules to predict what amino acid residues in the peptide might carry that modification. FindMod can currently predict 22 modifications including acetylation, methylation, palmitoylation, phosphorylation, etc. For each of these modifications, at least one rule has been established by carefully examining the relevant annotations in the Swiss-Prot and PROSITE [29] databases as well as the literature, with respect to the type of organism, position and amino acid at which the modification can be observed. The same algorithm is applied to suggest possible single-amino-acid substitutions in peptides. In this way, the tool assists in characterizing a gene product and its possible interactions, activities and role in normal and disease states.

Glycosylation is one of the most abundant forms of covalent protein modifications and one of the most complex ones (see also Chapter 45). The range of monomers of which carbohydrate structures in glycopeptides can be composed is broad, and these monomers can be joined in many ways to form linear and branching structures. The diversity of carbohydrate compositions and structures results in a very large number of different potential PTMs that by far exceeds the relatively small number of modifications considered in FindMod. This diversity, as well as a variety of parameters specific to glycosylation, requires a specialized tool, GlycoMod (http://www.expasy.org/tools/glycomod) [18]. MS of glycopeptides can provide useful information on the composition of the attached oligosaccharides: if a peptide is presumed to be glycosylated, the mass of the oligosaccharide can be deduced as the difference between the experimental peptide mass and the mass predicted from the peptide sequence. The potential oligosaccharide compositions corresponding to this mass difference can be calculated from a combination of the masses of possible monosaccharide constituents [64]. GlycoMod considerably facilitates this assignment of mass to composition. The program is linked to Swiss-Prot so that peptide masses of known proteins can be accessed, screened for potential glycosylation sites (both *N*- and *O*-linked) and used in the identification of potential glycopeptides.

Other methods directly predict PTMs from the protein sequence, without any information from mass spectra. Even though they are outside the scope of pure proteomics, they are at least worth to be named. Usually these methods use machine learning or probabilistic approaches to predict modification sites on sequences. The server of the Center for Biological Sequence Analysis (CBS) in Denmark (http:// www.cbs.dtu.dk/services) proposes various predictors based on neural networks. These tools predict specific *N*-linked glycosylation sites in human proteins (NetNGlyc), *O*-glycosylation sites in mammalian (NetOGlyc [45] and YinOYang) and *Dictyostelium discoideum* proteins (DictyOGlyc [38]), acetylation sites (NetAcet [47]), and phosphorylation sites (NetPhos [11]). Myristoylator, a tool developed by the ExPASy team at the Swiss Institute of Bioinformatics, also uses a neural network model to predict the addition of a myristate to a glycine in the N-terminal chain [13]. The Sulfinator on the other hand uses hidden Markov models to localize sulfated tyrosine residues [59].

5 Proteome Databases

Biological related databases can be classified according to the type of information provided, i.e. protein sequences, nucleotide sequences, patterns/profiles, proteomes, 3-D structures, PTMs, genomic and metabolic data. Historically, the expression *proteome databases* was used to only describe databases holding proteomics data, i.e. the data produced by the technologies described in the previous sections, mainly 2-DE gel images and mass spectra. However, according to a more comprehensive definition of current proteomics, this expression has embraced other data resources available to the scientific community. This section briefly describes some of the relevant data resources. A more extensive list is published on a yearly basis by *Nucleic Acids Research*. Here we focus on sequence databases, 2-DE and MS, as well as PTM databases.

5.1 Protein Sequence Databases

The most comprehensive source of protein information is found in protein sequence databases. These can be divided into universal databases, which store protein information from all types of biological sources, and specialized databases, which concentrate their efforts on restricted groups of protein families or organisms. Universal protein sequence databases can be categorized into databases that are simple repositories of sequence data, mostly translated from DNA sequences, and in annotated databases. The latter requires the assistance of curators who screen the original literature, review articles as well as electronic archives. Here we mainly describe Swiss-Prot [12], an annotated universal sequence database, and TrEMBL, an automatically generated sequence database that supplements Swiss-Prot, as well as their integration with other proteomics resources.

Swiss-Prot (http://www.expasy.org/sprot) is a protein sequence database particularly known for its extensive annotation, minimum level of redundancy and maximum level of integration with other databases. Swiss-Prot is mainly manually curated, whereas the vast majority of TrEMBL entries are unannotated or automatically annotated. Created in 1986, release 46.4 includes more than 170 000 entries from more than 9000 different species. Swiss-Prot's main host is the ExPASy server and its eight mirror sites.

Swiss-Prot entries consist of different line types that are grouped into sections. The description section includes, among others, the accession number (a unique entry identifier), the update dates, the protein description (its *name*), the gene name and the taxonomic origin. It is then followed by the reference section, which, for each bibliographical reference, includes the type of experimental work contributing to the entry (sequencing, 3-D structure determination, mutagenesis studies, etc.), the author list and the literature references. The comment section follows then with a variety of textual remarks classified into topics such as function, subunit, similarity, PTM, MS source, etc. The subsequent section is the database cross-reference that provides active links to more than 60 different biological databases. The links to other proteomics databases like SWISS-2DPAGE, PROSITE/InterPro and PDB allow for rapid access to experimental proteomic data, like position and number of protein spots on a 2-DE gel, other members of the same family, or the 3-D structure of the protein. After a keyword section follows the so-called *feature table* section. It describes regions or sites of interest in the sequence as well as documented PTMs, binding sites, active sites, secondary structures, variants, conflicts, etc. The entry ends with the amino acid sequence itself, which is the unprocessed precursor of the protein, before any PTM or processing. Tools that identify proteins from mass spectra should ideally use the information held within the feature table. In order to achieve an optimal approximation of the protein in its mature state, the signal sequence and propeptides should be removed before computing pI and M_r. ExPASy-based proteomics tools such as Aldente and FindMod benefit from the annotation of Swiss-Prot to improve their capacities of identifying and characterizing active chains and proteins annotated with PTMs.

Since its creation, Swiss-Prot has been developed using high-quality manual and computer-assisted annotation, despite the currently large number of genome sequencing projects and, as a consequence the increasing number of sequences that have to be incorporated into Swiss-Prot. This is where TrEMBL (Translation of EMBL Nucleotide Sequence Database [8]) steps in. TrEMBL was created in 1996 as a supplement to Swiss-Prot and consists of computer-annotated entries in Swiss-Prot-like format. It is populated by protein sequences translated from the coding sequences (CDS) in EMBL. In a way, it can be considered as a waiting room to Swiss-Prot; indeed, once annotated, the entries are transferred to Swiss-Prot.

Since 2003, when the maintainers of Swiss-Prot and TrEMBL (the Swiss Institute of Bioinformatics and the European Bioinformatics Institute) joined forces with the PIR group at Georgetown University to form the UniProt Consortium [7], Swiss-Prot and TrEMBL are also known as the “UniProt Knowledgebase”.

As said in the beginning of this section, there are many specialized protein sequence databases available. Their contents vary a lot in terms of range of interest, number of entries, type of information and quality of the data. They are listed and detailed in the special issue on databases of *Nucleic Acids Research* as well as on the ExPASy server (http://www.expasy.org/links.html).

5.2 2-DE Gel Databases

Among proteomics databases, those containing 2-DE gel images with identified proteins, also known as reference maps, are widely used. These databases, usually freely accessible for academics through the Internet, contain clickable maps. The identified spots are linked to their identification method and the description of their identified protein. SWISS-2DPAGE [43] (http://www.expasy.org/ch2d) is the oldest and largest such 2-DE database. Created and maintained at the Swiss Institute of Bioinformatics in collaboration with the University Hospital of Geneva, in August 2006 it contained nearly 40 reference maps of various species including human, mouse, *E. coli*, etc. More than 1300 entries document over 4000 identified "spots". The proteins represented by these spots were identified by matching with other gels, by amino acid composition, by Edman sequencing, by immunoblotting and, mostly, by MS. The text format for each entry is similar to the Swiss-Prot model. It includes specific fields such as the type of master gel from which the protein spot has been identified, the list of gel images associated with the protein entry, as well as other 2-DE specific data, such as the mapping procedure, the spot identifier, the experimental pI and M_r, the MS data, and quantitative data about the protein expression (i.e. physiological and pathological levels, polymorphisms or modifications in specific conditions). The database has cross-references to Swiss-Prot and when no identified spot exists in SWISS-2DPAGE for a given entry in Swiss-Prot, an image is generated highlighting the theoretical position of the corresponding protein. Relevant literature references are provided with links to PubMed. SWISS-2DPAGE data are curated following the Swiss-Prot database standards, i.e. experts manually review the information before making it available. In addition, they follow the MIAPE (Minimum Information About a Proteomics Experiment) guidelines for reporting proteomics experiments recommended by the Human Proteome Organization (HUPO) Proteomics Standards Initiative (PSI) [63]. The MIAPE data exchange model is named as such by analogy to the MIAME (Minimum Information About a Microarray Experiment) model.

The 2-D database of the Max Planck Institute for Infection Biology (http://www.mpiib-berlin.mpg.de/2D-PAGE) is also among the most frequently updated proteomic databases, containing over 20 gels of microbial organisms as well as human, mouse and rat [58]. This database is now part of an interconnected proteome system containing information such as MS spectra, isotope-coded affinity tag (ICAT)-LC-MS spectra, textual descriptions of experimental protocols or results of protein identification [67]. The whole relational database and querying system is implemented in MySQL and uses other open source software such as R for data analysis and graphics. The proteomics local databases are extensively linked to other external public genomic and metabolic databases.

The number of 2-D PAGE databases and related data is slowly but continuously increasing. An up-to-date list can be found in WORLD-2DPAGE (http://www.expasy.org/ch2d/2d-index.html), an index of 2-DE databases and services. More than 25 species are represented in about 300 2-DE maps all over the world. The databases are established in various formats. However, an increasing number follows the principle of federated 2-DE databases [4], according to which the organization of and access to a database must comply with five simple rules. This set of rules was created to homogenize the querying and presentation of such proteomic databases and assist in interconnecting similar data through a cross-reference system, and as a consequence in sharing and distributing 2-DE data in a more effective way. Following those guidelines, the Make2D-DB II package was developed to help research groups to create their own 2-DE databases [60]. This free package not only helps nonexperts to publish their data on the Internet, but it also provides a graphical interface with query capabilities. It can be obtained at http://www.expasy.org/ch2d/make2ddb.html.

5.3 Mass Spectra Repositories

Mass spectra databases are still in their early stages. Three public repositories exist so far. The Open Proteomics database (http://bioinformatics.icmb.-utexas.edu/OPD) is a collection that contains approximately 400 000 spectra representing different experiments from *E. coli*, *Homo sapiens*, *Saccharomyces cerevisiae* and *Mycobacterium smegmatis* [71]. The mzXML Data Repository (http://sashimi.sourceforge.net/index.html) also contains a small number of collections of MS data obtained with different instruments (mainly ThermoFinnigan LCQ and Micromass Q-TOF Ultima) and various mixtures of proteins. The group that maintains this repertoire also distributes tools for MS analysis and has created the mzXML format for the representation of MS data. The third repository, PeptideAtlas (http://www.peptideatlas.org), contains a collection of identified peptides from LC-MS/MS experiments. Currently the experimental results contained in these repositories are not very detailed and data formats are excessively diverse, making their use by other groups difficult.

5.4 PTM Databases

In an era in which more than 100 complete genomes are sequenced per year, the issue of understanding proteins and proteomes relies also on understanding protein modifications that cannot be predicted from the nucleic acid sequences. Most proteins indeed contain PTMs and are not functional unless they are modified. While Swiss-Prot, as a universal database, places a considerable emphasis on the documentation of PTMs within the sequence records, several specialized databases have been set up in recent years to feed this growing field.

RESID [33] is a general database of protein structure modifications (http://www-nbrf.georgetown.edu/pirwww/dbinfo/resid.html), maintained by the National Biomedical Research Foundation in the USA and the PIR group. The database contains descriptive, chemical, structural and bibliographical information on 424 (Release 46.00, June 2006) types of modified amino acid residues. Apart from text-based searches, RESID can also be queried by molecular weight: an average or mono-isotopic mass can be entered (together with a mass variance) to search for all modified amino acid residues in the database with masses similar to the input mass. Unimod (http://www.unimod.org) can be seen as a complementary database to RESID [20]. It is a database for verifiable spectrometric mass values of natural or artificial modifications. It is especially dedicated to mass spectrometric analysis software.

Other databases that are specialized in one particular type of PTM are available. For example, two databases have so far been devoted to glycosylations. The public O-GLYCBASE v6.00 contains about 240 descriptions of glycoproteins that have been experimentally verified to have an O- or C-glycosylation site [37]. O-GLYCBASE entries show the type of *O*-linked sugar involved, the species, the sequence, links to the literature, and cross-references to sequence and structure databases such as Swiss-Prot and PDB. GlycoSuiteDB (http://www.glycosuite.com) is an annotated database of glycan structures restricted to accredited users and submitted to license fees. The database is provided by Proteome Systems, and contains information about most published *O*- and *N*-linked glycans [19]. It is cross-referenced to Swiss-Prot/TrEMBL and it can be queried by mass, by attached protein, by oligosaccharide composition or different modes of textual queries (taxonomy, biological source, etc.).

Protein phosphorylations are currently described in at least three databases differing in the curation levels, details of information and scope of organisms. Phospho.ELM [25] and Phosphorylation site [90] databases (http://phospho.-elm.eu.org and http://vigen.biochem.vt.edu/xpd/xpd.htm, respectively) describe experimentally verified covalent phosphorylations of serine, threonine or tyrosine residues in proteins from eukaryotes (human, mouse, rat and a thousand other organisms) and prokaryotes respectively. PhosphoSite^{TM} (http://www.phosphosite.org) is a curated database dedicated to *in vivo* phosphorylation sites, particularly in human and mouse proteins [44]. Lipoproteins are the object of DOLOP (http://www.mrc-lmb.cam.ac.uk/genomes/dolop), which is restricted to bacterial lipoproteins only. This server also has a predictive algorithm for querying unknown prokaryotic sequences looking for lipoboxes and lists of predicted lipoproteins for multiple completed bacterial genomes [56].

Although the current number of specific PTM databases is still quite small considering the number of known PTMs, it has doubled in the last few years. It is expected that they will multiply because of the increasing amount of data on PTM structures becoming available.

5.5 General Considerations on Databases

It is clear that the databases described above do not cover all the aspects of proteomics. We did not mention databases that use sequence databases to perform calculation and analysis, such as sequence clustering, phylogeny or profile searching, and thus create added-value databases. Other databases report results from functional studies and mutational experiments, or from 3-D structure determination, or describe metabolic pathways. Those were not mentioned here either. It would be impossible to be exhaustive. Some of the databases have already been treated in other chapters. Some of them are permanently updated, some of them have only a short existence, and some of them are not even publicly available. Proteomics databases, as well as data formats, are developed in a dynamic, nonorganized way. To overcome this issue and to facilitate the exchange, dissemination and analysis of the multitude of proteomics data produced by many laboratories, the HUPO PSI has been working on generalized standards representations [63]. Among them are guidelines for reporting proteomics experiments through the MIAPE data integration model, XML formats for microarray and MS data exchange, a list of proteomics ontologies, and guidelines for the comparability of search engine results.

Proteomics information in most databases is accumulated rather than enlarged to a systemic view. The biology understanding is incomplete without quantification and chronology. If the goal of accumulating information is to discover or reveal the function and related biochemical mechanisms, available information has yet to be interconnected, weighed and ordered. Proteome databases are moving from the stage of simple repositories to interconnected systems with intelligent knowledge production means.

6 Conclusion

The development of diagnostic and predictive tools as well as successful therapies for complex polygenic diseases including diabetes, cancer and cardiovascular diseases requires the understanding of the fundamental biological mechanisms implicated in these disorders. This can be achieved under defined environmental conditions with strategies that combine genetic and proteomic tools. Proteome analysis has the ability to detect and identify polypeptides that correlate with disease states, and further lead to the discovery of potential molecular markers and therapeutic targets. Furthermore, proteomic technologies can display the pharmacological and toxic effects of candidate drugs on a disease process. There is a close relationship between drug treatment, protein expression and resulting physiological effects. Most of the time, pharmacological mechanisms entail the secondary regulation or modulation of gene product expressions, in a similar way that complex disease processes alter global protein expression. From this, we can assert that the best drug should be the one that restores global protein expression of a disturbed organism to a normal state. In addition, it is quite unusual that a drug only modulates gene products implied in the disorder. Most of the time, it also causes perturbations in the expression of proteins that are not involved in the disease. This leads to side effects of drugs. Proteomics and bioinformatics are deeply implicated in the understanding of disease and drug effect mechanisms and the design of new drug therapies. This chapter has just given a brief overview of their joined capabilities.

Acknowledgment

The authors would like to acknowledge Dr Manfredo Quadroni (Protein Analysis Facility, Lausanne University, Switzerland) for the LC-MS data.

Part 8 Protein Function Prediction

29
Ontologies for Molecular Biology

Chris Wroe and Robert Stevens

1 Introduction

This chapter provides an overview of the application of ontologies within the bioinformatics domain, specifically for the representation of protein function. We will provide a background of the ontology field and its technical basis as well as the current developments. We will then link the features of ontologies with the issues faced in bioinformatics, underscoring how ontologies can help. Having done this, we will provide some case studies pertinent to bioinformatics, in general, and protein function, in particular.

Molecular biology currently lacks the mathematical support prevalent in disciplines such as physics and chemistry. In physics, we have laws based in mathematics that allow us to predict planetary orbits, behavior of waves and particles, etc., from first principles. In molecular biology, we cannot yet take a protein sequence and use the amino acid residues present to calculate the structure, molecular function, biological role or location of that protein. All that can be stated is that: "Sequence is related to molecular function and structure". Using this "law", a biologist must compare a novel protein sequence to others that are already well charaterized. If the uncharaterized sequence is sufficiently similar to a charaterized sequence, then it is inferred that the characteristics of one can be transferred to the uncharaterized protein – hence the sequence similarity search. The characterization of single sequences lies at the heart of most bioinformatics, even the new high-throughput techniques that investigate the modes of action of thousands of proteins per experiment. When performing a sequence similarity search, it is not simply the similarity statistics that determine biological insight into the uncharaterized protein.

Bioinformatics – From Genomes to Therapies Vol. 3. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

The bioinformatician uses the knowledge about the proteins already characterized in order to arrive at any insights. Thus, it has been said that biology is a knowledge-based discipline [3].

Much of the community's knowledge is contained within its curated databases. In a database such as UniProt/Swiss-Prot, the protein sequence data itself is a relatively small part of the entry. Most of the entry is taken up by "annotation", which can be considered the knowledge component of the database. This knowledge is usually captured as stylized natural language. Even this form of text provides flexibility in the way information can be expressed. The same function can be described using different terms in different resources or the same term can ambiguously describe different concepts in different resources [6, 12]. This semantic heterogeneity is a perennial problem in integrating bioinformatics resources. Although this style of representation is suitable for human readers, the current representation of the knowledge component is difficult to process by machine. Automated integration of data from different resources is becoming essential because of the following features of bioinformatics data:

- *Large quantity of data.* The genome-sequencing projects now imply that data is being produced at increasingly fast rates; a new sequence is deposited in the public genome database EMBL every 10 s. Microarray experiments measuring gene expression and other high-throughput techniques now imply that other data are also being produced in vast quantity, at petabytes per year [13].

- *Complexity of data.* It is difficult to represent most biological data directly in numeric form. As well as the basic data representation, a characteristic of biological data is the many relationships held by each entity. For instance, any one protein has a sequence, functions, processes in which it acts, locations, a structure, physical interactions it makes, diseases in which it may be implicated and many more relationships. Not all relationships are present in a single resource. Information must be integrated to build a complete picture.

- *Volatility of data.* The content of bioinformatics databases reflects the current knowledge of the community and so is constantly evolving.

- *Distribution of data.* In bioinformatics, each small community of researchers often takes the initiative for publishing their data and analysis tools. Bioinformatics uses over 700 of these data resources and analysis tools found all over the Internet [9]. They often have web interfaces through which biologists enter data for analysis, cut and paste results to new web resources or explore results through rich annotation with cross-links [17].

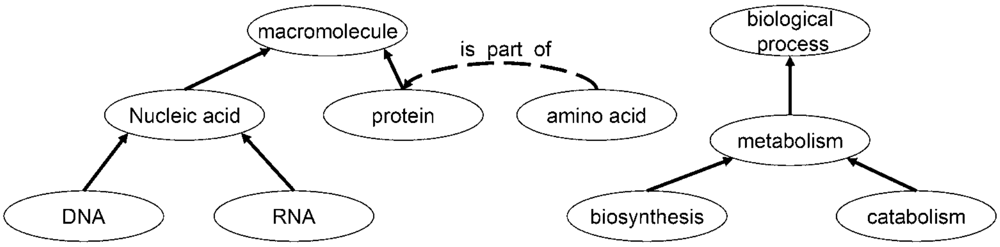

Figure 1 A simple illustration of what can constitute an ontology. Ovals represent concepts, which are classes of instances; the solid arrows represent "is a" relationships, such that all members of a child class are also members of a parent class. The dotted arrow shows a part of relationship between amino acid and protein.

This scene leaves both the maintainers of bioinformatics resources and their users with significant challenges if they are to integrate knowledge from a number of distributed databases. Annotations in each database must be captured in a consistent manner if they are to be comparable to other data. Given the quantity and volatility of the data, it is no longer tenable to manually sift through data for novel insights. Some form of automated assistance is needed to integrate disparate knowledge and filter only relevant data. Therefore, the knowledge component must also be machine interpretable, i.e. computer applications must be able to understand to some extent what the data means: its semantics.

2 Ontologies and their Components

An ontology attempts to capture a community's understanding of a domain as a structured collection of vocabulary terms and definitions [38]. An ontology describes what a community understands and how it communicates about its domain of interest, e.g. the functions of proteins. It describes, in a conceptual form, the things that exist in the domain, both concrete and abstract, such as protein molecule, amino acid, enzyme, α-helix, species, protein function, process, location, disease, etc. It also describes the relationships between these concepts. For example, an ontology can describe knowledge such as the fact that all proteins are comprised of amino acids. Figure 1 shows a simple ontology of some of the basic components of molecular biology.

The term ontology has its origins with Aristotle and in the philosophical domain it is the art of describing things that exist in the world. Computer science has taken this term and altered it. In computer science, an ontology is a conceptualization of a domain of interest, rather than a description of reality. Concepts are units of thought that refer to things in the world – protein, function, sequence [27]. Words are symbols that we use to communicate about things in the world and, in an ontology, terms are used to label concepts. It is these terms that are used by a community to talk about the domain of interest. If the conceptual model of the world (ontology) and the terms for those concepts (lexicon) can be agreed upon by the community, then ambiguity in communication can be reduced. This shared or common understanding of a domain is one of the primary aims of an ontology. A goal of computer science research into ontology representation is to make these conceptualizations of human knowledge processable by computers in a manner that enables them to make inferences about the knowledge stored in them. In summary, the main components of an ontology are:

- The concepts representing entities that exist in the domain. A concept can either be a class that represents a set of instances or a particular instance itself.

- The terms or symbols that label those concepts and allow humans to communicate about those concept or entities in the world.

- The relationships between those concepts. The principle among these is the "is a" relationship that describes a parent–child relationship, or class–subclass, where every instance of the child concept is also a kind of the parent concept. The second major relationship is the "part of" relationship that describes parts and their wholes [39], such as parts of proteins (active site, α-helix, amino acid residue) and their relationship to the whole protein. Other associative relationships are used: causative, nominative, etc.

- Other statements about the concepts and relationships. In logic systems, for example, it is possible to say that sibling concepts are disjoint – it is not possible for an instance to be a member of both classes. Other statements might include equivalence between classes or that the members of child classes completely covers all the members of the parent class.

Although biologists may not have used the term "ontology", the use of classification and description as a technique for collecting, representing and using biological knowledge has a long history in the field. For example, the Linnaean classification of species is ubiquitous and the Enzyme Commission has a classification of enzymes by the reaction that they catalyze [16]. Families of proteins are also classified along axes such as function and structural architecture [12]. Over the past years there has been a surge of interest in using ontologies to describe and share biological data, reflecting the surge in size, range and diversity of data, and the need to assemble it from a broad constituency of sources.

2.1 Ontology Representation

The computer science ontology field is a direct descendant of the knowledge representation (KR) and reasoning work done within the artificial intelligence community over the last several decades. There is not sufficient space in this chapter to provide a complete history of KR; however, it is important to understand that a whole range of formalisms have been developed which capture differing degrees and types of expressivity, computability, and satisfiability, and each has applicability within a particular problem space. Two key styles of representation – frame-based and description logics – have relevance to current ontology work and so we will provide a brief definition.

Frame-based systems are most like object-oriented systems and provide a high degree of structure. They are centered around the idea of a frame, or a class, where each frame represents a set of instances of that frame or class. Each frame has associated slots which represent attributes of the frame. Slots are filled by specific values or by other frames. Slots may be of various kinds. So, for example, frames may have an associated "is a" slot, mentioned earlier, which is used to create a taxonomy within the frame system. The "part of" slot, another highly important slot or relationship, may also be represented in a frame-based system. The frame-based representation system is the most widely used of the KR formalisms and has been used extensively within the life sciences community, e.g. in EcoCyc described in Section 3.6.1.

Description logics (DLs) allow ontologies to be built in a very different way from frame-based systems. Rather than making the author build a taxonomy explicitly (an error-prone task for complex ontologies), a DL provides reasoning capabilities, in the form of a classifier, that will build the ontology from smaller conceptual units. These smaller conceptual units provide sufficient description, a concept with one or more associated relationships, so that the DL reasoner can classify the new concept in the proper place within the ontology. DLs have been of significant interest in the last several years and provide the underlying representation for the Web Ontology Language (OWL).

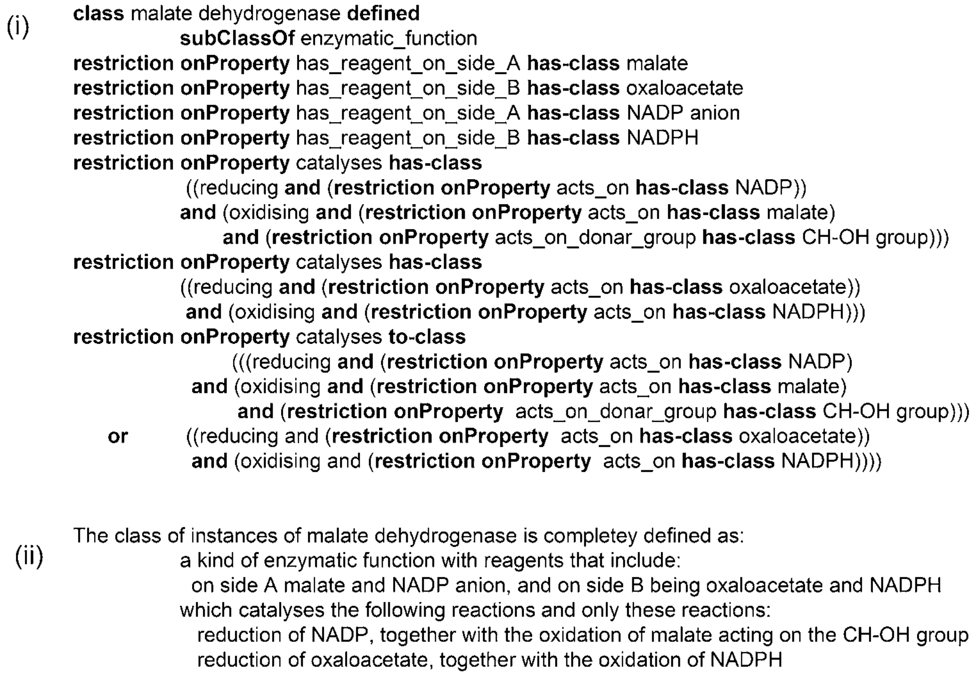
OWL is a KR and transfer language for building ontologies that delivers vocabularies with a formal semantics. It became a W3C recommendation in February 2004 and is descended from the earlier language DAML+OIL [14]. OWL has three increasingly expressive sublanguages: OWL-Lite, OWL-DL, and OWL-Full. It also has a rules language under development for capturing knowledge that cannot be contained in an ontology [1]. The OWL languages are:

- OWL-Lite – provides the capability to describe simple taxonomic classifications and lacks the expressivity to make rich descriptions of classes of instances. It provides a migration path for thesauri and simple taxonomies, such as those commonly seen in current bio-ontologies.

- OWL-DL – an expressive language that is a fragment of first-order logic. This means that it is amenable to machine reasoning. Ontologies described in OWL DL can be checked for logical consistency and subsumption hierarchies (the lattice of "is a" links) inferred from the descriptions of classes formed from the links made between classes [34,35]. This form of OWL will be our focus.
- OWL-Full – more expressive than OWL-DL, but is not yet fully amenable to machine reasoning.

In OWL, classes describe sets of instances or individuals that belong together because they have properties in common (enzyme function is the class of all functionality which can catalyze a reaction – lipase, dehydrogenase, etc.). Classes may be arranged into subsumption hierarchies using the subclass relationship. By stating that receptor binding is a subclass of signal transducer activity, we are stating that all instances of receptor binding are also instances of signal transducer activity. Properties can be used to state relationships between classes and individuals or from individuals to data values. For example, we can say that instances of the class peptide binding act on instances of the class peptide. In OWL DL, we can place restrictions on how properties form relationships that make what that relationship means explicit. We can use existential quantification, to state that all instances of one class have a relationship to some instance of another class, i.e. all peptide binding acts on some peptide (but might also bind something else too), or we can use universal quantification to restrict the target of a relationship to only instances of a certain class – all peptide binding (if it acts on anything) acts on only peptide. We can form more complex expressions by saying that all instances of the class peptide binding acts on some peptide and acts on only some peptide.

OWL-DL is much more expressive than this fragment indicates. For instance, we can describe properties of properties such as transitivity, range and domain constraints, and form hierarchies of properties. It is also possible to say that the instances of two sibling classes do not overlap by using a disjointness axiom – the classes protein and nucleic acid are both kinds of macromolecule, but being disjoint it is not possible for an individual protein to also be a nucleic acid. We can also describe a class as being partial or complete. When the properties of a class are partial, those properties are necessary conditions of class membership, i.e. an instance must have those properties. Describing a class as complete means that an instance having those properties is sufficient to recognize it as a member of that class. So, labeling our class peptide binding as complete would mean that any instance



```
(i)   class malate dehydrogenase defined
                 subClassOf enzymatic_function
      restriction onProperty has_reagent_on_side_A has-class malate
      restriction onProperty has_reagent_on_side_B has-class oxaloacetate
      restriction onProperty has_reagent_on_side_A has-class NADP anion
      restriction onProperty has_reagent_on_side_B has-class NADPH
      restriction onProperty catalyses has-class
                  ((reducing and (restriction onProperty acts_on has-class NADP))
                 and (oxidising and (restriction onProperty acts_on has-class malate)
                     and (restriction onProperty acts_on_donar_group has-class CH-OH group)))
      restriction onProperty catalyses has-class
                 ((reducing and (restriction onProperty acts_on has-class oxaloacetate))
                  and (oxidising and (restriction onProperty acts_on has-class NADPH)))
      restriction onProperty catalyses to-class
                      (((reducing and (restriction onProperty acts_on has-class NADP)
                  and (oxidising and (restriction onProperty acts_on has-class malate)
                      and (restriction onProperty  acts_on_donar_group has-class CH-OH group)))
         or       ((reducing and (restriction onProperty  acts_on has-class oxaloacetate))
                  and (oxidising and (restriction onProperty  acts_on has-class NADPH))))

      The class of instances of malate dehydrogenase is completey defined as:
(ii)             a kind of enzymatic function with reagents that include:
                  on side A malate and NADP anion, and on side B being oxaloacetate and NADPH
                 which catalyses the following reactions and only these reactions:
                   reduction of NADP, together with the oxidation of malate acting on the CH-OH group
                   reduction of oxaloacetate, together with the oxidation of NADPH
```

Figure 2 A complex illustration of the detail an ontology can capture. (i) Human-readable OWL syntax showing the definition for malate dehydrogenase. (ii) A paraphrase of the definition in English

of binding that acts on peptide would have to be a peptide binding. Figure 2 shows how complex an OWL definition can become by showing a candidate definition for the concept malate dehydrogenase in OWL abstract syntax and a paraphrase of the definition in English.

3 Ontologies in the Real World

The previous sections have described the high-level purpose of ontologies and how the ontology language OWL provides us with a wide range of features to formally capture the key concepts of a domain. However, it must be appreciated that building a life science ontology is a significant undertaking. Formal definitions take time to author, with expertise required both in life sciences and KR. Definitions must be checked by the community to ensure they adequately capture their shared understanding. As the communities' knowledge evolves so must the ontology and so at least as much effort is needed to maintain an ontology as was required to build an initial version.

Several approaches have been used by existing ontology developers to mitigate the large amount of effort needed to embark on such a programme.

- *Use of ontology tools.* Sophisticated editing tools can greatly improve the productivity of ontology authors, especially when it becomes necessary to build large ontologies or ontologies with complex concept definitions.
- *Use of existing ontologies where possible.* Having multiple ontologies covering the same areas can be both wasteful and defeat the purpose of a *common* understanding.
- *Incremental development.* By only representing what is currently needed both in terms of coverage and also the degree to which concepts are formally defined, it is possible to greatly reduce development and maintenance effort.

It is important therefore to be aware of current ontology tools, life science ontologies and the way representational features in ontologies support different requirements. Section 3.1 provides an overview of ontology tools and Section 3.2 provides an overview of how the bio-ontology community has begun to support a clearinghouse of community ontologies. To provide both an overview of current ontologies and of phased development, key ontologies will be examined from Section 3.3 onwards to illustrate how the features they include directly support the requirements of that community.

3.1 Ontology Tools

There are now a number of commercial and open source tools for the development, maintenance, merging and visualization of ontologies. A comprehensive survey of ontology tools was conducted in July 2004 by XML.com [7]. We will not attempt to reproduce that survey here, but it is worth mentioning some tools and organizations that are notable within the ontology field.

Undoubtedly, the best-known ontology authoring tool is Protege, from the Stanford Medical Informatics group at Stanford University (http://protege.stanford.edu) [11]. This tool has been in use for over 10 years and it could be argued that it has been around longer than that, since it is an outgrowth of the KR initiatives at Stanford University that have been in existence since the 1970s. Protege has a large and very active user community within a number of commercial and academic projects, and is open source, so that it can be downloaded at no cost and is easily installed. There are several mailing lists to which developers and new users may subscribe, and the tool comes with example ontologies to help new users get started on a project. Protege has a core engine which is extended with plugins. There are a number of plugins and the user community is actively involved with creating new ones. Two recent plug ins are the "OWL-plugin" for writing ontologies in OWL and the "Protege Wizards" plugin developed by the Co-ODE project (http://www.co-ode.org) for simplifying repetitive tasks while writing a large ontology in OWL.

Another tool that is widely used in the life sciences community is DAG-Edit (http://www.geneontology.org/doc/GO.tools.html#dagedit). DAG-Edit was developed at the Berkeley *Drosophila* Genome Project (BDGP) to be used as a part of the knowledge acquisition effort of the Gene Ontology (GO) Consortium. DAG-Edit was initially limited in its representational capabilities, and has been primarily used to represent simple "is a" and "part of" relations; however, it is simple to use, and has been a very effective tool in the development of the very successful GO effort and others. The success of DAG-Edit is in its ability to rapidly assimilate new content for GO.

In addition to these two tools, there are well over 50 other ontology authoring tools, of varying degrees of sophistication and ease of use, from universities and research organizations around the world. There are a large number of commercial organizations that offer commercial ontology authoring tools. Some of the more prominent of these commercial tools are: LinkFactory Workbench from Language and Computing, Integrated Ontology Development Environment (IODE) from Ontology Works, OntoEdit from Ontoprise, OpenCyc Knowledge Server from Cycorp and Construct from Network Inference. Although none of these tools, commercial or academic, yet have complete support for all of the representational capabilities of ontology languages such as OWL or DAML+OIL or the reasoning capabilities of DLs, there are a number of sophisticated tools and a lively marketplace for developing the next breed of tools.

3.2 Bio-ontology Communities

To be effective, an ontology must comprise the shared understanding of a community for a particular subject area. It is therefore important once an ontology has been built to disseminate it so that the effort in building it is not needlessly repeated; the community can contribute to its maintenance and other allied communities can build upon it in their work. The organizations that are promoting the development and the adoption of ontologies in the life sciences field include the GO Consortium, Microarray Gene Expression Data (MGED) group, the Bio-Ontologies Consortium, and the Bio-Pathways Consortium. The GO Consortium (http://www.geneontology.org) brings together 17 model organism databases (at the time of writing) to develop GO. As each new organization joins, they commit to using the GO terms to describe the functionality of gene products in their databases. As a consequence, each new group drives the development of the GO to make available terms needed for that species.

Sequence Ontology (SO) is also part of the GO Consortium. It is a grouping of genome annotation centers, including WormBase, BDGP, FlyBase, the Mouse Genome Informatics group and the Sanger Institute. The aim is to provide a shared vocabulary for the features described on nucleotide and protein sequences. It is intended to range from the basic features seen on a sequence, through interpretations such as "pseudogene" to mutations [8].

The Open Bio-Ontologies effort (OBO) acts as an umbrella under which bio-ontologies may be developed and disseminated (http://obo.sourceforge.net). OBO has a set of principles that govern inclusion:

- Submitted ontologies must be open, but cannot be altered and re-distributed under the same name.
- Use cannot be restricted – ontologies are for sharing.
- A common representation should be used – either the form accepted by DAG-Edit or OWL.
- Ontologies should be nonoverlapping.
- Namespace identifiers should be used in order that any entity within an ontology can be identified as to its source.
- All terms should have a textual definition to prevent ambiguity in interpretation by human readers.

OBO offers access to a wide range of ontologies. Prominent amongst these are several ontologies of anatomy for various species. These are of particular interest to the community as they can be used to identify the biological source of material in experiments – "This microarray experiment used mouse lung", etc. In addition to anatomies, there are also several ontologies of development within species. Finally, there are a growing number of phenotype ontologies available, including traits, disease and behavior.

BioPAX (http://www.biopax.org) is a consortium of pathway databases that aims to develop an exchange language for biological pathways. Pathways include the metabolic, regulatory and signal pathways. The BioPAX initiative aims to overcome the heterogeneity of formats and conceptualizations in the many pathway databases. Initially, BioPAX has used an ontology, written in OWL, to develop a schema for describing the entities and their attributes to be exchanged. Further levels of BioPAX will be developed to provide for controlled vocabularies for the description of pathway data.

MGED has a similar goal to that of BioPAX in that it aims to develop both schema and the vocabularies that fill attributes of that schema for the description of microarray experiments. MGED has been in existence longer than BioPAX, and has a developed an ontology to provide vocabularies for the description of biological samples, their treatments and the experimental conditions pertaining during hybridizations [36]. This ontology is now moving away from the world of model organisms to include toxicology and environmental genomics experiments. As proteomics experimentation develops, there are efforts being made to share descriptions of experiments across broader communities.

While BioPAX, GO and MGED are the most prominent and mature molecular biology ontologies, they are not the only efforts within the life sciences community to develop open-source ontologies. There are also active efforts to develop ontologies in a number of other areas, including:

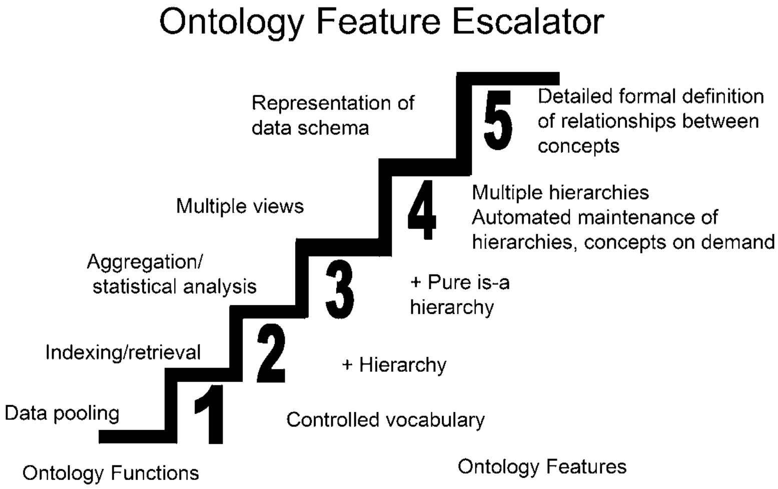
- Foundational Model of Anatomy (FMA) [31]: an ontology of human anatomy.
- Tissue Ontology [32]: offers a controlled vocabulary for describing tissues across a range of contributing databases.
- Chemical Entities of Biological Interest (ChEBI): a dictionary of small molecular entities that are either products of nature or synthetic products used to intervene in the processes of living organisms (http://www.ebi.ac.uk/chebi/).

All of these organizations have common goals. There is a recognition that this is a community effort and that inclusion of the community will make an ontology work [2,21].

3.3 Incremental Development of Ontologies

Specifications for rich ontology languages such as OWL do not demand that all their features be used. As few features can be used as necessary. Therefore, most successful life science ontology activities narrow the scope and features of the ontology to match their essential set of requirements. They then put in place a procedure to manage the continuing development of the ontology, to ensure it both keeps pace with changing requirements and the changing knowledge of the community [2].

The following section details how a wide range of current bio-ontology-like resources capture different aspects of protein function with different degrees of formality. Their differing design is a result of different requirements. Each resource can be placed on a "feature escalator" as shown in Figure 3. Adding new representational features to the ontology adds more functionality at the cost of complexity to maintain. Fortunately, the decision need not be fixed. Later examples will show how an ontology can be moved along the escalator to meet changing requirements.



Ontology Feature Escalator

+ Hierarchy
Data pooling
1
Controlled vocabulary
Ontology Functions
Ontology Features

Figure 3 A five-level escalator in which increasing features provide more advanced functionality, but at the cost of complexity.

As stated earlier, the challenges of bioinformatics dictate that some of the key uses of an ontology in life sciences are:

- Pooling knowledge based content between databases by use of a shared vocabulary.
- Supporting database browsing by using the structure of the ontology.
- Aggregating database content by again using the structure of the ontology.
- Supporting the integration or exchange of data by using an ontology to describe its schema.

3.4 Ontology Features to Manage Database Content

3.4.1 A Controlled Vocabulary with Human Readable Definitions

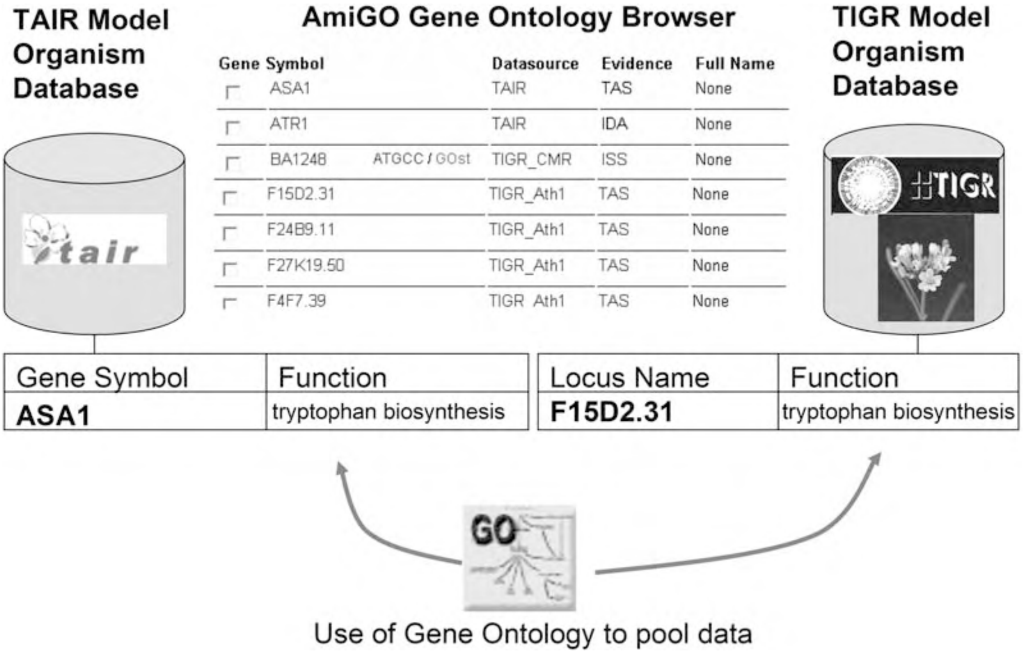
A controlled vocabulary is a constrained list of classes and associated terms used to describe qualitative data. When a community agrees on such a list for aspects of their data, it is possible for computer applications to pool data across distributed databases. This was one of the primary aims of the GO Consortium when developing the GO [37].

3.4.1.1 **Gene Ontology** It is clear that organisms across the spectrum of life, to varying degrees, possess large numbers of gene products with similar sequences and roles. Knowledge about a given gene product (i.e. a biologically active molecule that is the deciphered end-product of the code stored in a gene) can often be determined experimentally or inferred from its similarity to gene products in other organisms. Research into different biological systems uses different organisms that are chosen because they are amenable to advancing these investigations, e.g. the rat is a good model for the study of human heart disease and the fly is a good model to study cellular differentiation. For each of these model systems, there is a database project employing curators who collect and store the body of biological knowledge for that organism. This enormous amount of data can potentially add insight to related molecules found in other organisms. A reliable wet-lab biological experiment performed in one organism can be used to deduce attributes of an analogous (or related) gene product in another organism, thereby reducing the need to reproduce experiments in each individual organism (which would be expensive, time consuming and, in many organisms, technically impossible). However, querying these heterogeneous, independent databases in order to draw these inferences is difficult – the different organism database projects may use different terms to refer to the same concept and the same terms to refer to different concepts. Furthermore, these terms are typically not formally linked with each other in any way. GO seeks to reveal these underlying biological functionalities by providing a controlled vocabulary that can be used to describe gene products and is shared between biological databases. The terminology of GO is used to annotate gene products with respect to three attributes: the specific molecular functions that these products possess, the higher-level biological processes in which they participate and the cellular components in which they can be found. GO has currently been used for over 1 million annotations of gene products within the various participating databases. This facilitates querying for gene products that share biologically meaningful attributes, whether from separate databases or within the same database. Figure 4 shows how it is straightforward to pool data using GO.

GO does not aim to capture a full description of a particular gene product's function. A protein may have a many functions in different circumstances and the exact nature of that functionality may differ subtly in different conditions. Annotation with a GO term simply states that a gene product has been demonstrated or inferred to have a certain capability, without describing in what circumstances.

Appropriate and consistent use of GO concepts requires all annotators to have a common understanding of what each concept represents. Therefore the GO Consortium places a great deal of effort in providing a definition for each concept. The vast majority of GO concepts have a textual definition.

3.4.1.2 **MGED Ontology** When interpreting biological data it is important to consider the experimental conditions under which it was obtained. This is particularly true in microarray experiments where very small variations in conditions or technique lead to incomparable data. As introduced in Sec-



TAIR Model Organism Database
tair
AmiGO Gene Ontology Browser
TIGR Model Organism Database
TIGR
GO
Use of Gene Ontology to pool data

Gene Symbol		Datasource	Evidence	Full Name
ASA1		TAIR	TAS	None
ATR1		TAIR	IDA	None
BA1248	ATGCC / GOst	TIGR_CMR	ISS	None
F15D2.31		TIGR_Ath1	TAS	None

F27K19.50		TIGR_Ath1	TAS	None
F4F7.39		TIGR Ath1	TAS	None

Gene Symbol	Function
ASA1	tryptophan biosynthesis

Locus Name	Function
F15D2.31	tryptophan biosynthesis

Figure 4 Two model organism databases, TIGR and TAIR, both use GO concepts to annotate the biological processes in which the gene product has been found to participate. In this case two gene products ASA1 and F15D2.31 are involved in tryptophan biosynthesis. The GO browser AmiGO (http://www.godatabase.org) can quickly access this pooled information.

tion 3.2, MGED facilitates the sharing of microarray data generated by functional genomics and proteomics experiments. The main products of MGED are the Minimum Information About a Microarray Experiment (MIAME) guidelines [4] which have been formalized in the Microarray Gene Expression Object Model (MAGE-OM), markup language (MAGE-ML) and associated ontology, the MGED ontology. Information about an array experiment is separated into a number of packages such as array design, experiment and biomaterial. For each package MAGE-OM and MAGE-ML specify the structure of relevant information. For example, that one specific kind of biomaterial "biosource" denotes the initial source of material used in the experiment such as the specific tissue of an organism. The MGED ontology has a structure which mirrors to some extent this organization of packages in MAGE. It has a term that corresponds to "biosource". However, in this case it does not provide terms needed to describe the source in detail, e.g. the species of originating organism. In line with the principles described in Section 3 the annotator is expected to use an existing controlled vocabulary such as the National Center for Biotechnology Information (NCBI) organism taxonomy. In other cases, where an existing vocabulary is not available, the MGED ontology *does* provide a list of controlled terms. There are a list of 51 terms to describe the actions that can be performed on a biomaterial, e.g. “dissect”, “harvest” and “purify”. Each term has an associated text definition to assist annotators in choosing the appropriate term. There is, however, no organization of these lists of terms.

3.4.2 A Structured Controlled Vocabulary

If the number of concepts grows, there is a requirement to organize the concepts into related groups to form a tree, where each concept has a parent. However, the principles by which the concepts are organized can differ greatly. The Medical Subject Headings (MeSH) [22] is an example of a controlled vocabulary in a thesaurus structure used to assign keywords to life science publications. In a thesaurus-like vocabulary the relationship between parent and child concepts is a vague “narrower than, broader than” one. The shape of the tree is designed to (i) assist manual navigation around the tree and (ii) help retrieval of items associated with concepts. A parent–child relationship is added if a search for documents with the parent term should return documents annotated with the child term. Therefore, Accident Prevention G03.850.110.060 is a child of Accidents G03.850.110, despite not being a subclass of the parent term. A computer system can use this structure to support retrieval of data (publications in the case of MeSH).

3.4.3 A Subsumption Hierarchy

Many ontology-like resources have been used, not just for manual navigation and retrieval, but for statistical aggregation of data. For example, GO allows scientists to produce statistics of the number of gene products demonstrating a particular class of function. Figure 5 shows the AmiGO browser (http://www.godatabase.org) with which it is possible to show that currently 27% all annotated gene products demonstrate a binding function (GO:0005488). In order to provide this information a vague “broader than, narrower than” parent–child relationship is not sufficient. In the example above if there is an instance of Accident Prevention it does not hold that it is also an instance of Accidents. If a gene product is annotated with a descendent of binding such as peptide receptor activity (GO:0001653), it must be true that the gene product also shows binding functionality. The GO Consortium call this the “true path rule: the pathway from a child term all the way up to its top-level parent(s) must always be true”. In KR, the relationship in which membership of a child class implies membership of the parent class is called *subsumption*. OWL uses the subclass keyword to denote a subsumption relationship. Limiting the hierarchy to just subsumption relationships, whilst making the structure more amenable to machine processing, makes it more

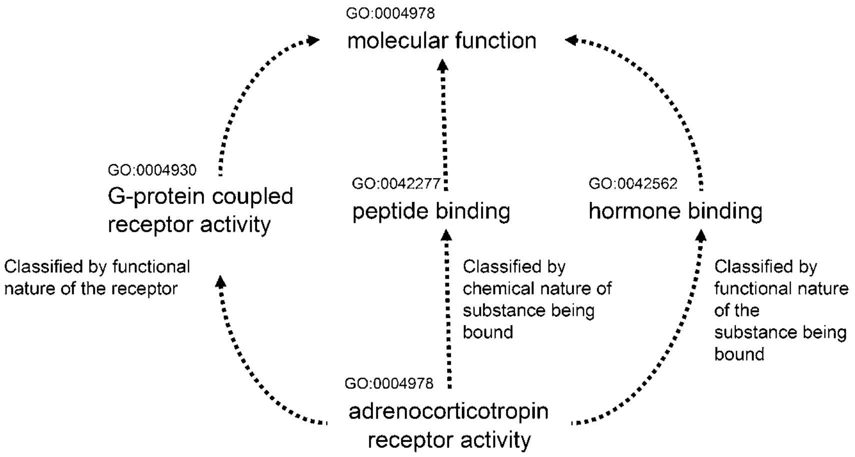
Figure 5 Screen shots from the AmiGO browser (http://www.godatabase.org). The left-hand side shows the subsumption hierarchy for molecular function. The right-hand side shows the aggregated statistics for gene products from all databases annotated with descendants of molecular function terms. In total, 150 732 gene products have been annotated with a molecular function. Of those, 40 263 (27%) have been annotated with binding.

difficult to navigate by users, because seemingly closely related concepts may be in distant parts of the subsumption hierarchy.

GO provides two primary hierarchical relationships that provide structure to the controlled vocabulary, i.e. "is a", and "part of". Although these can both be represented in OWL, or its predecessors, in the spirit of incremental development, the GO Consortium chose the simplest possible representation, a directed acyclic graph, and a simple textual format for its storage, the GO format. "is a" can be interpreted as a subsumption relationship equivalent to the subclass relationship in OWL. "part of" groups structurally related concepts, e.g. components of the nucleus such as nucleolus (GO:0005730), or concepts that are related in terms of subprocesses, e.g. receptor recycling (GO:0001881) is a "part of" (interpreted as "subprocess of") signal transduction (GO:0007165). "part of" is equivalent to an OWL property. Aggregation is still possible using this structure because although it is not true to say that if we have an instance of a nucleolus, we have an instance of its "part of" parent nucleus, it is true to say that a gene product annotated as being localized to the nucleolus belongs to the class of gene products localized to the nucleus.

3.4.4 Multiple Hierarchies

When the nature of concepts in the ontology becomes complex, there are multiple ways in which they can be classified using just subsumption relationships. For example, as shown in Figure 6, the concept adrenocorti-



GO:0004978
molecular function

Classified by functional nature of the receptor
Classified by chemical nature of substance being bound
Classified by functional nature of the substance being bound
GO:0004978
adrenocorticotropin receptor activity

Figure 6 Extract of the multiple classification of adrenocorticotropin receptor activity (GO:0004978) in GO. It is classified in at least three different ways based on the chemical and functional nature of the chemical it binds, and the functional nature of the receptor itself.

cotropin receptor activity (GO:0004978) in GO is classified both in terms of (i) the chemical nature of the substance being bound, e.g., it is a subclass of peptide binding (GO:0042277), (ii) the functional nature of the substance being bound, e.g., it is a subclass of hormone binding (GO:0042562), and (iii) the functional nature of the receptor itself, e.g. G-protein-coupled receptor activity (GO:0004930). Using this more complex structure, protein function annotations can be analyzed along these different axes of classification. The term multiaxial denotes classification structures which simultaneously include different axes of classification. Both OWL and the directed acyclic graph-based GO format allow each concept to have multiple parent concepts and so support multiaxial classification.

This added functionality, however, comes at a cost to the maintainers of the ontology. Maintaining an exhaustive multiaxial hierarchy by hand has been shown to be difficult, leading to a significant rate of omitted parent–child links if the ontology becomes large or the number of parents for each concept becomes significant [30, 40]. Omissions in the classification structure impact on the validity of results from computer applications using that structure.

3.4.5 Formal Definition of Concepts

As mentioned in Section 2, OWL provides many more features that allow ontology authors to capture much more of a concept's definition in a formal manner. DL applications can then interpret these definitions to actually infer multiple subsumption hierarchies automatically. This moves the focus of ontology authors from building the hierarchical structure of the ontology to formally capturing the definitions for each concept.

The GO Next Generation project (GONG) (http://gong.man.ac.uk) demonstrated that, in principle, migrating to a finer grained formal conceptualization in DAML+OIL (and more recently OWL) will allow computation techniques, such as DL to ensure logical consistency, freeing the highly trained curators to focus on capturing biological knowledge [40]. GO is large, so GONG proposed a staged approach in which progressively more semantic information is added *in situ*. DL reasoning is used early and often, and suggested amendments sent to the GO editorial team.

To use the DL to maintain the multiple hierarchy automatically, each GO concept is dissected, explicitly stating the concepts' definition in OWL. This provides the substrate for DL reasoners to infer new and remove redundant subsumption relationships.

Within a large phrased-based ontology such as GO, which contains many concepts within a narrow semantic range, it is possible to use automated techniques to construct candidate dissections by simply parsing the term name. For example, many metabolism terms in GO follow the pattern "chemical name" followed by either "metabolism", "catabolism" or "biosynthesis". If a term name fits this pattern, a dissection can be created from the relevant phrase constituents as shown in Figure 7. These patterns have to be spotted by a developer and the scripts that generate the DL representation targeted at the appropriate regions of the GO. This provides a semiautomated, targeted approach, which avoids patterns being too general, e.g. confusing "Protein Expression" and "Gene Expression", which may fit a general pattern, but where the former describes a "target" and the latter a "source".

The process of dissection breaks down the existing concept into more atomic concepts that are related in a formal semantic manner. These elemental concepts are then placed in orthogonal taxonomies. Taxonomic information such as the classification of chemical substances which was previously implicit and repeated in many sections of the GO ontology is now made explicit in an independent chemical ontology. The reasoner combines the information in these independent taxonomies to produce a complete and consistent multi-axial classification. The changes reported by the DL reasoner represent mostly additional relationships hard to spot by the human eye and not errors

→

Figure 7 (i) A tangle of subsumption relationships between GO:0030210 heparin biosynthesis and its ancestor concepts as shown in the QuickGO browser (http://www.ebi.ac.uk/ego). The relationship shown in grey has been added by the GONG project. (ii) Two distilled views of this tangle showing ancestors involving more general classes of chemical and more general class of metabolic process. Note that glycosaminoglycan biosynthesis (in grey) should be a parent, but in the version of GO prior to the GONG project there was no subsumption relationship between heparin biosynthesis and glycosaminoglycan biosynthesis. (iii) The formal definitions of these two concepts necessary for the reasoner to infer this subsumption relationship.

    restriction onProperty acts_on hasClass heparin
                                        (acts_on is unique)
```

Paraphrase: biosynthesis which acts solely on heparin

glycosaminoglycan biosynthesis

```
class glycosaminoglycan biosynthesis defined
    subClassOf biosynthesis
    restriction onProperty acts_on hasClass glycosaminoglycan
```

in biological knowledge. The effect of adding descriptions and using the reasoner can be seen in Figure 7. For example, the reasoner reported that "heparin biosynthesis" has a new "is a" parent "glycosaminoglycan biosynthesis". These reports can then be sent to the editorial team for comment and action if necessary. Even at this preliminary stage of migration, the utility of the approach can be recognized. Many missing and redundant "is a" relationships have been spotted, making GO more complete and robust. Members of the GO editorial team have recognized the potential of using such a logic-based approach to automatically place concepts in the correct location – a task seen as difficult by the team in GO's current hand-crafted form.

The use of reasoning to help maintain the structure of the GO is now being adopted within the GO Consortium [25]. To support the representation of formal definitions and also communities outside the GO Consortium, the language used to represent the GO has been significantly extended to become the Open Bio-ontology Language (OBOL). It now overlaps with the OWL language and it is possible to convert ontologies between these two representations where appropriate. The editing tool DAG-Edit is also being extended to support the formal definition of concepts in this way.

Formal definitions not only support the maintenance of the ontology itself, but also provides other applications with machine-interpretable information for each concept. For example, instead of relying on sequence similarity to retrieve similar proteins, they could be functionally clustered based on their GO functional annotations. This requires several measures of "semantic similarity", e.g. those of Refs. [23, 24] which exploit both the DAG structure of GO and the frequency of use of GO terms within the various databases now annotated with GO. The definition of a metric for "semantic similarity" between GO terms allows us to exploit the machine-interpretable semantics of GO for large data sets. By comparing these metrics to sequence similarity measures we were able to isolate a number of issues in either GO or the use of GO within the annotated databases [23]. We have also investigated the use of these metrics as the basis for a search tool to allow querying within a database (http://gosst.man.ac.uk).

3.5 Ontology Features to Manage Data Schemata

The previous sections examined the ontology features required to represent vocabularies. However, several major life science ontologies describe the *structure* of data rather than specific annotations of its content. Here, the requirements on an ontology are different. Ontologies to describe data schemata are much smaller than vocabulary ontologies. Therefore, less emphasis is needed on paring down their features to the minimum required. In fact, the emphasis is on capturing the relationships between a small number of classes in as much formal detail as possible. The features of the OWL language which can capture the nature of relationships are more often used. For example, the cardinality feature is used to describe the number of instances with which a relationship holds. Domain and range constraints in OWL describe the classes of individuals which can form the source and target of a relationship. Subproperties capture the fact that one relationship can be considered a type of another, e.g. hasStructuralComponent could be a subproperty of hasPart.

The BioPAX ontology is such a case as introduced in Section 3.2. It defines the key entities present in pathway databases and the relationships between them. It complements existing ontologies such as GO. A key class is of course pathway. BioPAX does not itself provide subclasses to describe all the different types of pathway. Instead, it is left to other ontologies to provide this detail. For example, much of the GO biological process taxonomy could be included under pathway. The pathway class has a pathway-component relationship with the class interaction. The interaction class defines a single biochemical interaction with two or more entities. BioPAX does not enumerate a expansive taxonomy of such interactions, which again could be obtained from GO. In this way BioPAX is providing a specification of the relationships between high level classes that span more specific vocabulary ontologies such as GO.

3.5.1 **TAMBIS**

Once an ontology is available that provides a common understanding of multiple overlapping database schemata it can be used to build software applications that guide the scientist in asking a biological question and then transparently translate that question into a number of queries over distributed databases. The TAMBIS (Transparent Access to Multiple Bioinformatics Sources) project built such an ontology-based system [10]. The scientist asks a question by constructing a novel concept using classes and relationships that describes the information of interest. A small sample of such queries are: “Find the active sites of hydrolase enzymes, with protein substrates and metal cofactors” and “Find all chimpanzee proteins similar to human apoptosis proteins”. A concept is a description of a set of instances, so a concept can also be viewed as a query. The TAMBIS system is used for retrieving instances described by concepts in the model, so for example the aforementioned example query could be restated as “Find all instances of the class of chimpanzee proteins similar to human apoptosis proteins”. This contrasts with queries phrased in terms of the structures used to store the data, as in conventional database query environments. This approach allows a biologist to ask complex questions that access and combine data from different sources. However, in TAMBIS, the user does not have to choose the sources, identify the location of the sources, express requests in the language of the source or transfer data items between sources.

The TAMBIS ontology is described using an early DL called GRAIL [28]. The GRAIL representation has a useful extra property in its ability to describe constraints about when relationships are allowed to be formed. For example, it is true that a motif is a component of a biopolymer, but not all motifs are components of all biopolymers. For example, a phosphorylation site can be a component of a protein, but not a component of a nucleic acid, both of which are biopolymers. The constraint mechanism allows the TAMBIS model to capture this distinction and thus only allow the description of biologically meaningful concepts.

3.6 Ontologies for Prediction and Simulation

None of the ontologies described above actually represent in any detail all the communities' knowledge about how a specific protein functions in any one context. Schrager [33] has commented on this shortcoming. Currently, most ontologies only help in the management of information about proteins – pooling information about proteins with similar functions in different species or helping exchange protein function data between databases. Now researchers in the emerging field of systems biology are beginning to look to ontologies to structure much more detailed models at various levels of detail including protein function, to perform predictive analysis or complex simulations of biological systems.

3.6.1 **EcoCyc**

The developers of EcoCyc are a founding member of the BioPAX work group. EcoCyc uses an ontology to describe the richness and complexity of the pathway domain, and the constraints acting within that domain, to specify a database schema [18]. Classes within the ontology form a schema; instances of classes, with values for the attributes, form the facts that with the ontology form the knowledge base. EcoCyc is presented to biologists using an encyclopaedia metaphor. It covers *Escherichia coli* genes, metabolism, regulation and signal transduction, which a biologist can explore and use to visualize information [19].

The instances in the knowledge base currently include 165 Pathways, involving 2604 Reactions, catalyzed by 905 Enzymes and supported by 162 Transporters and other proteins expressed by 4393 Genes [19]. EcoCyc uses the classification of gene product function from Riley [29] as part of this description. Scientists can visualize the layout of genes within the *E. coli* chromosome of an individual biochemical reaction or of a complete biochemical pathway (with compound structures displayed).

EcoCyc's ontology has now been used to form a generic schema MetaCyc, that is used to form the basis for a host of genomic knowledge bases [19].

These ontologies are used to drive pathway prediction tools based upon the genomic information stored in the knowledge base. From the presence of genes and knowledge of their product's function, knowledge can be inferred about the metabolomes of the species in question [20]. Such computations are not only possible with the use of ontology, but EcoCyc's developers would argue that their ontology-based system and the software it supports makes such a complex task easier.

3.7 The Physiome Project

The Physiome project is an international effort to support the computational modeling of the human body, incorporating biochemical, biophysical and anatomical information on cells, tissues and organs [15]. The Physiome Committee of the International Union of Physiological Sciences is encouraging the development of common standards through the use of open markup languages, such as CellML (http://www.cellml.org). Whereas the GO provides a vocabulary to describe the capability of a protein to perform a function, the Physiome project is providing a framework to describe mathematical models of protein function and the contexts within which they apply. Ontologies form a key part of the framework, providing a consistent terminology with which to relate simulation model components with the biological entities described in current bioinformatics databases. They help to describe the context in which a particular model of function operates. The parameters for a particular model may change in specific phenotypes or genotypes. For example, the electrophysiological model of conduction in cardiac cells changes when mutations occur in ion channels within the cell membrane [26]. Capturing these relationships in a consistent manner will become essential if we are to transfer the genetic and proteomic information we gather into an understanding of its impact on a functioning system.

Ontologies are also to be used to relate simulation model components at different spatial scales [5]. For example, a model of tumor growth at the tissue scale will be dependent on the outcome of simulations of the cell cycle within individual cells. Ontologies hold the promise of being an essential *inter lingua* between systems built by diverse communities stretching from biochemists to research clinicians.

4 Summary

Significant progress has been made in the last decade in the creation and adoption of ontologies in the life sciences. There now exist several prominent efforts in the field, the GO Consortium and the wider OBO effort, BioPAX and the MGED Society. These organizations have successfully defined a number of key ontologies in molecular biology and are extending their reach to ontologies in other subdomains within the life sciences. There is strong evidence of the adoption of these ontologies within the community: we have seen GO identifiers used by a number of prominent bioinformatics databases and many of the key conferences in the bioinformatics domain are including tracks on life science ontologies.

In addition to the adoption of ontologies within the biological community, there is also significant work going on in the computer science field to develop richer and more sophisticated ontologies. Adoption of OWL by the W3C is also a significant step in making ontology languages a key building block of IT infrastructure components.

While progress has been substantial, there are still challenges for the broad adoption of biological ontologies in the biological community. The primary obstacles that remain are:

- Adoption of a common language for the representation and exchange of life sciences ontologies.
- Creation of standard ontologies that represent the various key domains of knowledge within the bioinformatics field.
- Improved software tools to assist building ontologies with complex features such as formal definitions, to support the maintenance of ontologies and to support the use of ontologies in applications.

With the recent adoption by the W3C of OWL, OWL has strong support from the Semantic Web community and that community is actively reaching out to life scientists to assist in its adoption. It also has good prospects for continued development as the W3C working group that supports it is very active and comprises some of the top researchers in the field. Most major bio-ontology groups recognize OWL as a standard, including OBO, MGED and BioPAX, so the life science community is well on the way to adopting a common standard.

With respect to standard ontologies, it is unrealistic to expect that there will be a single standard ontology for every domain within the life sciences. However, even convergence on a small number of ontologies within each community is a very positive step forward and would mean progress in the field. The expectation is that leading ontologies such as GO, MGED and others will dominate their field, and will be adopted by the user community as a useful tool.

There is a substantial amount of effort dedicated to improving ontology software tools. Given the standardization and uptake of the OWL language, the hope is that tools will appear not just from within the bioinformatics community, but also from other areas such as the Semantic Web community.

It is heartening to note that bio-ontologies are having an impact within the life sciences community. There is serious work being performed, with good results. Active research underway in the computer science field is planting seeds for the next generation. We can expect bio-ontologies to grow significantly in the years to come.

Inferring Protein Function from Sequence

Douglas Lee Brutlag

1 Introduction

Inferring gene or protein function from sequence information has been an incredibly valuable approach to interpreting genomes without having to perform detailed biochemical studies on individual gene products. Learning conserved families of proteins and representing conserved functional regions within these families with motifs leverages the known biological attributes of proteins, permitting one to infer proteins belonging to the same family and containing the same conserved functional sites. This procedure can dramatically reduce the amount of experimental work that must be done to characterize the genes in a new genome or gene products in a new proteome. Protein families and motifs also form a much more compact representation of the biological, structural and functional properties of the protein sequence database.

In this chapter we will discuss various methods for representing and learning conserved protein motifs. We will discuss these methods within the standard machine learning paradigms by which motifs can be discovered in a largely unsupervised fashion, being driven primarily by sequence similarity and automatic discovery of protein families and conserved regions. We will also discuss more highly supervised learning of motifs that are driven by finding motifs in smaller subfamilies of proteins defined by biological properties other than sequence.

The simplest way to infer the function of novel proteins is via a pairwise sequence similarity search such as Smith–Waterman local alignment or a BLAST similarity search [1,2] (see also Chapter 3). Pairwise similarity search, in effect, uses every known protein sequence as a pattern to compare with a query protein of unknown function. Sequence-similarity methods require that one find a protein sequence that is closely related to the query protein within a database of proteins with known function. It also requires that one have a database of proteins whose function is known by experiment and not itself inferred from sequence similarity [32]. Otherwise one develops a chain

of inferences, each of unknown or dubious significance, often leading to false and unreliable predictions. Other limits on the accuracy of inferring functional or structural information via pairwise alignments have been discussed in depth elsewhere [44, 45, 119, 123].

Another limitation of inferring function from pairwise-similarity search is that such methods usually employ a dynamic programming algorithm that permits arbitrary amino acid substitutions or insertion/deletion gaps (*indels*). If such substitutions or gaps occur within the functional sites of proteins, then the inference of a common function may be in error despite a highly significant overall similarity. The protein in question may, in fact, catalyze a different reaction with a different substrate or cofactor. Even worse, the protein in question may not be functional at all as for pseudogenes. Nevertheless, most users of sequence-similarity search to infer function never check the experimental validity of the target sequence or the impact of the sequence changes between the novel protein and known protein sequence.

A more rigorous method for inferring protein function from sequence is to compare the query sequence with families of sequences (family-wise comparisons) rather than pairwise with individual sequences. The first method for family-wise comparisons was to generate conserved sequence motifs from protein family alignments (Prosite database [15,69,90]). The first advantage of using protein families is that they consist of many proteins that can represent a wide evolutionary or taxonomic range of the functional protein. More importantly, motifs represent the functionally conserved positions in the protein. By learning motifs, one discovers which residues are essential for function and what the range of allowed variation is at each position in the functional site. In this way, the conserved motif (or consensus sequence) is a much better representation of the functional sites. When comparing a sequence motif against a protein of unknown function, only the critical residues are compared. This increases the signal-to-noise ratio and the specificity of the motif, and permits inference to be drawn over a much wider evolutionary or taxonomic range than possible with pairwise sequence comparisons. Conserved motifs also ensure the validity of the functional inference. Insertions, deletions or substitutions in the important conserved residues of the motif will eliminate the inference.

Of course, a major limitation of representing function using sequence motifs is that biological function is not always encoded in a single contiguous series of amino acid residues. Often, functional regions are distributed over several noncontiguous sites in a protein requiring multiple noncontiguous motifs to represent a single biological function (e.g. binding site, interaction site or catalytic site). A good example is the catalytic triad in serine proteases in which each of the three essential residues in the catalytic site is contained in one of three separate conserved motifs (Figure 1) [37, 77, 78]. Another

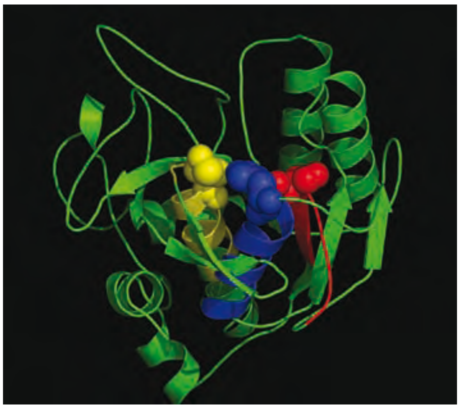

Figure 1 Three conserved motifs containing the three residues of the catalytic triad in the serine protease subtilisin BPN′ of *Bacillus amyloliquefaciens*. The first conserved motif is shown in red (residues 135–146; Prosite PS00136) and contains the active site aspartate (red spheres). The second conserved motif is shown in blue (residues 171–181; Prosite PS00137) and contains the active site histidine (blue spheres). The third motif is shown in yellow (residues 326–336; Prosite PS00138) and contains the active site serine (yellow spheres). Although the three motifs are widely separated in the protein's sequence, the three residues of the catalytic triad are immediately adjacent to each other in the three-dimensional structure.

example is the Walker motifs that encode a nucleotide-binding site (a Rossman fold) and involve two conserved motifs [120]. In such cases one can use a disjunction of motifs or other more sophisticated representations of multiple ordered or unordered sets of motifs.

Another limitation of the motif methods described in this chapter is that biological functions can be conserved without detectable sequence conservation. Examples include conserved chemistry and conserved structure without significant conservation of sequence [14,38,39,52,123]. These problems can be partially addressed by motifs that encode properties of amino acids other than sequence. In the chapter we will discuss network-based motifs (both neural network and Bayesian networks) that can represent patterns of hydrophobicity, charge, volume, contacts, bonding and pairwise correlations. These motifs can represent motifs in a more structural way than sequence based motifs. Other approaches involving structural motifs themselves will not be discussed in this chapter [83,84,107,128].

2 Sequence-based Motif Representations

2.1 Consensus Sequences as Regular Expressions

There are a wide variety of different representations of protein sequence families. As mentioned above, the first method was a consensus sequence or a sequence pattern. Consensus sequences are usually derived from a multiple protein sequence alignment in which the critical functional regions are detected and aligned. The most common representation of the sequence pattern is a regular expression defined by the regular expression syntax such as used in the Unix grep command. The full regular expression syntax can be used to represent protein motifs or one can limit patterns to just fixed-length regular expressions. The full regular expression syntax permits one to represent lists of residues permitted at each position in the consensus sequence as well as variable length regions of "don't care" regions. For fixed-length regular expressions, one has to use multiple regular expressions to represent variable-length sequence motifs.

Regular expressions have some limitations for representing functional motifs. The first is that they are deterministic and discrete. A new sequence either matches or does not match the pattern. Normally there are no approximate matches or concept of suboptimal matches in the regular expression syntax. However, the publicly available program agrep does permit one to search for patterns with a limited number of mismatches [86]. Unfortunately agrep requires one to sacrifice the linear time performance of the grep algorithm making the computation time for pattern search polynomial in terms of the number of variations allowed.

Another limitation of regular expressions is that there are no weights for different positions in the pattern. Each position is weighted equally to the other positions. One can have different mixtures of residues permitted at each position ranging from a single specific amino acid to a "don't care" character and one could assign an information content to each position based on the frequency of residues known at each position; however, apart from such positional composition, each position is weighted equally.

Another problem with consensus sequences prepared manually from protein sequence alignments is they often overfit the existing data. The result of this overfitting is that the motif works well on the existing protein family from which it was derived (the training set), but it does not work nearly as well at inferring function from newly sequenced proteins or proteomes. This overfitting can be evaluated by the cross-validation methods described below.

Finally, the sequence motif pattern, like most of the other motif representation methods discussed below, assumes positional independence of the residues. Sequence variation allowed at one position of a regular expression is not correlated with positional variation at another position. Positional dependencies can arise in a number of ways. First, conserved sequences can represent two or more related sets of proteins that have evolved independently from a common ancestor. These paralogous sets will have their functional positions conserved within each set, but some other positions will have residues that are distinctive for each subset. The distinctive positions in each subset will appear to be correlated with each other. The correlation results from their correlation with their subset.

Another source of covariation between conserved positions could be due to selection for a particular affinity with a substrate, cofactor or other binding site. Most biological interactions are meta-stable so that they can easily associate and dissociate. If a mutation at one position in a binding site over-stabilizes an interaction, this over-stabilization can be compensated for by a change at another position to weaken the interaction. Thus, positional correlations in binding sites may reflect the meta-stable nature of an interaction.

A final source of covariation in protein sequences is due to side-chain–side-chain interactions. These interactions can be van der Waals contacts, electrostatic interactions, charged pairs, hydrogen bonds and general hydrophobic interactions. Changes in one residue in any of these interactions can often be compensated for by a change in another residue, sometimes at great distance in sequence, even though close in three-dimensional space. Positional correlations are often used to detect structural interactions in both proteins and nucleic acids.

One way to represent positional correlation would be to use several motifs to represent subfamilies of proteins within the family. One could use any standard clustering or phylogenetic method to classify all the proteins within a family and then build a separate motif for each subfamily. Such a group of motifs could capture both the conserved and correlated residues in a functional protein motif. One could also apply a minimal length encoding approach to discovering the requisite subfamilies and then obtain a different motif for each subclass. More distant correlated changes often have to be represented by mutual correlations or Bayesian networks or even neural networks.

2.2 Accuracy and Precision of Motifs

Despite their deterministic nature, there are several quantitative measures of how accurate motif representations are. The most important of these measures are specificity, sensitivity and positive predictive value (PPV). The sensitivity of a motif is a measure of what fraction of known members of the functional family are detected by the motif. If a functional family is very diverse or contains multiple subfamilies, one often must construct multiple motifs, one for each subfamily. The sensitivity of each motif is measured relative to its subfamily and the sensitivity of the disjunction of these motifs is measured relative to the entire family.

The specificity of a motif measures the fraction of the nonfunctional proteins that are correctly classified by not having the motif. A more useful measure is (1 – specificity) which measures the number of nonfunctional proteins that do contain the motif. This is a measure of the expected frequency of false-positive prediction by the motif. The expected frequency of false-positive predictions is the fraction of the nonfunctional proteins that contain the motif by chance. The expected frequency of false-positive predictions is usually measured on a protein-by-protein basis; however, it can also be estimated on a residue-by-residue basis. Motifs with an expected frequency of 10^{-3} or less per residue can be used to detect motifs in individual proteins, but are not useful for searching entire proteomes. Highly specific motifs (those with an expected occurrence of false-positive predictions below 10^{-6} per residue) are needed to predict functions in entire bacterial proteomes and even more specific motifs are required for eukaryotic proteomes.

Finally, the PPV of a motif measures what fraction of the sites discovered by the motif are, in fact, correct. The PPV is the ratio of the true sites divided by the true sites plus the false positives.

In order to measure the sensitivity, specificity and positive predictive value of a motif accurately, one must have a "gold standard" set of proteins in which one knows precisely which proteins have the specific function represented by the motif (positive set) and another set of proteins that are known not to have this function (negative set). It is also best if the size of these sets of proteins approximates the expected size of the sets in the sequence databases or proteomes being searched. This usually means that the size of the positive set should be much smaller than that of the negative set. Given these two sets of protein sequences one can apply the motif to both sets and calculate the sensitivity, specificity and PPV as:

$$\begin{aligned}
\text{Sensitivity} &= \text{TP}/(\text{TP} + \text{FN}) \\
&= \text{ fraction of the positive set containing motifs} \\
\text{Specificity} &= \text{TN}/(\text{TN} + \text{FP}) \\
&= \text{ fraction of the negative set not containing motifs} \\
\text{1 - Specificity} &= \text{FP}/(\text{TN} + \text{FP}) \\
&= \text{ expected frequency of false predictions} \\
\text{PPV} &= \text{TP}/(\text{TP} + \text{FP}) \\
&= \text{ fraction of proteins with motifs that are functional,}
\end{aligned}$$

where:

TP = true positives, functional proteins with the motif

FN = false negatives, functional proteins without the motif

FP = false positives, nonfunction proteins with the motif

TN = true negatives, nonfunctional proteins without the motif.

The Prosite database analyzes the occurrences of its motifs in the entire Swiss-Prot database and characterizes each hit as a true-positive or a false-positive hit [17]. In addition, using the known members of a functional family, it determines the number of false negatives and true negatives. From these numbers one could calculate all of the measures described above. However these measures would be an overestimate of the accuracy of the motifs because the Prosite motifs were generated from the sequences in the Swiss-Prot database. This procedure of using the same set for training and evaluation gives rise to resubstitution estimates of sensitivity and specificity which are usually an overestimate of the true sensitivity and specificity of the motifs.

In order to obtain an accurate measure of sensitivity, specificity and PPV for a motif it is essential that the protein set from which the motif is built (training set) be distinct from the protein set on which the motif is tested (test set). One example would be to divide the "gold standard" protein sets into two independent sets – a training set and a test set. Then one would generate motifs from the training set and measure the accuracy on the test set. One could, of course, repeat this training and test procedure reversing the roles of the training set and test sets. This procedure is called cross-validation, and is used to ensure that training and test sets are truly independent. Alternatively, if there is not sufficient data in one-half of the "gold standard" set of functional proteins to build motifs, one can carry out repeated cross-validations using 80 or 90% of the "gold standard" set of proteins and test on the remaining 20 or 10% of the proteins. Repeating this procedure 5 or 10 times so that every protein has served in the test set once gives accurate measures of the sensitivity, specificity and PPV for the motifs.

In addition to these direct measurements of (1 – specificity), the expected frequency of false motifs can also be estimated in a number of different ways. The simplest way to estimate the expected frequency of a motif on a residue basis is by calculating the likelihood of each conserved position in the motif based on amino acid composition alone. This permits one to calculate the expected number of motifs in a protein or a proteome of any length, giving a measure of 1 – specificity of the motif. A more sophisticated method for calculating the expected frequency of a motif in protein sequences which takes into account Markov dependencies of protein sequences and other properties of the regular expression syntax have been developed [8]. In addition to algorithmic methods, empirical methods for estimating the likelihoods of protein motifs have also been generated from random permutations of protein sequence and examining the background frequency of motifs. To get accurate measures of the frequency distribution of motifs it is critical to preserve not only the amino acid composition during the permutation, but also frequencies of peptides of length two and three (the so-called Markov dependencies of length 2 and 3) as well during the permutation process.

2.3 Position-specific Scoring Matrix (PSSM) Motifs

A PSSM is a probabilistic representation of a conserved functional region of a protein [61, 63] (see also Chapter 11). Scoring matrices are generally derived from multiple sequence alignments of proteins generated by a number of alignment algorithms, e.g. ClustalW [118], T-COFFEE [96], DIALIGN [89], PSI-BLAST [2], hidden Markov models (HMMs) [19, 47, 48, 79], etc. (see also Chapter 3). The most highly conserved ungapped regions of the alignments are extracted and referred to as *blocks*. Blocks include contiguous ungapped regions of the protein sequence. These blocks are then converted to probability matrices that give the relative probability of each amino acid in each position in the motif. Finally, the matrix is converted to a log-likelihood form by dividing the probability of each amino acid at each position by the probability of the amino acid in the database of proteins being searched and taking the logarithm of this ratio. If the amino acid is more likely to be found in a particular position in the matrix than in the background distribution of amino acids, then the ratio will be greater than unity and the log-likelihood score will be positive. If the amino acid is less likely to be found at a position in the matrix than the background, then the ratio will be less than unity and the log-likelihood score will be negative. One can then use this log-likelihood scoring matrix to estimate a score for any segment of a newly sequenced protein or proteome by using the protein sequence as an index into the log-likelihood matrix and adding up the likelihood of each residue at each position along the segment. Since we have taken the logarithm of the probabilities, adding the log-likelihood scores is equivalent to multiplying the probabilities at each position. Clearly this method assumes positional independence, just as the regular-expression approach. However, unlike the regular-expression approach, the PSSM approach is probabilistic. The score is a measure of the likelihood that a protein segment belongs to the same functional class as the training set.

2.4 Dirichlet-mixture Prior Probabilities and Pseudocounts

One technical problem occurs when trying to estimate the likelihood of an amino acid when it has never been observed at a position in an alignment or motif. If a particular amino acid has never been observed at a position of a motif, then the frequency and the probability is zero, and one cannot take the logarithm of zero. To circumvent this problem it is common to add a small value to every position in the matrix. For example if one were to add the number 1 to every term in the frequency matrix before taking the log-likelihood ratio, every entry in the matrix would be nonzero. This is conceptually like assuming an observation that contains a uniform distribution of every amino acid at every position. These additions are sometimes referred to as pseudocounts.

Another approach would be to add a small number (not necessarily an integer) proportional to the known amino acid composition of the protein motifs. In this way, the average composition of each column of the matrix would tend toward the average composition of the amino acids. Such probabilities are referred to as Dirichlet-mixture prior probability distributions. The net effect of adding either an integer or a probability distribution to each column of the frequency matrix is to smooth the distribution of amino acids from the observed frequencies towards the average distribution. Hence, these terms are also referred to as smoothing or regularizing parameters.

An important question is how much smoothing is appropriate or, put another way, how many pseudocounts are appropriate when building a scoring matrix. If one has too few protein sequences in the training set, then the matrix may have statistical fluctuations due to small numbers. Under these conditions a large number of pseudocounts would be appropriate. On the other hand, if there are a large number of sequences contributing to the scoring matrix, then very little smoothing may be needed because one already has good estimates of the likelihoods of each amino acid. Basic statistical considerations suggest a minimum of five samples for each probability being estimated which would require 100 sequences in the block to estimate probabilities for 20 amino acids. In fact, scoring matrices are often made for protein families with as few as 10–20 examples. Clearly background smoothing is needed in these cases. Some databases of PSSMs just use a fixed number of pseudocounts to be added to each position (usually 5 or 50); however, it should be clear from the argument above that their should be a variable number of pseudocounts based on the size of the training set. Wu and coworkers [127] demonstrated that the ideal number of pseudocounts can be estimated based on calculating the minimal risk that one would miss a motif. This approach estimates this risk based on the size of the training set and the size of the database that is being searched. By using the number of pseudocounts that minimizes the risk of missing a motif, the overall sensitivity of the motif is maximal.

2.5 Sensitivity and Specificity of PSSM Motifs

Since a PSSM yields a score for every overlapping protein segment to be tested, one must also have a threshold score above which one believes that the segment is an example of a functional motif. How is such a threshold score estimated? Again we usually compare the matrix against a “gold standard” test set of proteins that are known to either contain a functional site or not. We then attempt to find a score that every known site will exceed and all nonfunctional sites will not. However, the scoring matrix will often not cleanly distinguish sites from nonsites perfectly, especially since there are usually many more nonsites than sites. Most often some scores for some nonfunctional sites will exceed the scores for some functional sites. Due to this overlap in the score distributions for sites and nonsites, any given threshold will have some false-positive results and some false-negative results. If one wants to just minimize the number of false calls, one can choose the equivalence point – the threshold score at which there are an equal number of false-positive and false-negative results. If sensitivity (finding all sites) is more critical than getting false positives, then one can lower the threshold score. If specificity is more critical (not getting any false predictions, as in an entire proteome search), then one can increase the threshold score. Hence, the threshold is a parameter that balances sensitivity and specificity.

Because one can vary the score threshold changing the sensitivity and specificity of a scoring matrix, one usually plots the relationship between sensitivity and specificity as the function of the threshold value. Such plots are usually known as receiver operating characteristic (ROC) curves [115]. Each point on an ROC curve represents a different value of the threshold score. See Figure 2 for the definition of the threshold and Figure 3 for an example of an ROC curve for two PSSM motifs. Usually one plots the number of true-positive sites discovered on the y-axis and the number of false positive sites on the x-axis for each threshold. An ideal scoring matrix would only find true sites at high threshold values and then below some score threshold only false positives would appear.

Such an ROC curve would rise vertically up the y-axis to the maximal number of true sites and then turn horizontally as false sites were detected at lower thresholds. More usual ROC curves would show a number of false sites before all of the true sties were found and the curve would fall away from the y-axis. The closer the ROC curve is to the y-axis and the further it is from the x-axis, the more discriminating is the motif. Motifs are often compared by measuring the area under their ROC curves (AUC). The greater this area, the more sensitive and specific the motif is. One can also plot the sensitivity and specificity of discrete motifs (regular expressions) as single points on an ROC curve. If the curve for a PSSM falls underneath this point, then the regular

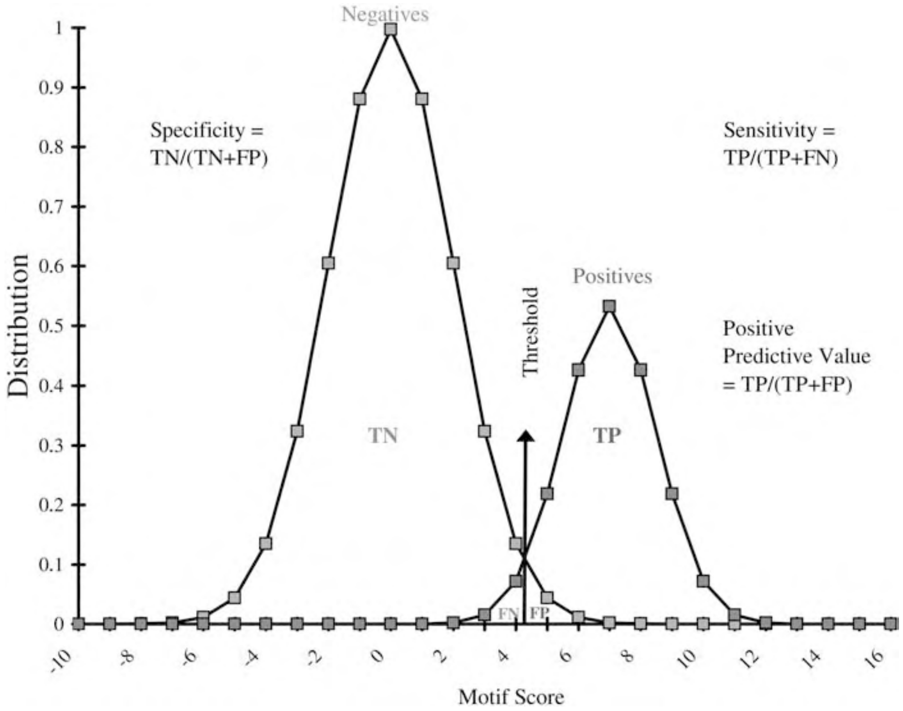

Figure 2 The distribution of motif scores for the positive and negative classes of protein sites often overlap leading to both false-positive and false-negative predictions. The threshold is the value that best separates the positive class from the negative class. Here, we have chosen the equivalence point for the threshold. The equivalence point is the threshold at which the total numbers of false negatives and false positives are equal, and which minimizes the total number of misclassified sites. For some experiments, one wants to maximize the specificity and will raise the threshold value to minimize false predictions. In other experiments, one might want to maximize sensitivity and so will lower the threshold to maximize the number of positives found.

expression is a better motif. If the ROC curve passes over this point, then the matrix is a better motif. An excellent tool for presenting ROC curves is described by Sing and coworkers [104].

Finally, since the size of the true-positive set is very often much smaller than the size of the database as a whole, one often only plots the ROC curve up to a limited number of false positives. One common choice is to plot the ROC curve until the number of false positives equals the number of known true positives in the training set. Another choice would be to plot the ROC curve to some fixed number of false predictions, such as an ROC-50 or an ROC-100 curve [56].

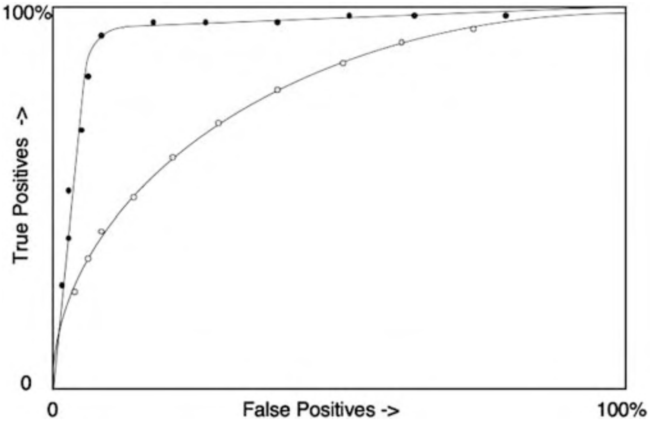

Figure 3 Typical receiver operating characteristic curves for two different PSSM motifs. Each point on each curve represents the fraction of true-positive and false-positive predictions made at a specific threshold (Figure 2). As the threshold score for motif prediction is lowered, the number of true-positive predictions increases for both motifs. However, the motif represented by the upper curve shows more true predictions and fewer false predictions than the lower curve at every threshold. Hence, the AUC for the upper curve is larger than for the lower curve. An ideal motif would have all the true predictions occur before any false predictions and the curve would go from 0,0 to 0,100 along the y-axis and then pass along the top of the graph to 100,100. The area under this ideal motif would be 1.0.

2.6 HMMs

While position specific scoring matrices are excellent for modeling contiguous regions of conserved protein sequence, they cannot model protein regions that have suffered insertion and deletions as can pairwise sequence alignments. A more general representation for conserved proteins that is more global in nature and can model longer conserved regions including regions with variable length insertions and deletions are the HMMs [18, 20, 59, 79]. HMMs were first used to represent protein families. The use of HMMs to represent protein families and protein domains is described in Chapter 3, and one should look there for details on the method. We mention them here only in comparison with other motif representations.

Unlike the PSSMs, HMMs model longer conserved regions that can include multiple motifs, entire protein domains and even represent large protein families [5, 21, 53, 58, 66, 85, 90, 109, 110]. Because of this, they can represent multiple conserved motifs linked by less highly conserved regions. More importantly, many HMM models for protein domains and families can have different likelihoods for insertions and deletions at each position. Such a powerful representation permits a more biological representation of protein domains. For example, in highly structured regions such as α-helices and β-strands, the likelihood of either an insertion or a deletion is generally very low. Insertions or deletions in such structured regions would throw the pattern of hydrophobicity out of register, destroying the structural element. However, in loops or turns in a protein structure, insertions and deletions are more likely. Hence, by examining the probability of insertions and deletions along a protein family represented by an HMM, one can often identify the structured regions and the loops and turns. Even more critically, tight loops (β-turns) can often have insertions but not deletions and these regions can also be recognized.

HMMs are learned from a training set of proteins by an iterative method of repeatedly aligning each sequence in the training set to the model until the model converges. During this process, many different transition probabilities are being estimated at each position, including the likelihood of substitutions, insertions, deletions, extending insertions and extending deletions, terminating an insertion and terminating a deletion. A common HMM will have 25–30 probabilities estimated per position. Statistically one would like at least 150 sequences in the training set in order to estimate all these transition probabilities. However, as with PSSMs, one can use fewer sequences to train an HMM if one has an estimate of the prior probability of the distribution of amino acids. By examining large protein families, a set of distinct types of amino distributions has been calculated referred to as Dirichlet-mixture priors (see Section 2.4) [34, 72, 106]. By using these sets of amino acid distributions that have been seen in previous large HMM models, one can often build an HMM model from fewer than 150 proteins.

Since HMMs are a more general representation of conserved biological functions or structures, they can also be used to represent motifs. Since they are more global in scope, they can also represent structural domains and entire protein families. Since an entire domain often mediates biological function, one can consider protein domain assignment as a critical form of functional assignment. Also, because HMMs are a probabilistic representation, one can derive measures of the likelihood that a novel sequence is a member of a protein domain or family.

2.7 Network Models

All of the motif representations discussed so far have made the assumption of positional independence, i.e. the likelihood of each residue is independent of any of its neighboring residues. Even the HMMs make this assumption in order to be able to use dynamic-programming methods for training and inference. No sequence-based Markov dependencies are permitted. However, we know that this assumption of positional independence is not valid. For example, in order to accurately predict the likelihood of a motif, whether represented by a regular expression or a PSSM, we must use a measure of the Markov dependencies within the background protein database [8, 128]. Accurate estimation of prior probabilities of motifs requires measurement of background Markov dependencies. Also side-chain–side-chain interactions between distant sites in proteins can result in positional correlations.

Studies of many protein families, domains and motifs have shown very important positional dependencies required for structure and function. The most general representation of all positional dependencies would require an estimation of L^2 parameters where $L$is the length of the protein sequence. Generally, one does not have enough examples to estimate this number of parameters so one has to limit one's search for positional dependencies to either local regions or to repetitive regions in a longer structure. Another approach is to look for positional dependencies in reduced representations of the amino acids. Instead of looking for correlations between all 20 amino acids, one can reduce the amino acids into functional or structural subsets and then look for correlations among these properties [74, 75]. For example, if one reduces the amino acids into hydrophobic and hydrophilic subsets, one can discover correlations between these properties along protein sequences. Other properties such as size or volume can lead to discovery of contacts, or charge can lead to discovery of charged pairs or ionic bridges in protein structures. One can also use quantitative methods for search for patterns of hydrophobicity by assigning a measure of hydrophobicity to each residue. Some of the early methods for looking for motifs with positional dependencies involved looking for autocorrelation with protein sequences or performing Fourier analysis of protein sequences. Eisenberg, for example found patterns of hydrophobicity that were typical of α-helices or β-strands in protein sequences [49, 50]. Such patterns of hydrophobicity are extremely useful for inferring protein structure.

Other representations that permit positional dependencies explicitly include network models. Both Bayesian networks and neural networks have been used to represent structural and functional protein motifs. One of the first applications of Bayesian networks to protein structure rediscovered the hydrophobic patterns of helices and strands. Bayesian networks were also used to discover the motif [Phe Xxx Yyy Zzz His] that terminates α-helices. Structural analysis of this so-called C-terminal capping sequence shows that the histidine bends back and interacts with the phenylalanine, terminating the α-helical structure [46, 75]. Bayesian approaches have also been used to represent patterns of amino acids in repeating proteins such as coiled coils or triple helices such as found in many structural proteins (myosin, collagen, etc.) [27–29, 33, 87, 124]. Chapter 35 also discusses Bayesian networks.

2.8 Neural Networks

Neural networks permit the examination of local regions of amino acid sequence for nonlinear combinations of properties other than just the sequence itself. Thus, neural networks can learn patterns of hydrophobicity, charge, hydrogen bonds and other properties in combination with more classical amino acid patterns [92, 93, 98]. Due to their extreme flexibility, neural networks can learn arbitrary quantitative patterns of amino acids that may not be obvious in the sequence itself. Such powerful methods are ideally suited to examining regions of proteins that are associated with membranes or with other proteins and which the association depends more on the physical properties of the protein than its sequence. Also, the extreme flexibility of the networks permits one to encode nearest-neighbor information as well as relationships extending over the entire region of the protein being evaluated. Such methods have been used to learn motifs that can infer protein structural regions such as helices and strands, coding regions, transmembrane regions, signal peptides, post-translation modification signals, nuclear localization and secretion signals, etc. [24, 30, 40, 51, 70, 73, 94, 95].

Discovering and training a neural network takes some effort to determine the factors necessary for recognition. Considerable biological knowledge can be built into the architecture of the network from the start (width, number of hidden layers, parameterization of the sequence, specific sequence patterns, etc.). Some biological insights can also be extracted from the neural network once it is trained as well (internal periodicities, relative importance of specific positions, etc.). Being probabilistic, the inference of neural networks can be measured by their sensitivity and specificity just as other more sequence-based motifs are.

3 Descriptions of Several Useful Motif Databases

The purpose of the following section on example databases of protein functional motifs is not to be an extensive review, but rather to give a few critical examples of useful resources for protein functional inference based on motifs. The web locations of the motif databases and methods is given in Table 1; however, one can readily find each by a simple Google search.

3.1 The Prosite Database

The Prosite database was one of the first family-based databases of protein consensus sequences. It was originally built largely by hand from well-characterized protein families that shared a common structural or functional

site [69]. Protein sequences in the family were aligned using both algorithmic and manual methods. The conserved patterns were optimized to maximize their sensitivity on the known family and to minimize the false inferences. The manual curation of the motifs invariably leads to overfitting of the data. As mentioned above, the Prosite database gives measures of the sensitivity and specificity of the motifs derived from the current Swiss-Prot database, but these measures are overestimates of the expected performance on future sequence data. A true cross-validation approach to estimating the sensitivity and specificity of the Prosite motifs would be very tedious due to the manual motif generation. Another possible approach would be to examine motifs constructed several years ago on proteins characterized subsequently using nonsequence based approaches.

The Prosite database is distinguished by its excellent manual curation and by its excellent annotations. The Prosite and Swiss-Prot databases were among the first to have extensive links to other molecular biology databases, even before the appearance of the Internet.

The Prosite database contains a set of very common motifs for sites of post-translational modification. Since these motifs are very short and not of high information content, they may only be used to discover hypothetical modification sites which must be validated experimentally. Other, more sophisticated models of post-translational modification sites involving network and HMM models given higher confidence inferences [31,70].

Even many of the Prosite patterns which are not post-translational modifications have a relatively low specificity, on the order of 0.1–1% false predictions. Due to this low specificity, these patterns are most useful when scanning a single protein to infer functional sites. The Prosite pattern database cannot be used to infer function on entire proteomes, as they will result in more false inferences than true ones.

The Prosite database has also developed quantitative models for motifs called Prosite Profiles [17,36]. These Profiles are an extension of the original profile of Gribskov that characterized protein families [54, 55, 57]. Like those profiles, the Prosite Profiles estimate the likelihood of insertion and deletion at each position in the motif. Prosite Profiles are intermediate models between PSSMs and HMMs in that they have both position specific insertion and deletion penalties, but they do not have the full range of transition probabilities used by the Haussler or Baldi groups. Since the Prosite Profiles are quantitative, one can use different thresholds to gain sensitivity or specificity depending on the protein or proteome to be searched.

Recently, the Prosite group had developed a ProRule database in which functional and structural information is mapped onto the Prosite Profiles [103]. ProRules are short sequence patterns that identify the most critical residues for structure or function in the profile. These patterns are often less specific than Prosite patterns themselves and they are designed to be used to annotate a positive hit from the Prosite Profile. As such, the ProRule points out the critical catalytic or functional residue in the site. For example, the ProRules for the three trypsin family Profiles annotate the active site histidine, aspartate and serine residues of the catalytic triad (Figure 1). Combining Prosite Profiles with Prosite-type patterns gives ProRules the power of both quantitative and qualitative motifs simultaneously. ProRules also permits a much greater amount of biological information to be encoded in the motif.

3.2 The Blocks Databases

The Blocks and PRINTS databases are among the first PSSM representations of conserved protein motifs [10, 11, 62, 64]. Scoring matrices are probabilistic representations of conserved protein regions, usually derived from ungapped, multiply aligned protein subsequences. Posfai et al. originally applied the term *block* to a conserved, ungapped protein alignments for conserved, functional regions they discovered in families of restriction and modification enzymes [100, 101]. Multiple sequence alignments of type II restriction and modification enzymes from many bacteria strains showed conserved regions involved in cofactor (SAM) binding and catalytic sites. The DNA-binding sites were highly variable both in sequence and length – as was expected since the sequence specificity varied from strain to strain. Posfai et al. discovered that many of these conserved regions contained three or four positions (columns) that were completely conserved suggesting that these residues were especially important for function.

Smith and coworkers used this observation for discovering conserved blocks in other protein families [108]. They developed an algorithm called MOTIF that discovered short conserved sequence patterns containing three different positions separated by zero to eight nonconserved residues in a contiguous amino-acid region in each member of a protein family. Regions containing these short three position motifs were aligned and adjacent regions were examined for conservation as well. Using a heuristic method, they built up blocks of conserved residues centered on the original three position motifs.

Henikoff and Henikoff then automated this procedure so that they could be applied to any protein family and built up blocks around conserved functional sites [64, 121]. The initial Blocks database was limited to the same protein families found in the Prosite database. Later, the automatic Blocks approach was extended to other protein families including PRINTS, Pfam, DOMO and Prodom families. This extended database was known as the BLOCKS+ database [60, 65]. In all cases, the Blocks from these families were built using the automated method that found a conserved triplet of amino acids each separated by up to eight residues. This approach limits the diversity of conserved regions that Blocks can discover. Blocks, like its predecessor MOTIF, requires a large fraction (usually 90% or more) of the sequences to contain a perfectly conserved triplet of amino acids within a segment three to 19 amino acids in length. The automated Block discovery program cannot discover blocks that do not have a perfectly conserved three-amino-acid motif.

The function of many of these conserved regions is known through studies of the protein family from which they derive and from other functional studies.

The Blocks website provides several useful functionalities. The most useful for inference is Blocks Searcher that compares the blocks database against a protein sequence or a translated DNA sequence. Another function, Block-Maker and Multiple Alignment Processor, can take a multiple sequence alignment and generate a series of conserved ungapped alignment blocks. Finally, CodeHop can develop the best DNA probe to detect the DNA encoding the Block function taking into account the sequence variability in the Block and the codon usage table for the amino acids [102].

The Block Searcher function identifies all regions similar to each Block in the database and gives the expectation value for each hit. If there are multiple blocks discovered from the same family, a function called Block-scan will then calculate the expectation value for finding all the blocks simultaneously. Finally, Block Searcher prints out the relative position of the blocks in the query sequence and compares them with the relative positions of the same blocks in the Block Family database. These statistics are very useful for identifying the function novel proteins and they overcome the major deficiency that multiple motifs are usually required to encode a single biological function.

3.3 The PRINTS Database

The PRINTs database was initially constructed in a manual approach similar to the Prosite database. Initially it began with a database of conserved regions within signal transduction proteins (G-proteins in particular); however, it was extended to most other families [9, 10, 13]. An automated method for taking protein alignments from ProDom and converting them to ungapped conserved regions and automatically annotating them generates a database referred to as PrePrints database [11, 35, 42]. Once these regions are curated and verified, they pass into the PRINTs database. A newer relational version of the PRINTS database referred to as Prints-S is also available for relational searches [12]. The ProDom database itself is built up by PSI-BLAST alignments of protein families which results in a database of conserved protein domains.

One of the useful features of the PRINTs database is that it tabulates how many members of the protein family contain all the conserved regions known in that family, say N motifs), how many proteins contain $N-1$ motifs, $N-2$ motifs, etc. Thus one can see which motifs are present in all members of a protein family and which motifs may add optional functionality.

3.4 The eBLOCKs Database

The eBLOCKs database contains ungapped sequence alignments of all conserved regions within the Swiss-Prot protein database [114]. These conserved regions include functional sites such as catalytic sites, substrate binding site, cofactor binding sites and protein–protein interaction sites. The eBLOCKs database is built by running all Swiss-Prot proteins as queries against all other Swiss-Prot proteins using PSI-BLAST, collecting all family alignments and then extracting all ungapped conserved regions within each family. Unlike the Blocks and Motif methods, eBLOCKs does not require three highly conserved positions in the conserved regions. The minimum requirements for a block in the eBLOCK database are that the block must be at least 10 amino acids wide, three sequences deep and contain at least 40 bits of information. These criteria eliminate common motifs such as post-translation modification motifs, and ensure that the resulting BLOCKs have enough specificity to be used for searching entire proteomes.

The eBLOCKs database also contains multiple overlapping blocks for many conserved regions. This permits having very sensitive motifs that can cover a wide taxonomic diversity of the functional region, as well as more specific motifs that cover the same functional site in a subset of species (bacterial, eukaryotic, vertebrate, primate, etc.). The more general eBLOCKs increase the sensitivity of motifs inference, while the more specific eBLOCKs can identify not only the function, but often the taxonomic family containing the motif. This also results in a redundancy in the eBLOCK output. This redundancy is minimized by presenting the most specific hit first and then only showing additional, more general motifs if the user chooses to drill down in the results page.

About 35% of conserved regions in eBLOCKs are similar to functionally conserved regions in the Prosite, Blocks, PRINTS and InterPro databases. About 65% are novel conserved regions whose precise molecular function is not known, but which may represent protein–protein interaction sites, protein–ligand interaction sites or other functional sites not yet characterized in known protein families. Even though the precise molecular function of these conserved regions is not known, one does know the family of Swiss-Prot proteins from which the conserved region was derived, thus permitting the inference of family membership, if not specific molecular function. Unlike other protein family and domain databases (ProDom, Pfam, TIGRFams, etc. [21, 35, 42, 58]), eBLOCKs only records the ungapped conserved sites. However, like Blocks [60] and PRINTS [11], eBLOCKs keeps all the conserved regions from one family together in a group. The eBLOCK-conserved regions are converted into both sequence patterns (eMOTIFs) [68, 91] and into PSSMs (eMATRICES) [126, 127].

3.5 The eMOTIF Database

The eMOTIF algorithm for building sequence patterns from alignments is completely automated, and results in multiple motifs for different subsets of the sequences and also multiple motifs at different levels of specificity [68,91]. Rather than attempting to make a single motif to cover an entire protein family, the eMOTIF build algorithm attempts to find a well-conserved subset of the family where it can construct a highly specific motif that will infer just that subset. In order to maintain sensitivity, eMOTIF then attempts to find motifs for additional highly conserved subsets. By using a disjunction of several motifs, each of which covers a different subset of sequences, eMOTIF can maintain a high degree of sensitivity and a very high specificity. The eMOTIF build process effectively subclassifies the protein family and builds motifs that are specific enough to scan entire proteomes with few false inferences. The eMOTIF build process generates multiple motifs that span the entire space of sensitivity and specificity.

In order to minimize overfitting of the training data, eMOTIF is prevented from using arbitrary subsets of amino acids at any position in the motif. Instead, eMOTIF is limited to using only individual amino acids or 20 specified groups of amino acids that have been determined to the 20 most significant sets of amino acids found in protein multiple sequence alignments [126]. These groups of amino acids have been determined by examining the statistical significance of all possible subsets of the 20 amino acids in protein alignments. Only 20 subsets were significantly overrepresented. These subsets of amino acids include hydrophobic, hydrophilic, charged, basic, acidic, small, β-branched, hydrogen bond donor and acceptor classes among others. By limiting the groups of amino acids in motifs to these 20 subsets and the 20 individual amino acids, we prevent the motif from being influenced by outliers and from overfitting the training set data.

The eMOTIF database was originally built from ungapped conserved alignments from Blocks, PRINTS and InterPro protein families [68]. More recently it is built from the eBLOCKs database, but with links from similar families in other databases [114]. The eMOTIF database can be used to scan either individual proteins or entire proteomes. For scanning entire proteomes, one must choose a set of eMOTIFs with a specificity that will give a low false discovery rate. eMOTIF scans of all proteomes have been tabulated in the ePROTEOME database. ePROTEOME is an SQL database of all eMOTIFs found in all open reading frames in over 180 proteomes (Saxonov, Xu and Brutlag, unpublished; http://eproteome.stanford.edu).

eMOTIF has several advantages in searching for functional sites in proteomes. (i) One can chose sets of very high specificity motifs to minimize the false discovery rate, effectively eliminating false predictions. (ii) eMO-

TIF provides motifs targeted at many subsets of a protein family including functional subsets as well as taxonomic subsets. eMOTIFs, being discrete patterns, also indicate the most critical residues for function and the degree of residue variation permitted at each position. (iii) Since eMOTIFs are fixed-length regular expressions, eMOTIF search can be implemented in a number of very rapid search procedures including bitmap compare and trie algorithms that permit searching for thousands of motifs simultaneously. One can search an entire bacterial proteome for over 500 000 different motifs in less than an hour on a single processor machine. eMOTIFs have also been mapped onto all the structures in PDB so that one can readily see three dimensional examples of the eMOTIFs is the 3MOTIF database [26].

3.6 The eMATRIX Database

The original eMATRIX database was a database of PSSMs build from protein alignments in Blocks, PRINTS and InterPro [126, 127]. More recently it includes scoring matrices built from the eBLOCKs database [114]. The primary differences between the eMATRIX approach and other PSSM methods are sensitivity and speed. As mentioned before, eMATRIX calculates its scores using a variable number of pseudocounts for each matrix. The calculation of the correct number of pseudocounts is based on the minimal risk criterion [127]. This approach can increase the sensitivity of eMATRICES over other PSSMs by as much as 25%.

In addition, the inference procedure used by eMATRIX is 100–500 times faster than other methods for two reasons [126]. Prior to performing an eMATRIX scan of a protein or a proteome, eMATRIX takes the minimal threshold probability and converts it to the minimal score that will meet this threshold. At each point in the scan of a protein segment, eMATRIX can tell if it can meet this threshold score. Most often, the initial score for the beginning of a comparison will be so negative that eMATRIX need not finish scoring the entire segment since it knows it can never exceed the threshold score. In this way, eMATRIX only calculates the score for protein segments that do, in fact, meet the threshold. Most protein segments (above 99.9% for a threshold probability of 0.001) never have their score calculated speeding up the inference procedure markedly. The second speed-up comes because eMATRIX does not calculate the segment score in the linear order of the sequence. eMATRIX sorts the columns of the PSSM in order of information content with the most highly conserved positions first and the least highly conserved positions last. By scoring segments in order of conservation; one can tell immediately if a particular protein segment is going to match the matrix after scoring only one or two positions. Taken together, using the minimum threshold for stopping segment scoring early and sorting the scoring matrix by conservation gives a

100- to 500-fold speed-up depending on the specificity of the matrix and its overall length. This increased speed is very important both for interactive use and for the ability to rebuild functional assignment databases as the eMATRIX database is incrementally improved. The eMATRIX database can scan an entire bacterial proteome for 156 000 functional motifs in less time than most other PSSM databases can scan a single protein sequence. Using this method ePROTEOME has been developed which contains all eMATRIX hits in over 180 proteomes.

Because of its more powerful representation, eMATRIX, like other PSSM databases (Blocks, PRINTS, Prosite Profile) generally shows a higher sensitivity at discovering protein functional sites than do eMOTIF or the Prosite Pattern databases. Nevertheless, the use of sequence patterns such as eMOTIFs, Prosite Patterns and ProRules are very useful for identifying the most critical residues for function and which residues are permitted at those positions. All of the eMATRIX motifs have also been mapped onto PDB structures so that examples of the three dimensional structure of the motifs may be observed [25].

3.7 HMM Databases

Unlike the sequence pattern and PSSMs, the HMMs of protein families are more global, representing longer regions and including gapped alignments. HMMs are often used to represent protein families (Pfam [21], TIGRFams [58]) as well as protein structural domains [3, 35, 53, 97]. Since the function of a protein is often linked to family membership, if one can find the family membership of new protein sequence, it will aid tremendously in helping to determine the function of the novel protein. Many of these HMM-based databases are built specifically to aide in proteome annotation. As mentioned above, HMM models have the advantage of linking multiple ungapped motifs together in a probabilistic framework that preserves the order of the conserved functional and structural regions, and can discount the less-conserved regions between them. The ability of an HMM to infer the functional class of a novel protein usually requires that some members of the training set be taxonomically close to the target sequence. For instance, if one were to use HMM models for protein families made from bacterial sequences alone, the models would not be as sensitive when attempting to infer the function of eukaryotic proteins. The same can be said of PSSM and sequence motifs. Ideally, one would like to have multiple HMM models that could span both the functional and the taxonomic axes. There are significant efforts along these lines [105, 116, 117].

HMM models can be used to model short motif regions as well as entire families. By using transition states that represent different regions of a protein, rather than different residues, models of signal peptides, transmembrane helices and even entire transmembrane proteins have been possible [71, 80, 111]. The TMHMM model for transmembrane proteins has different states for the membrane, cytoplasmic and extracellular segments of the protein.

3.8 The InterPro Database

The InterPro Database [4, 90] is a large integrated protein functional annotation resource. The InterPro database integrates several motif-finding algorithms including Prosite [69], PRINTS [11], SMART [81], ProDom [35], Pfam [21], TIGRFams [58], iProClass [67] and Panther [88, 116]. InterPro also contains several structural databases including SCOP [3], CATH [97], Superfamily [53], Gene3D [97] as well as protein structure modeling applications including SWISS-MODEL [76] and ModBase [99]. By integrating these resources into one site, InterPro permits a user to perform many of the relevant analyses on a single protein sequence in one step. The results are both tabulated and presented graphically in linear formats that show the location of the motifs, domains, family and other functional sites along the protein sequence. The InterPro interface basically takes the query and applies each inference engine to it independently and then integrates the output into a single graphical and tabular result. This approach is very attractive because it shows the relationship between the results of many methods. On the other hand, it gives the illusion that many of the functional motif-finding methods are in agreement with each other. The problem is that these methods are not independent from each other; often they are based on different motifs made with the same starting families. InterPro publications state that due to its internal consistency checking it can provide deeper coverage (higher sensitivity) for detection of functional sites. The current InterPro database covers 77% of the UniProt [6] protein database.

Many of the methods included in InterPro have associated measures of specificity, expectation or false discovery rates; however, the user has no ability to change the thresholds for defining a valid hit. Also several methods do not have reliable measures of expectation and hence the results must be examined carefully. Fortunately, the curators have assigned a match status to each hit of InterPro on the protein sequence database including a match descriptor of T for a known true hit, F for a known false positive, N for a known false negative, P for a partial hit and "?" for a match of unknown status. These match status markers can be valuable adjunct to ones confidence in the inferred site.

3.9 Supervised versus Unsupervised Learning of Motifs

Many motif databases have been specifically derived from known protein families with well-defined functional sites and often structures. This is the case for the Prosite patterns, Blocks, PRINTS, Pfam, TIGRFams and SMART motif databases. Many structural domain databases are also built from proteins of known fold, family or subfamily (SuperFamily and Gene3D are two examples). This procedure of building motifs from a well-defined subset of proteins is a classic example of supervised learning. Protein sequences are separated into those that are known to have the requisite function or structure from those that do not. The goal is to develop motifs that can discriminate between the two classes.

An alternative approach is to build motifs in an unsupervised way by comparing all protein sequences to all others, discovering protein families and conserved regions within these families driven only by sequence similarity. This data-driven approach has the advantage that it can find families of proteins and functional motifs for functions that have not yet been discovered or characterized experimentally. This is particularly important for learning protein–protein interaction motifs and other functions that have not been well explored experimentally. Of course unsupervised learning has the disadvantage that many of the conserved regions are anonymous, with their precise functions unknown. One of course learns the family of proteins containing the conserved motif, but not the specific function of the motif for that family.

One approach to annotating anonymous motifs is to associate the motifs with certain descriptors present in the protein sequence annotations. These descriptors can be functional such as Enzyme Commission (EC) classification numbers [16,41], Gene Ontology (GO) terms [7,82], substrate or cofactor binding sites [113], etc., or they could be more general classes such as taxonomic terms, protein family names or properties, or even uncontrolled vocabulary terms such as keywords. Some databases, such as InterPro, have assigned GO terms and other functional descriptors to motifs just based on the GO terms associated with the sequences identified by the motif.

A better approach is to classify the motifs themselves using standard classification methods. For example, using support vector machine (kernel methods) or *k*-nearest-neighbor classification one can discover which motifs from a large collection of anonymous motifs are predictive of enzyme mechanism (EC classification number) [22, 23]. EC numbers are determined experimentally and are assigned manually to each of the enzymes in the Swiss-Prot database; hence, they form a well-defined functional description that can serve as a "gold standard" for enzyme function. Classifying both individual and groups of motifs based on their ability to predict enzyme classification number overcomes the problem that biological functions may be encoded by multiple motifs. Using groups of motifs can also increase the specificity and sensitivity of motifs for predicting biological function. This classification of motifs by function also facilitates the annotation of anonymous motifs.

Another example of learning the function of motifs by comparison with other databases comes from the work of Wang and coworkers [122]. By examining motifs contained in proteins in an extensive protein–protein interaction network, they were able to learn pairs of motifs that were the most likely to be involved in the protein–protein interaction. The motif pairs were able to predict the interactions in nearly 70% of the highly significant interactions in yeast as well as 70% of the yeast protein structures in the Protein Structure Database. Similar efforts to predict interacting domains represented by HMMs have also been successful [43,112].

4 Summary and Conclusions

In this chapter, we have attempted to describe the primary methods for representing conserved functional regions, motifs, in protein sequences. Each method has its own advantages and limitations for representing function and for inferring function in novel proteomes. One of the most important considerations when attempting to infer the function of all the proteins in a proteome is the false discovery rate. As there are so many genes and so many functional motifs, even a relatively specific motif can yield more false inferences than correct ones when applied to an entire proteome. This is particularly true if one is using pairwise sequence similarities to draw functional inferences. Motifs discussed in this chapter have the advantage of providing a family-wise comparison that focuses on the most highly conserved regions and residues in the functional site. By focusing on the conserved residues one increases the signal-to-noise ratio tremendously and permits much more accurate functional inference.

In addition to sequence-based motifs, we have also mentioned network-based motifs and other quantitative motifs that can represent patterns of size, charge, hydrophobicity and other attributes not necessarily obvious in the sequences themselves. These network-based motifs are often more flexible at representing biological function and structural features than sequence based motifs. They also have the ability to represent correlated changes in protein sequence and structure that often elucidate features that nature is conserving that are sometimes hidden by pure sequence representations.

We have discussed two main approaches to learning motifs. The most common is to discover conserved regions in small sets of proteins known to have a common structure or function. This is a supervised method for learning motifs in which biological knowledge is provided via the training set of proteins. The unsupervised approach is to run a systematic comparison of all proteins against all others without regard to function. In such an unsupervised approach one learns the protein families, subfamilies and conserved regions or blocks. Functional annotation can be assigned to these conserved regions either through their component sequences or via motif classification approaches. Unfortunately, due to space limitations, we have not been able to discuss all the different methods for learning the different types of motifs in depth.

Finally, motifs are a compact representation of the critical structural and functional components of proteins. Rather than having to compare new protein sequences against all other protein sequences which are growing exponentially, comparison against a much smaller set of well known conserved regions from protein families is more accurate and much more rapid method for inferring function.

Analyzing Protein Interaction Networks

Johannes Goll and Peter Uetz

1 Introduction

Protein–protein interactions are essential for all biological processes [3]. Although protein interactions have been studied for decades, only recent advances have made them accessible to systematic computational analysis. (i) Large-scale experimental studies generate genomic and proteomic data at an ever-increasing rate, permitting us to analyze whole "interactomes" and related biological information. (ii) Recently established databases of protein–protein interactions make interaction data easily accessible to theoreticians and experimentalists alike. (iii) Increasing numbers of solved three-dimensional (3-D) structures of proteins and protein complexes enable us to study such assemblies in atomic detail *in silico*. However, in contrast to hundreds of completely sequenced genomes, only a handful of comprehensive interaction studies have been carried out and there is no organism for which all protein interactions are known. Thus, we are still at an early stage of computational interactome analysis [114]. The field has exploded since the first interaction maps were published in 1997 for a subset of yeast proteins and in 2000 for a genome-wide data set [40, 117]. In addition to the flood of data, there is an even bigger avalanche of computational studies that analyze interaction data sets (Figure 1). In this chapter we will describe methods for the computational analysis of interaction networks and some results from such studies. We will cover the validation of experimental data sets as well as the prediction of protein interactions (which is a related topic). We will describe graph-theoretic approaches as well as the integration of interaction data sets with other biological information. Finally, we will give a summary of our current knowledge on the evolution of protein interactions.

2 Experimental Methods and Interaction Data

Before interaction data can be analyzed properly, their origin and nature need to be defined. In the past authors often compiled interaction data from different experiments into single data sets although the interactions were not really comparable. Thus, computational biologists need to know at least the basics about the experimental methods with which their data has been generated. For example, protein complexes are often treated as if all the interactions in them are known, although in most cases we do not know any of them (Figure 2, see also Refs. [35, 103] for further experimental details).

Although there are many experimental methods for analyzing protein interactions (Table 1), the bulk of the data has been produced with just a handful of them. The two most popular are the yeast *two-hybrid system* (Y2H [13, 34]) and *protein (or complex) copurification* in conjunction with tandem mass spectrometry (MS [88]). Their popularity mostly stems from the fact that both can be automated to a large extent and therefore carried out in a high-throughput fashion to produce large data sets of fairly consistent quality.

Y2H was the first to be used for several large-scale studies (reviewed in Ref. [133]). It uses two fusion proteins ("hybrids") whose interaction results in the activation of a reporter gene or enzyme whose activity can be detected or measured quantitatively [13, 14, 34].

The requirement for two hybrid proteins is one of the reasons why the system suffers from *false negatives*, i.e. physiological interactions that the method does not detect. The reason are most likely steric effects that prevent the proteins from interacting because of the fused domains. Another source of false negatives is the fact that these assays are usually carried out in yeast. If non-yeast proteins are tested they may not have post-translational mod-

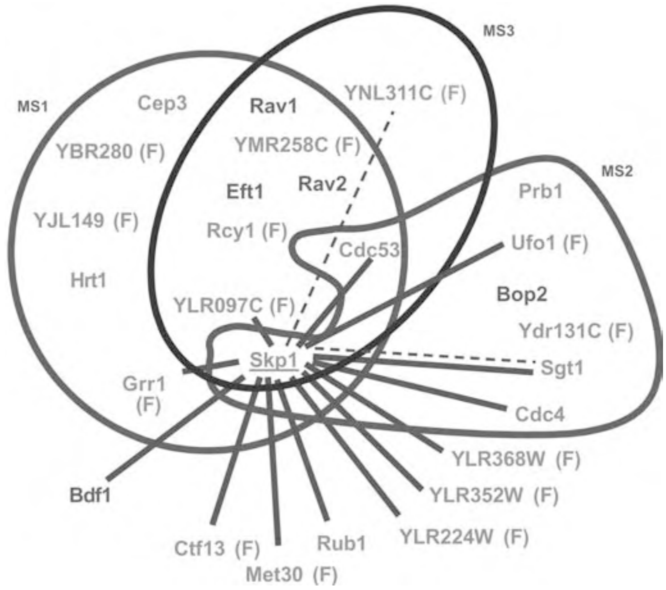

Figure 2 Interaction data gained by Y2H and MS. Skp1 is a protein involved in ubiquitin-mediated protein degradation, and has been epitope-tagged for both Y2H screens and MS analysis. The purified complexes of Skp1 from three independent MS studies (circles) and the binary interactions from two Y2H studies (solid and hatched lines) are shown. Despite the differences in the data sets, most of the discovered interactions seem to be plausible: most associated proteins are known to be involved in protein degradation. Skp1 is directed to its target proteins via so-called F-box proteins, which contain a short peptide motif, the F-box (F). (From Ref. [127].)

ifications that are necessary for interaction. Y2H has also a reputation of generating *false positives*, i.e. interaction signals that do not stem from real physical interactions. Most cases of false positives are not reproducible and are therefore not easy to explain. They are probably caused by mutations or other random events in the yeast cells used for the assay.

Protein *complex purification* (or copurification) and subsequent analysis by MS is the other major method for detecting protein interactions. However, this method is fundamentally different as it does not detect binary interactions (except in cases where only two proteins are copurified). Instead, a purified complex contains proteins that are held together by protein–protein interactions whose precise topology is usually not known (Figure 2).

Like Y2H, complex purification is also prone to generate false positives (proteins unspecifically binding to the complex) and false negatives (proteins that are lost from the native complex by too stringent washing).

Aloy and Russell [6] presented evidence that MS analysis of purified complexes tends to identify *stable complexes* while the Y2H assay tends to be biased towards *transient interactions*. Although it is difficult to classify experimentally

Table 1 Features of selected protein interaction detection methods

Class	Method	Analytical perspective[a]	Resolution level[a]	Advantages
Biochemical	affinity purification[b] + MS (MS)	perspective	complex	*in vivo*
	ELISA	analytical	protein	
	filter blot	analytical	protein	
	pull-down	analytical + perspective	protein/residues	
	comigration in non-denaturing gel	analytical	complex	*in vivo*
	Far Western[c]	analytical	protein	
	chemical cross-linking[d]	analytical + perspective	protein	
Biophysical	X-ray crystallography	analytical	atomic	
	NMR	analytical	atomic	
	surface plasmon resonance (Biacore)	analytical	protein	quantitative, kinetics
	isothermal titration calorimetry	analytical	protein	quantitative, kinetics
	scintillation proximity assay	analytical	protein	kinetics
Protein complementation	two-hybrid	perspective + analytical	protein	*in vivo*
	FRET	analytical	protein	*in vivo* location
Array technologies	protein array	perspective	protein	
	pep spot	perspective + analytical	residues	
	phage display	perspective	residues	

[a] *Perspective* applies to methods that have currently been used to explore uncharacterized protein interaction, whereas *analytical* applies to experimental procedures that investigate known interactions. Note that the resolution level is meant to be general. When mutants, etc., are used, the resolution of every method can be at the residue level.

[b] Also called coIP or protein complex purification. Note that copurifications are usually combined with subsequent mass spectrometric analysis of the copurified proteins.

[c] Far Western blots work like ordinary Western blots except that a blotted protein is detected by an interacting proteins as opposed to an antibody. The interacting protein can be labeled itself or detected by a labeled antibody.

[d] In cross-linking experiments proteins are cross-linked by bifunctional chemicals so that they cannot fall apart when purified. This allows more stringent purification protocols to be applied and thus cleaner preparations are achieved that can be analyzed more easily for their protein content.

found interactions as transient or stable, it is clear that the methods detect different kinds of interactions and are therefore highly complementary (Figure 2).

Table 2 High-throughput interaction detection experiments

Organism	No. purified complexes	No. binary interactions	Method	Reference
H. pylori	–	1465	two-hybrid pooling of fragment library	105
E. coli	530	5254[a]	tap tag coIP	21
P. falciparum	–	2846	two-hybrid pooling approach	80
S. cerevisiae	–	4549	two-hybrid pooling approach	62
S. cerevisiae	–	1511	two-hybrid array approach	132
S. cerevisiae	589	3757[a]	tap tag coIP	41
S. cerevisiae	741	2583[a]	flag tag coIP	58
C. elegans	–	4624	two-hybrid pooling approach	85
D. melanogaster	–	20676	two-hybrid pooling approach	45
D. melanogaster	–	$\sim$ 2300	two-hybrid pooling approach	37
H. sapiens	32	1814[a]	tap tag coIP	17
H. sapiens	–	2800	two-hybrid array approach	111
H. sapiens	–	3186	two-hybrid array approach	123

[a] Binary interactions are derived from co-purified complexes only as a set of bait–prey pairs, according to the "spoke model" (Figure 5).

Y2H screens and large-scale complex purifications have now generated large data sets (Table 2). Together with manually curated small-scale data, these interactions can now be downloaded from several protein interaction databases (Table 3).

3 Validation of Experimental Protein–Protein Interaction Data

Any experimental method suffers from a certain number of false positives and false negatives. However, high-throughput methods are more prone to such artifacts as they generate them as systematically as they generate valid data. Several computational methods have been proposed to evaluate the quality of interaction data. Critical for any method is the benchmark data set that is a "gold standard" of interactions that can be considered as reliable and compared to a new interaction data set. With such benchmarks most methods can suggest rough estimates of the rate of false negatives/positives. Some important approaches and benchmarks are summarized in the following sections.

3.1 Crystal Structures as Benchmarks

The crystal structure of a protein complex is the "gold standard" for a protein interaction as the structure provides the most detailed information. Unfortunately, there are not many structures available for protein complexes consisting of three or more proteins. One of the best studied cases is the crystal structure of yeast RNA polymerase II that consists of 10 subunits which are connected by 18 interactions [25]. While Y2H studies of a similar complex (RNA polymerase III and several associated proteins) found only 12 interactions among the 19 proteins [36], the crystal structure of RNA polymerase II shows a number of "interactions" where subunits barely touch each other. It is unlikely that such weak interactions will be detected by any method except by structure analysis. Of course, the polymerase complex interacts with many other associated proteins that are not detected when the purified complex is analyzed by MS because they are lost upon purification. Edwards and coworkers [30] estimated the false negative rate of various methods to be between 0% (for chemical cross-linking) and 67% (for Far Western experiments) based on the crystal structure of RNA polymerase II (which was treated as a "true gold standard"). Similarly, their estimates for false positives ranged from 41% (for chemical cross-linking) to 67% (Far Western).

3.2 Overlap with Protein Complex Data

In addition to structural information, data from purified complexes can be used for evaluation purposes as well. Edwards and coworkers [30] analyzed the overlap of various interaction data sets with the MIPS complex catalog [92] – a set of individually validated protein complexes. Based on the overlap with this data set, these authors estimated the rate of false negatives to be between 51 and 85% for various high-throughput two-hybrid data sets and to be 50% for high-throughput complex purification data. Note, however, that estimates of false positives and negatives heavily depend on the precise methods used, the biological object and the bioinformatics filtering applied to the raw data.

3.3 Correlation with Expression Data

Deane and coworkers [28] used expression data to measure the overall reliability of a given interaction data set. The idea is to take interacting proteins and see if their expression is coregulated, i.e. if interactions correlate with expression levels. Deane called their measure *expression profile reliability* (EPR) index. It compares the RNA expression profiles for the proteins whose interactions are found in a screen with expression profiles for known interacting and noninteracting pairs of proteins. Based on such correlation studies, Deane and coworkers estimated the error rates to be roughly 50% among the Y2H interactions in the Database of Interacting Proteins (DIP) [115]. Note that most such correlations can only evaluate *data sets* as opposed to *single interactions*. Similar studies involving correlations of expression data and protein interaction data were published by Ge and coworkers [42], Grigoriev [50], and Tornow and coworkers [128].

3.4 Functional Annotation

Interacting pairs can be also evaluated by means of their annotation in databases, e.g. Gene Ontology (GO) terms [44]. If two interacting proteins have the same annotation, e.g. "vesicular transport", this supports the validity of their interaction. This method was used by Sprinzak and coworkers [121] to validate interaction data. Of course, any other type of annotation can be used in similar ways. Other studies broadened this concept by not limiting it to annotations in databases, but by using "keyword retrieval" in general, e.g. from PubMed abstracts (see Section 4.5). However, even truly related proteins show only a partial keyword overlap and sometimes none at all.

3.5 Localization

Proteins can only interact if they occur in the same subcellular compartment, for example the nucleus. Sprinzak and coworkers [122] used functional annotation and localization data to estimate the false-positive rate among high-throughput two-hybrid data to be on the order of 50%.

3.6 Paralogous Proteins and Evolutionary Rate

The paralogous verification method (PVM) of Deane and coworkers [28] judges an interaction likely if the putatively interacting pair has paralogs that also interact. In contrast to the EPR index (see Section 3.3), which evaluates data sets of interactions, PVM scores individual interactions. On a test set, PVM identified correctly 40% of true interactions with an estimated false-positive rate of about 1%.

Fraser and coworkers [38, 39] suggested that the correlation between protein interaction and evolutionary rate may allow one to use sequence comparisons to statistically assess the quality of interaction data sets (see Section 8.2.1 for more details).

3.7 Other Approaches

There are a number of other criteria that can be used to evaluate interactions. In fact, any kind of information can be used that reflects similarities between putative interaction partners. In bacteria, genes that are *neighbors* in the genome are often organized in the same operon and thus often function together [26]. Similarly, protein pairs that are conserved throughout evolution may have been coselected because they are required for a common function and thus may interact. Pairs or groups of proteins with such shared evolutionary patterns are said to have common *phylogenetic profiles* [102] (see also Chapter 32). Finally, *genetic interactions*, i.e. mutations in two or more different genes that show a stronger phenotype any of the individual genes support a physical interaction between them or, in fact, the other way round [73, 142]. Note that genetic interactions provide rather indirect evidence that two proteins interact physically as opposed to biochemical or physical methods. Goldberg and Roth [49] exploited the *neighborhood cohesiveness* property of small-world networks (see Section 5.4), to assess confidence for individual protein–protein interactions. By ascertaining how well each protein–protein interaction fits the pattern of a small-world network, they were able to stratify even those interactions with identical experimental evidence. Another simple measure has been introduced by Saito and coworkers [112, 113]. Their *interaction generality* measure is basically the number of proteins involved in a given interaction. Saito and coworkers found that interactions with low generalities are more likely to be reproducible in other independent assays. However, this strategy appears to work only for raw interaction data that have not been filtered for "sticky" proteins (i.e. proteins that appear to have many unspecific interactions).

3.8 Combined Approaches

Ideally, several different sources of information should be combined to evaluate interaction data, particularly high-throughput data. This approach was chosen by von Mering and coworkers [137], who demonstrated that the number of false-positive interactions can be reduced by focusing on the intersection of interactions generated by different kinds of experimental technologies [e.g. the overlap between Y2H interactions and coimmunoprecipitation (coIP) data]. Furthermore they showed that such overlapping data mainly consist of interactions in which both partners have the same functional annotation and cellular localization. Similar studies have been carried out by Sprinzak and coworkers [122] (who combined localization and annotation data) and other authors [9]. Figures 3 and 4 show examples of data quality evaluations and how to improve them by integrating several sources.

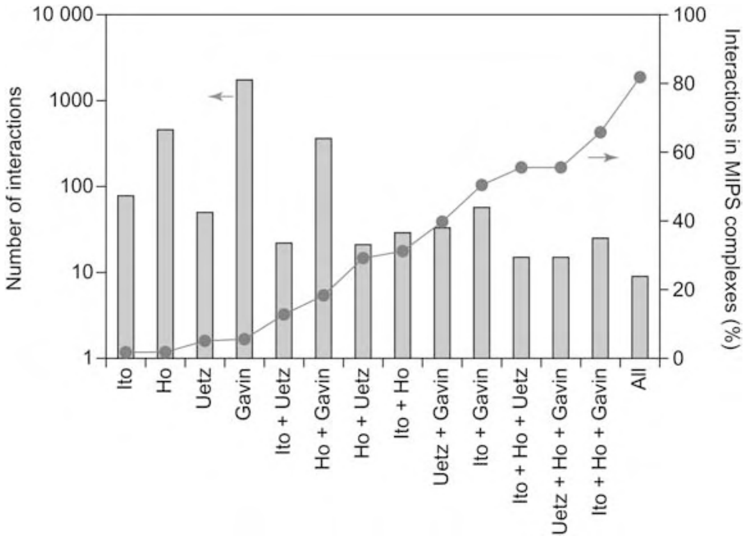

Figure 3 The size of the different genome-wide data sets and their possible intersections and their consistency with the MIPS complexes catalog [92]. The bars (relating to the left y-axis) indicate the number of interactions in each individual data set and each possible intersection of the data sets (e.g. 'Ito + Uetz' contains only interactions that are both within Ito and Uetz). The line (relating to the right y-axis) shows what fraction of these interactions overlaps with protein pairs within the same MIPS complex. The individual data sets are arranged on the left, pairwise intersections of data sets in middle and higher-order intersections (three or more data sets) on the right. As the degree of intersection among the data sets increases, the fraction of interactions within the same MIPS complex increases. The different data sets are complementary and cover more interactions than each data set individually. (From Ref. [30].)

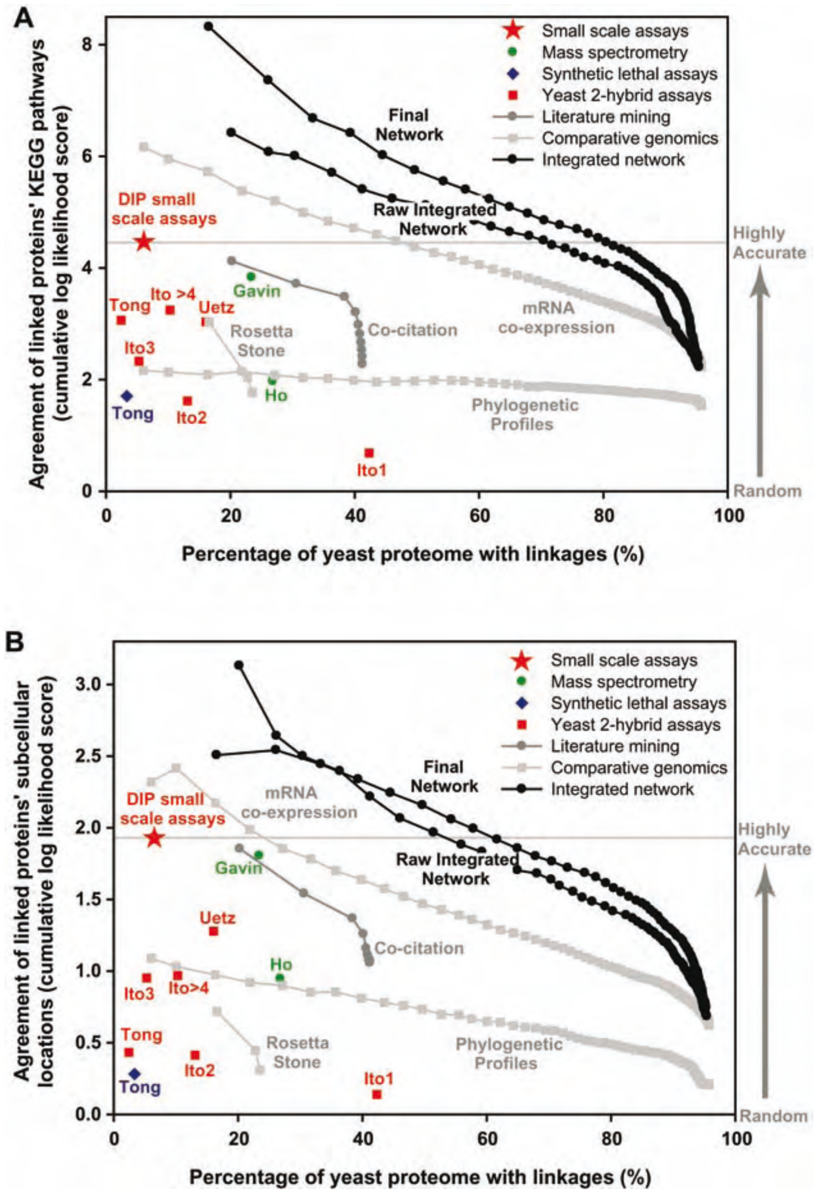
However, as long as automated validation methods are not significantly improved, validation by manual expert analysis remains key.

3.9 Comparison of Specific Data Sets

A lot of effort has been spent on comparing the quality of different data sets [30]. Such comparisons also serve as cross-validation as shown by the following example (data from Ref. [24]).

3.9.1 **Comparison of Tandem Affinity Purification (TAP) and High-throughput MS (HMS) complex purification data**

Protein complex purification has been used most extensively in yeast and two main methodological variations have been used: TAP [41] and HMS [58] protein complex identification (HMS-PCI). The two approaches differ in the way proteins were expressed (from their natural chromosomal location in TAP



and from overexpressing plasmids in HMS-PCI) and in the tags that were used for the purification of the protein complexes. Such technical details can cause tremendous differences in the resulting interaction data.

On average, the number of proteins common to the TAP and HMS-PCI data sets is less than 9% of the total number of proteins in both data sets. For example, employment of Yju2p as a bait identified 15 proteins using TAP

Figure 4 Benchmarked accuracy and extent of functional genomics data sets and the integrated networks. A critical point is the comparable performance of the networks on distinct benchmarks, which assess the tendencies for linked genes to share (A) KEGG pathway annotations [70] and (B) protein subcellular locations [59]. Each x-axis indicates the percentage of protein-encoding yeast genes provided with linkages by the plotted data; each y-axis indicates relative accuracy, measured as the agreement of the linked genes' annotations on that benchmark. The "gold standards" of accuracy (red star) for calibrating the benchmarks are small-scale protein–protein interaction data from DIP [115]. Colored markers indicate experimental linkages; gray markers, computational. The initial integrated network (lower black line), trained using only the KEGG benchmark, has measurably higher accuracy than any individual data set on the subcellular localization benchmark; adding context-inferred linkages in the final network (upper black line) further improves the size and accuracy of the network (see Ref. [81] for details and additional benchmarks).

and 15 using HMS-PCI. Only one protein (Prp19p) is common to both sets. This shows that experimental details have to be borne in mind when interaction data sets are compared. As another example, there can be considerable disparity between the size of complexes generated by TAP and HMS-PCI. Complexes generated using baits Pwp2p and Kap104p contain 54 and four proteins, respectively, using TAP, compared to seven and 36 using HMS-PCI.

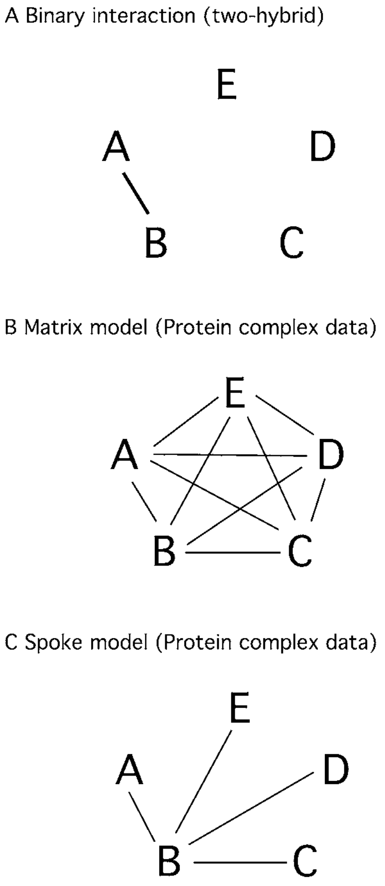
3.9.2 Comparison between Y2H and MS data sets

The largest overlap found by Cornell and coworkers was between the TAP and the Uetz Y2H data sets [41, 132] where 21% of the interactions found by Y2H are supported by affinity purification. In contrast, less than 7% of the Y2H interactions in the Ito data set are supported by TAP.

3.9.3 Comparison of Spoke versus Matrix Models

Cornell and coworkers [24] compared TAP and HMS-PCI complexes using the spoke and matrix models (Figure 5). The two data sets were validated by counting coexpressed proteins and by comparing functional annotations of all proteins in a complex. For example, a protein complex is considered to be of high quality if all proteins in it are expressed in the same cell at similar levels and if all proteins have similar functional annotations (Figure 6). According to Cornell et al. [24], the spoke model generated 3163 protein pairs from TAP complexes and 3503 pairs from HMS-PCI. The matrix model generates 17 281 protein pairs from TAP complexes and 30 672 pairs from HMS-PCI. Interestingly, Cornell and coworkers [24] found that the experimental approach (TAP versus HMS-PCI) affected their analysis more than the choice of data model (here, matrix versus spoke model). This shows that data sets may be more important than data models!

Thus, the *choice of data sets* is often critical. This is also true for subsets of proteins which can be selected by a wide range of fairly arbitrary criteria. For



A Binary interaction (two-hybrid)

B Matrix model (Protein complex data)

C Spoke model (Protein complex data)

Figure 5 Data models for protein interactions in complexes. (A) A protein complex may consist of five subunits, A–E, hold together by five interactions. A two-hybrid assay may detect only interaction A–B, while other methods may detect the other interactions (dotted lines). (B) The matrix model assumes that each subunit interacts with every other subunit. (C) The spoke model assumes that the bait protein interacts with all other proteins.

example, a protein pair that occurs in more than one complex can be defined as a frequently observed pair (FOP), while those that occur only once may be defined as singly observed pairs (SOPs). Furthermore, those SOPs in which each protein occurs only once in that data set have been defined as unique SOPs (U-SOPs). Analysis of expression profile correlation shows that FOPs tend to have much greater correlation coefficients than SOPs. The correlation coefficients for SOPs are similar to those of random protein pairs [24].

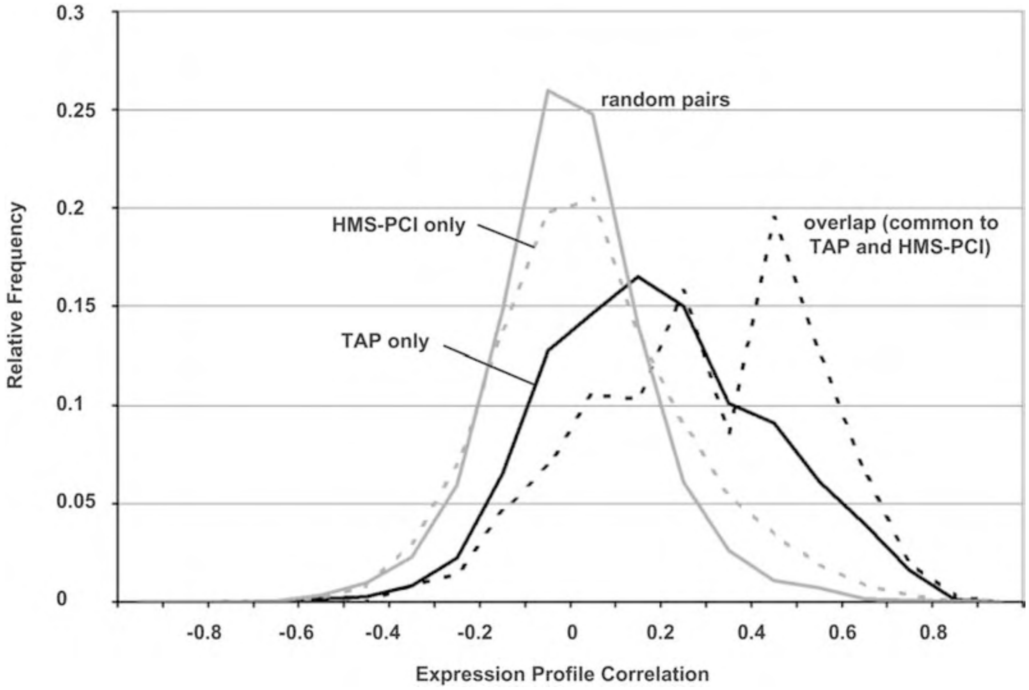


Figure 6 Frequency distribution of expression profile correlations for pairs of proteins in affinity-purified protein complexes, purified using the same bait protein by TAP and HMS-PCI. Key: black dashed line, overlap – pairs of proteins common to both TAP and HMS-PCI complexes; grey dashed line, HMS-PCI only – pairs of proteins purified only by HMS-PCI; black solid line, TAP only – pairs of proteins purified by TAP only; grey solid line, random pairs – a set of 4010 pairs of randomly chosen proteins [24].

4 Predicting Protein–Protein Interactions

Predicting interactions is conceptionally similar to validation. While validation involves the comparison of interaction data to certain benchmarks such as colocalization data, such criteria can also be used to predict protein–protein interactions. In other words, *potentially interacting* proteins can be selected from the pool of *all possible* protein pairs of a genome by applying such filtering criteria.

The maximum number of possible protein–protein interactions in a proteome is approximately:

$$\binom{n+k-1}{k} = \frac{(n+k-1)!}{k!(n-1)!}$$

with n being the size of the proteome (i.e. the number of proteins) and $k = 2$ for binary interactions including homodimers, and counting an interaction

Figure 7 Methods for predicting protein interaction partners from genomic and sequence information. The methods are presented according to the amount of information they include, ranging from simple patterns of gene presence in genomes to detailed sequence information (amino acids in each position) in protein families. (a) Phylogenetic profiles [102]. A profile is constructed for each protein (Prot a–Prot d), recording its presence (1) or absence (0) in a set of organisms (Org 1–Org 4). Pairs of proteins with identical (or similar) phylogenetic profiles are predicted to interact (Prot a and Prot c in this case). (b) Conservation of gene neighborhood [26]. Proteins whose genes are physically close in the genomes of various organisms are predicted to interact (Prot a and Prot b). (c) Gene fusion [31, 89]. Two proteins of a given organism (Prot a and Prot b of Org 1) are predict to interact if they form part of a single protein in other organisms (Org 2). (d) Similarity of phylogenetic trees (mirrortree) [46, 101]. To obtain a quantitative indicator of the interaction between two proteins (Prot a and Prot b), the multiple sequence alignments (MSAs) of both proteins are reduced to the set of organisms common to the two proteins (Org 1–Org 5). Each of the reduced alignments is used to construct the corresponding intersequence distance matrix. These matrices are commonly used to construct the corresponding phylogenetic trees. Finally, the linear correlation between these distance matrices is calculated. High correlation values are interpreted as indicative of the similarity between phylogenetic trees and hence are taken as predicted interactions. (e) Correlated mutations (i2h) [100]. The first step (reduction of the MSAs to a set of common organisms) is the same as that described for the mirrortree method (d). A correlation coefficient is calculated for every pair of residues. The pairs are divided into three sets: two for the intraprotein pairs (Caa and Cbb; pairs of positions within Prot a and within Prot b) and one for the interprotein pairs (Cab; one position from Prot a and one from Prot b). The distributions of correlation values are recorded for these three sets. The “interaction index” is calculated by comparing the distribution of interprotein correlations with the two distributions of intraprotein correlations [100].

pair A–B and B–A as a single interaction. For example, a proteome of a small prokaryote ($n = 1000$) corresponds to a maximum of 500 500 potential binary interactions.

Note that interacting protein pairs may behave differently depending on their “orientation” in an experiment. For example, when an antibody against protein A precipitates protein B, an antibody against protein B may not precipitate protein A. For that reason, many experiments have to be carried out in both “orientations” for full coverage. This leads to exponentially growing numbers in experiments required for genome-wide studies. For example, while a small bacterium with 1000 genes has 10^6 interaction pairs to be tested, a medium-sized eukaryotic genome requires already 100×10^6 pairwise combinations to be tested. Given that the number of binary protein combinations grows exponentially it is unlikely that the interactomes of higher eukaryotes will be fully covered by experimental means in the near future. Note that eukaryotes also exhibit variations such as alternative splicing or post-translational modifications which often affect protein interactions and thus increase complexity by at least another order of magnitude. In addition, all experimental methods show a certain degree of false negatives so that

even experiments rarely identify all interactions. The experimental bottleneck motivated the design of algorithms for predicting protein interactions (Table 3 lists databases of predicted functional associations). It is usually much more efficient to verify predicted interactions experimentally than just doing experiments randomly without such preselection. One has to bear in mind, however, that predictions are often based on experimental limitations. For example, interactions among membrane proteins are usually underpredicted because they are also underrepresented in the data sets that are used to make the predictions.

One can distinguish three main types of algorithms:

(i) Predictions based on functional relationships such as colocalization, genomic context, etc. Text mining is a special case of such relationships where protein interactions may be already encoded in the literature.

(ii) Docking of known protein structures.

(iii) Homologous interactions in organism A can be predicted based on existing interaction data in organism B and *vice versa*.

4.1 Predictions Based on Genomic Context

Several algorithms predict protein associations on the basis of sequence data from completely sequenced genomes and are inspired by comparative genomics techniques (for details see Chapter 32). The main methods are as follows (Figure 7).

4.1.1 The Rosetta Stone Method

This method is based on the fact that multi-domain proteins found in one organism may be split in another. It is thus likely that the fused domains interact within the multi-domain protein and thus the separate domains may interact as well [89]. Illuminating in this respect are some observations by Aloy and coworkers [4] who found that SH2 and SH3 domains within a single multi-domain protein can "interact" in at least three different ways in a protein crystal. This indicates that the two domains do not always interact in the same way, i.e. their interaction surfaces are not strictly conserved. It is equally possible that they have been oriented in different ways in the crystal because there are equally different ways to crystallize.

Interestingly, Aloy and coworkers [4] also found several different classes of successful Rosetta predictions – fused domains can interact similarly or differently when compared to their separated counterparts. For example, the enzyme imidazole glycerophosphate synthase is composed of two different structural domains – a histidine biosynthesis domain and a class I glutamine amido-transferase domain. These domains are encoded by separate genes in archaea but fused in eukarya. Despite the huge evolutionary distance between these organisms, the interaction is conserved. However, for other fusions the interaction is different. For example, despite significant sequence similarity (PID = 34%, where PID is the percentage sequence identity, i.e. the number of identical residues divided by the number of structurally equivalent residues), the FAD/NAD(P) binding and thioredoxin-like domains interact differently when separated.

4.1.2 **Gene Neighborhood**

The gene neighborhood approach rests on the fact that many functionally related genes in bacteria are organized in operons, i.e. they are gene neighbors. Furthermore, often proteins encoded in one operon interact in a protein complex, e.g. a multi-protein enzyme complex. Neighboring genes in bacteria are therefore more likely to interact than proteins encoded in other regions of the chromosome. Unfortunately this is not true for eukaryotes which usually do not have operons.

4.1.3 **Phylogenetic Profiles**

The phylogenetic profile method [102] deduces functional links between genes that have similar occurrence patterns of orthologs in a set of reference genomes. In other words, if pairs or groups of proteins are maintained in many different genomes this may be because they have been selected as groups and thus may functionally or physically interact. Phylogenetic links are collected by the STRING database ([136] and see also Chapter 32) and other websites listed in Table 3.

The Protein Link EXplorer (PLEX) is a web-based environment that allows the construction of a phylogenetic profile for any given amino acid sequence, and its comparison with profiles of approximately 350 000 predicted genes from 89 genomes [27].

4.1.4 Similarity of Phylogenetic Trees (SPT)

As we have seen, interacting protein pairs coevolve, e.g. insulin and its receptors. In such cases, the corresponding phylogenetic trees of the interacting proteins show a greater degree of similarity (symmetry) than those of non-interacting proteins. Thus, similar phylogenetic trees of potential interactors support their interaction. In fact, the phylogenetic profile method is related to this procedure, but goes even one step further because gain or loss of a gene is the ultimate step in protein evolution. In other words, while phylogenetic profiles look for the absence or presence of homologous proteins, the SPT method quantifies homology. The SPT method is also called the *mirrortree* method [101, 134].

4.1.5 *In Silico* Two-hybrid (I2H)

As a refinement of the previous method, the coevolution of interacting proteins can be followed more closely by quantifying the degree of covariation between pairs of residues from these proteins (correlated mutations). These positions may correspond to compensatory mutations that stabilize the mutations in one protein with changes in the other. The relationship between correlated residues and interacting surfaces has been used to predict interacting protein pairs based on the differential accumulation of correlated mutations between the interacting partners and within the individual proteins [100].

As in the case of the mirrortree method, the main limitation of the I2H approach is the need for complete alignments with a good coverage of species common to the two proteins under study.

4.2 Predictions Based on Known 3-D Structures

If the structures of all proteins were known, their interactions should be predictable by docking methods. Although docking of rigid structures is theoretically possible, the problem turned out to be much more difficult to solve because proteins are not rigid. In fact, many interactions do require some amount of induced fit for optimal binding [33, 48]. The problem and methods for solving it are discussed in more detail in Chapter 17.

4.3 Predicting Interaction Domains

Protein–protein interactions are usually mediated by specific protein domains. Some of the best-characterized domains are indeed interaction domains such as the SH2 or SH3 domains [84]. Several authors made use of this fact in order to identify interacting domains computationally [29, 95, 121]. Briefly, when certain proteins with a shared domain A interact with other proteins that share a domain B, this suggests that domains A and B mediate this interaction (Figure 8).

4.4 Predicting Homologous Interactions: Interologs

Proteins and their functions are usually well conserved throughout evolution. It has also been known for a long time that protein–protein interactions are conserved, e.g. in hemoglobins whose heterotetrameric structure is found throughout all vertebrates. Yu and coworkers [146] found that protein–protein interactions can be predicted when a pair of homologous proteins has a joint sequence identity above 80% or a joint E-value lower than 10^{-70}. These "joint "quantities are the geometric means of the identities or E-values for the two pairs of interacting proteins. This corresponds to an E-value lower than 10^{-10} for each orthologous protein and both having a sequence coverage of at least 80% of their residues. Similarly, Matthews and coworkers [91] used interaction data from yeast to predict interaction partners in *C. elegans*, many of which were indeed confirmed experimentally.

Thus, given that proteins A and B interact in yeast, we would predict that homologous proteins A′ and B′ in *Caenorhabditis elegans* interact as well (Figure 9). Such homologous, interacting pairs have been called *interologs* by Matthews and coworkers [91].

Interestingly, Matthews and coworkers [91] did not find a clear correlation between sequence similarity and the likelihood of an interaction being conserved between yeast and worm. However, this may be explained by different experimental systems and a small sample size. More importantly, given that interactions are usually mediated by protein domains or even short peptides, the *overall* similarity between interologs does not need to correlate with the propensity to interact.

Several studies used an interolog approach to predict human protein–protein interactions from model organism interaction data [19, 82, 110]. First, all reciprocal best BLAST hits were selected in the human and model organism proteomes (see Chapter 3 for details on BLAST). Then interaction data from yeast, worm and fly were mapped onto the human proteome. Using this approach, the three studies predicted between 23 889 and about 70 000 human interactions, respectively. The differences stem mostly from different starting interaction data sets and different cutoff criteria for protein similarity although Rhodes and coworkers [110] also used other criteria such as expression data and functional annotations.

There are not many attempts to predict interactions in bacteria as there are only a few systematic studies [21, 87, 105]. Wojcik and coworkers [140] predicted 1280 interactions in *Escherichia coli* based on two-hybrid data from

Figure 8 Computational identification of interaction domains. In the upper panel, each row contains the sequences of a pair of proteins (A,B) whose interaction was determined experimentally. Each sequence is characterized by its signatures, denoted here schematically by colored shapes. In the lower panel, a contingency table of the signature combinations is described, where each entry (i,j) in the table shows the number of protein pairs that contain signatures i and j in concert, i.e. where one protein contains signature i and its pair mate contains signature j. For example, the sequence-signature pair represented by an orange rectangle and a pink triangle appears in two pairs of interacting proteins. The most abundant pair of sequence-signatures is that of a red ellipse and a green trapezium which appears in four different pairs of interacting proteins. In the next step of the analysis the likelihood of the identified sequence-signature pairs is evaluated. (From Ref. [121].)

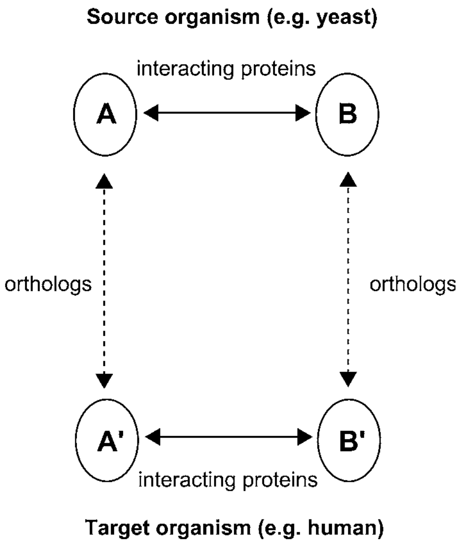

Figure 9 Protein–protein interologs. A–A′ and B–B′ are orthologs between the two organisms. Interolog mapping can be generalized when paralogs or whole protein *families* are considered (as opposed to single orthologs) (Modified after Ref. [146]).

Helicobacter pylori. However, they considered only 154 interactions to be reliable, based on their interacting domain profile pair (IDPP) method (Figure 10).

4.5 Predictions based on Literature Mining

Many protein–protein interactions are buried in the primary literature. In order to retrieve this information, Natural Language Processing (NLP) algorithms are used. These algorithms use abstracts and/or full texts of articles to extract links between genes and proteins. Knowledge extraction is not a trivial task as literature information is extremely noisy, due to insufficient synonym definitions, synonym variations and gene families with fuzzy naming conventions. Nevertheless, with the ongoing establishment of synonym databases and systematic names (HUGO [32], Entrez Gene [86]) for gene or gene product names, the predictions are getting more and more sophisticated. Jenssen et al. [66] analyzed over 10 million Medline titles and abstracts, and identified a cocitation network of almost 14 000 human proteins. Obviously, such relationships often do not represent physical interactions, e.g. when several oncogenes need to be mutated to cause cancer. Other attempts to mine Medline abstracts for protein interactions have been published by Marcotte and coworkers [90], Bunescu and coworkers [20], LaBaer [79], Oyama and

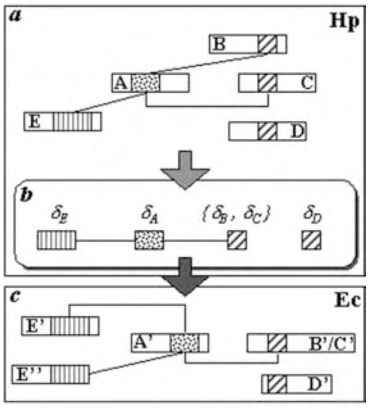

Figure 10 The IDPP method (p. 1143). An abstract domain cluster interaction map (b) was derived from the initial protein interaction map of *H. pylori* (Hp) (a). Domains were clustered together if (i) they shared significant sequence similarity and (ii) they shared a common interaction property with a third partner (e.g. interacting domains of proteins B and C both interact with A). Each domain or profile was then used as a probe for screening a library of *E. coli* (Ec) protein sequences and domain cluster interactions were transferred (c) (see Ref. [141] for further details).

coworkers [98], and Hao and coworkers [55]. More details on literature mining can be found in Chapter 34.

4.6 Validation of Predicted Protein–Protein Interactions

Even more than experimental techniques, predictive methods call for validation of their results and for assessment of their sensitivity and selectivity. In fact, validation of predicted protein interactions can be performed the same way as for experimental interactions (see Section 3).

Again, the first and most important way of validation is the comparison of predictions with some "gold standard" data set, i.e. manually or automatically collected data of high reliability, such as subsets of MIPS [92], DIP [115] or IntAct [56], or specifically collected data [137, 146]. The significance of the predictions is evaluated by calculating the fold improvement over a virtual random experiment and/or the correlation between the predicted and the standard data set.

Huynen and coworkers [61] compared the three methods based on genomic information. In their analysis, the method based on gene order could be applied to 37% of the *Mycoplasma genitalium* genes, whereas the phylogenetic profile method and the method based on gene fusion could only be applied to 11 and 6%, respectively. The combination of the three methods yielded predictions for 50% of *M. genitalium* genes, with just a small degree of overlap in the techniques. With respect to the accuracy of this test set, the percentage of pairs predicted by the three methods that either present a physical interaction, belong to the same macromolecular complex, form part of the same pathway or are implicated in the same process are: 78% for "gene fusion" (with no false positives), 80% for "conservation of gene order" and 63% for "phylogenetic profiles". The percentages for physical interactions only are 56, 30 and 23%, respectively.

5 Representing Protein–Protein Interactions as Graphs

Protein interactions within a cell form large networks and thus can be represented by graphs (Figure 11 and Ref. [12]) and be mathematically analyzed using graph theory [139]. Surprisingly, protein networks and many other natural networks are governed by a few simple organizing laws.

5.1 Graph Terminology

A graph G is a set of *vertices* (or *nodes* or *points*, here *proteins*) and *edges* (or *lines*, here *interactions)* denoted by $G = (V,E)$, where the elements of V are vertices and the elements of E are edges, two-element subsets of V, with $E \subseteq V \times V$. Often n is used to represent the number of vertices $|V|$ and m to represent the number of edges $|E|$. The usual way to picture a graph is by drawing a dot for each vertex and joining two of these dots by a line if the corresponding two vertices form an edge (Figure 12). How these points and lines are drawn is potentially relevant as the vertices represent different proteins and the interactions may differ in their nature.

It is the job of graph drawing algorithms to layout and display this information optimally. A graph is *undirected* if its edges are undirected, otherwise it is called *directed* (or a *digraph)*. Edges in a digraph are usually represented by arrowed lines. Vertices joined by an edge are said to be *adjacent*. A *neighbor* of a vertex v is a node adjacent to v. The *neighborhood* is the set of neighbors of vertex denoted by $N(v)$.

The *closed neighborhood* is the set of neighbors including v. A graph G is *complete* (or called a *clique)* if all its vertices are pairwise adjacent.

The *degree (or valency)* of a vertex v is the number of edges incident with v; this is equal to the number of neighbors of v. A vertex of degree 0 is *isolated*. In directed graphs one has to distinguish between the incoming degree, the number of edges ending at the node and the outgoing degree, the number of edges originating at the node.

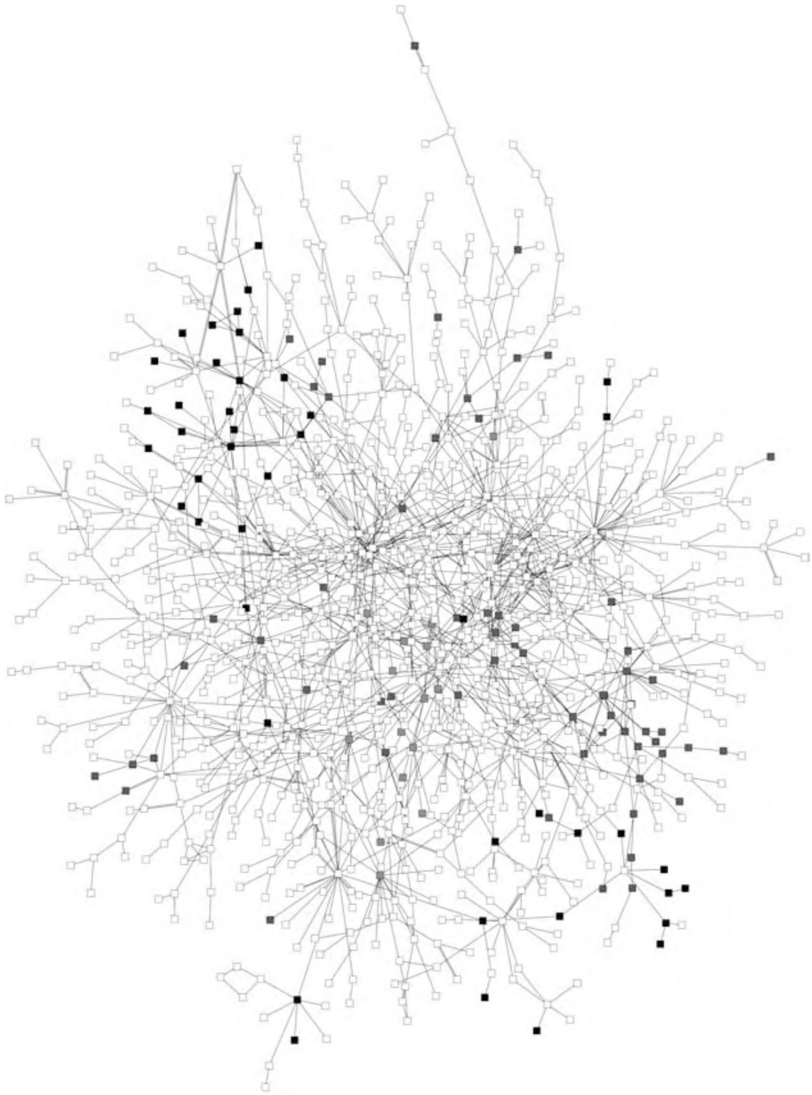

Figure 11 Yeast protein interaction network of around 1200 interacting proteins based on published interactions. Highlighted as dark nodes are cell structure proteins (a single functional class). Proteins in this category can be observed to cluster primarily in one region. Although interacting proteins are not depicted in a way that is consistent with their known cellular location (i.e. those proteins known to be present in the nucleus in the center of the interaction map and those present in plasma membranes in the periphery), signal-transduction pathways (or at least protein contact paths) can be inferred from this diagram. The graph was generated with the AGD software library (http://www.ads.tuwien.ac.at/AGD [130]).

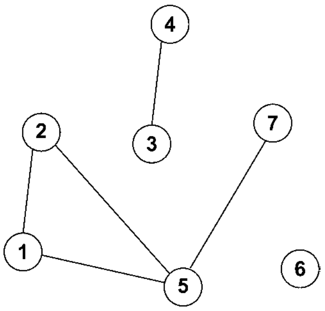

Figure 12 The graph on V = {1,2,3,4,5,6,7} with edge set E = {{1,2}, {1,5}, {2,5}, {3,4}, {5,7}}.

A *path* in a protein graph is a unique sequence of proteins and interactions starting and ending with a protein. The path *length* is the number of vertices in that sequence. A path which contains k vertices is commonly denoted by P_k. A graph G is called *connected* if any two vertices are linked by a path in G otherwise it is called *disconnected*. All known protein networks are disconnected because not all proteins belonging to a proteome are connected (maybe they are but we do not know all interactions).

The *distance* $d(u,v)$ in G between two vertices u, v is the length of a shortest u–v path in G. Here length is measured either by the number of edges on the path or, if each edge is weighted with a length, as the sum of the lengths of all edges on the path. The *diameter* of G is the greatest distance between any two vertices in G (although it is sometimes defined as the distance between two vertices averaged over all vertices). If a graph is disconnected, the diameter is equal to the maximum of the diameters of its connected components.

For an undirected graph the *clustering coefficient* of a vertex v is defined as $C_v = \frac{2 \cdot E_v}{k_v(k_v - 1)}$. It describes the ratio between E_v, the number of observed edges between the neighbors of v and the number of edges that could possibly exist between them. It is 1 if every neighbor connected to v is also connected to every other vertex within the neighborhood, and 0 if no vertex connected to v connects to any other vertex that is connected to v.

A directed graph with weighted edges is called a *network* (Figure 13). However, it should be noted that within network analysis, the definition of the term network may differ and may often refer to an undirected, unweighted graph. Actually, this is the case for most protein–protein interaction networks which often represent unweighted and undirected graphs, and which therefore strictly should be called protein–protein interaction graphs. Nevertheless, in this chapter we will also use the term network.

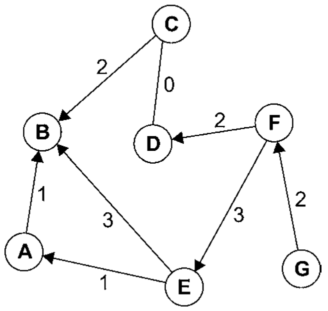

Figure 13 A simple network – a directed graph with weighted edges (*cf.* Figure 12). In protein–protein interaction networks directed edges are used to reflect protocols where one protein is used as a bait (arrow source) and associated proteins are identified as preys (arrow targets; especially in Y2H and protein complex purifications). Weights are used to numerically assess an interaction, for example the number of times it has been reproduced or its coexpression correlation, etc.

The most elementary global features of networks are:

1. The *connectivity distribution* (or *node degree distribution*) $P(k)$.
2. The *average path length* (or *average distance*) $\langle l \rangle = \frac{2}{n(n-1)} \sum_{u<v} d(u,v)$ defined by the average of the distances between any two vertices u, v within the network.
3. The *average clustering coefficient* $\langle C \rangle = \frac{1}{n} \sum_{i=1}^{n} C_i$ defined by the average of the clustering coefficients of all vertices within the network.

A detailed treatise on graph theory has been published by West [139]. A comprehensive online textbook about graph theory can be found at http://www.math.uni-hamburg.de/home/diestel/books/graph.theory. The MathWorld online encyclopedia provides more information on graph theory at http://mathworld.wolfram.com/topics/GraphTheory.html.

5.2 Network Models

Since the 1950s various network models have been proposed. Initially, random networks with no apparent design principles were constructed and described by Erdos and Renyi [107–109]. These authors simply assigned random edges to a set of randomly selected nodes. Later, other authors suggested rules for assigning edges and nodes resulting in nonrandom networks. Although metabolic networks have been known for decades, they have been treated as graphs only since the 1990s. Finally, Wagner [138] and Barabási and Albert [10, 11] introduced the concept of scale-free networks to protein networks. These models will be described in more detail below.

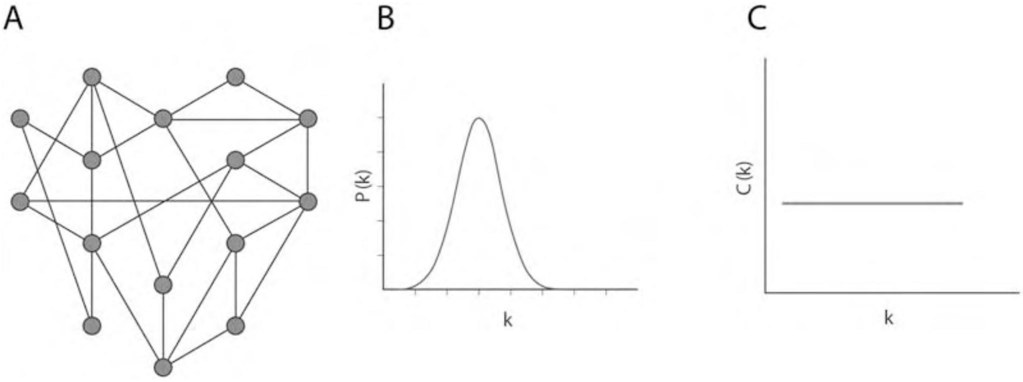

Figure 14 Random network. (A) small random network. The node degrees follow a Poisson distribution (B), which indicates that most nodes have approximately the same number of links (close to the average degree $\langle k \rangle$). The tail (high k region) of the degree distribution $P(k)$ decreases exponentially, which indicates that nodes that significantly deviate from the average are extremely rare. The clustering coefficient is independent of a node's degree, so $C(k)$ appears as a horizontal line if plotted as a function of k (C). The mean path length is proportional to the logarithm of the network size, $\langle l \rangle \sim \log(n)$, which indicates that it is characterized by the small-world property. (From Ref. [12].)

5.3 Random Networks

Random networks were invented by Erdös and Renyi [107–109] and are based on the principle that the probability p that there is an edge between any pair of vertices is distributed uniformly (Figure 14). The connectivity distribution $P(k)$ of a random network follows a Poisson distribution that peaks at the average vertex degree $\langle k \rangle$ (see Figure 14). Nodes that have a significantly lower or higher degree than $\langle k \rangle$ are absent or very rare. Moreover, random graphs have a relatively short average path length $\langle l \rangle$ which is proportional to the logarithm of the network size $\langle l \rangle \sim \log(n)$. The clustering coefficient for a random graph is expected to be constant with $\langle C \rangle = p$ (Figure 14). A detailed review of random graphs can be found in Bollobás [16].

5.4 Small-world Networks

Although complex networks do not look small at the first glance, there are many ways to travel from one vertex to another using a path of a few vertices only. This circumstance is also popularly known as "six degrees of separation" which goes back to a study by psychologist Stanley Milgram in 1967 [93]. Milgram concluded that two randomly chosen people are socially connected by an average of only five other people (resulting in six "degrees" between them). Such *small-world networks* have a short average path length

$\langle l \rangle$, a relatively large clustering coefficient $\langle C \rangle$, which is independent of the network size n, and a connectivity distribution $P(k)$, which is similar to that of a random graph. In a small-world network local perturbations can reach the whole network very quickly.

5.5 Scale-free Networks

If the connectivity of a network follows a power-law distribution, $P(k) \sim k^{-\gamma}$, the network is called scale-free. This relationship can also be seen as a straight line on a log-log plot since the above equation is equal to $\log(P(k)) \sim -y \cdot \log(k)$ (Figure 15B). Therefore, unlike that of a random graph, most vertices have only a few edges whereas a few vertices have a large number of edges, so called hubs (see light vertices in Figure 15A). However, they are also highly vulnerable to perturbations of highly connected nodes: when such hubs are removed the diameter increases rapidly and the network breaks into many isolated fragments [2]. By contrast, scale-free networks have a high degree of robustness against *random* errors.

If a network is scale-free, it is also a small-world. Scale-free networks with a degree exponent y between 2 and 3 are ultra-small with an average path length $\langle l \rangle \sim \log(\log(n))$ which is significantly shorter than $\langle l \rangle$ of a random graph which is proportionate to $\log(n)$, indicating that a heterogeneous scale-free topology is more efficient in bringing nodes close together than the homogeneous random graph topology [22, 23]. The clustering coefficient $\langle C \rangle$ of a scale-free network is about 5 times bigger than that of a random graph [1].

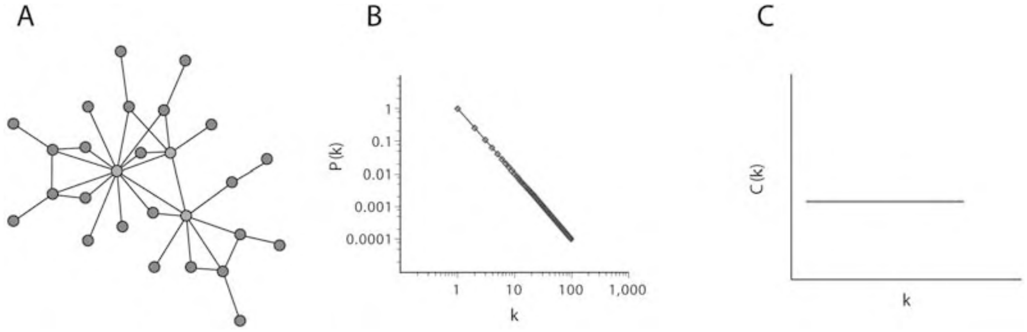

Figure 15 Scale-free network. (A) Small network with hubs (light). (B) Connectivity distribution of the network shown in (A). (C) Distribution of the clustering coefficient as a function of the vertex degree. For a large scale-free network see Figure 11 (From Ref. [12].)

5.6 Connectivity Distributions of Protein–Protein Interaction Networks

Several authors demonstrated that the connectivity distribution of the *Saccharomyces cerevisiae* protein–protein interaction network follows a power-law distribution [12]. They also determined that the interaction map of *H. pylori* [105] shows a heterogeneous scale-free network topology with a few highly connected and numerous less connected proteins. Furthermore, it has been shown that the interaction networks of *Drosophila melanogaster* [45] and *C. elegans* [85] proteins exhibit a distinct scale-free behavior.

This demonstrates that although the protein–protein interaction data sets have been derived from different sources and methods, the emergence of the scale-free property appears to be a robust feature [145]. However, several authors have argued that the scale-free nature of protein interaction networks may be an artifact of sampling and that these networks may be equally well described by other models [53, 124].

5.7 Error Tolerance and Attack Vulnerability

An important consequence of the scale-free connectivity distribution is the network's tolerance to random errors, coupled with fragility against the removal of the most connected nodes [2]. In fact, Jeong and coworkers [67] showed that highly connected proteins are 3 times more likely to be essential than proteins with only a small number of links to other proteins. In other words, when highly connected proteins are deleted the deletion is likely to be lethal. Similarly, Przulj and coworkers [104] demonstrated that nonessential proteins have a degree that is half that of essential proteins, whose deletion causes lethality. Interestingly, lethal mutations were not only found in highly connected proteins but also in proteins whose removal caused a disruption in network structure – removal of essential proteins disconnected one part of the network from the other. The importance of hubs is further validated by their evolutionary conservation. Fraser and coworkers demonstrated that highly interacting *S. cerevisiae* proteins have a smaller evolutionary distance to their orthologs in *C. elegans* than less-connected proteins [38], and Krylov and coworkers showed that yeast hubs are more likely to have orthologs proteins in higher organisms [78] (see also Sections 8.1 and 8.2).

Many cellular networks are fairly tolerant to random perturbations such as mutations, but they collapse when hubs are disrupted (by mutations or drugs). Network topology will also have an impact on drug development. For instance, highly connected proteins of pathogens may be suitable targets for an antibiotic therapy, whereas proteins which are less interconnected may be more appropriate targets for a highly specific drug in humans. A small degree is favored in human drug targets because it is more likely to avoid side effects (see also Chapters 18, 19 and 36).

5.8 Modules and Motifs in Networks

Another topological feature which reflects biological behavior is the hierarchical organization of scale-free networks [106]. Biological functions in a cell are organized in functional modules. Each module contains a group of physically or functionally linked molecules that work together to achieve a distinct function. For example, cells produce ATP via a set of modules, such as the glycolytic pathway, the Krebs cycle and the protein complexes involved in oxidative phosphorylation.

In networks, subgraphs (subsets of interconnected vertices) form triangles, squares, pentagons, etc. [94, 119]. Interestingly, some subgraphs, which are known as motifs, are more common in real networks than in randomized versions of the same network [94]. For example, triangle motifs are overrepresented in both transcription-regulatory and neural networks and four-node subgraphs are overrepresented in electric circuits. Each network is characterized by its own set of distinct motifs [63, 119].

A study on the evolutionary conservation of motif constituents within a network of yeast protein interactions uncovers a trend towards the preferential retention of highly cohesive motifs [144] (Figure 16).

Furthermore, empirical observations indicate that specific motif types aggregate to form large motif clusters. A number of algorithms have been developed to identify such modules (complexes or pathways) using either the network's topology [120] or combining it with functional genomics data [8, 65, 128]. Spirin and Mirny developed an algorithm that was able to recover many previously known modules such as the anaphase-promoting complex and the yeast pheromone response pathway [120] (Figure 17). The systematic identification of these modules provides essential knowledge linking proteome dynamics to cellular function and phenotype.

5.9 Comparing Protein Interaction Networks: Pathblast

Kelley and coworkers took the concept of interologs one step further by not only finding homologous interactions, but homologous pathways, here defined as paths of proteins that are connected by protein–protein interactions [71, 72] (Figure 18).

Pathblast can be used to compare, i.e. align, whole interaction networks. By using pathways even protein pairs with very weak sequence similarities can be identified because their position in the network provides additional information for the unambiguous identification of homologies. Thus, Kelley

Motif	Number in yeast	Natural conservation	Random conservation	Conservation ratio
	9,266	13.67 %	4.63 %	2.94
	167,304	4.99 %	0.81 %	6.15
	3,846	20.51 %	1.01 %	20.28
	3,649,591	0.73 %	0.12 %	5.97
	1,763,891	2.64 %	0.18 %	14.67

	25,749	14.77 %	0.05 %	279.71
	1,433	47.24 %	0.02 %	2,256.67

Figure 16 The evolutionary conservation of motif constituents in yeast. Orthologs in five higher eukaryotes have been used to rate the conservation of yeast motifs (subgraphs of two to five nodes). The *number in yeast* is the absolute number found in a network of 3183 proteins taken from the DIP database [115]. The *natural conservation* rate is the fraction of yeast motifs that consists of proteins with orthologs in the five higher eukaryotes used. If the topology of motifs does not interfere with the conservation rate of its constituting proteins, a random ortholog distribution should give the same motif conservation rates as seen in the natural sample. The *random conservation* rate therefore represents the fraction of motifs that is fully conserved for the random ortholog distribution. The *conservation ratio* is the ratio between the natural and the random conservation ratios, indicating that all motifs are highly conserved. From Ref. [144].

and coworkers were able to compare protein interaction maps of yeast and *H. pylori*, i.e. between eukaryotes and prokaryotes. Completely unexpected similarities were found among the homologous pathways, e.g. membrane proteins in *Helicobacter* that are homologous to yeast proteins which are involved in transport through the nuclear pore (Figure 18).

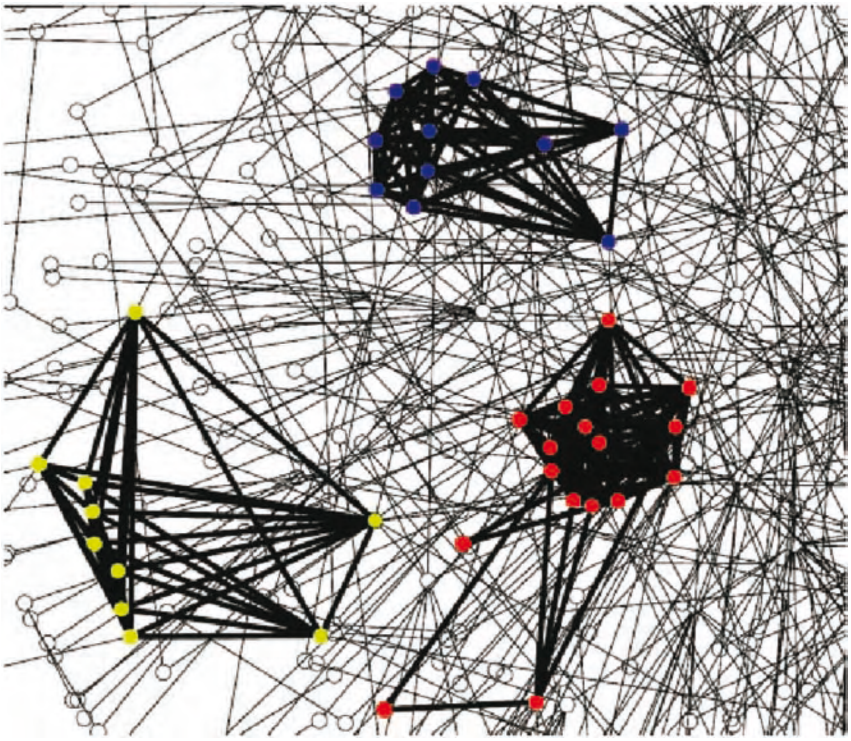

Figure 17 Computer algorithms can deduce molecular modules (protein complexes and pathways) directly from the topology of protein interaction networks. (From Ref. [120].)

6 Integrating Multiple Protein–Protein Interaction Evidence

Integrating protein interaction data means combining them with and relating them to other data (see also Chapter 42 for biological data integration).

There are two main reasons why integration of interaction data is useful:

- Integration aims at *collecting* all available data on certain proteins or groups of proteins, even whole genomes. Databases collect nonredundant information that is made available in machine-readable form so that computational analysis and relating data is possible. Such databases are also required for *visualization*, i.e. display of multidimensional information for human users (Figure 19; see also examples in Section 10).
- Integration of multiple data sets improves *annotation*, function *prediction*, *validation* and *experimental design* significantly. High-throughput data is often 1-D, i.e. a certain study may collect only information on protein interactions. In order to interpret this information it is necessary to add

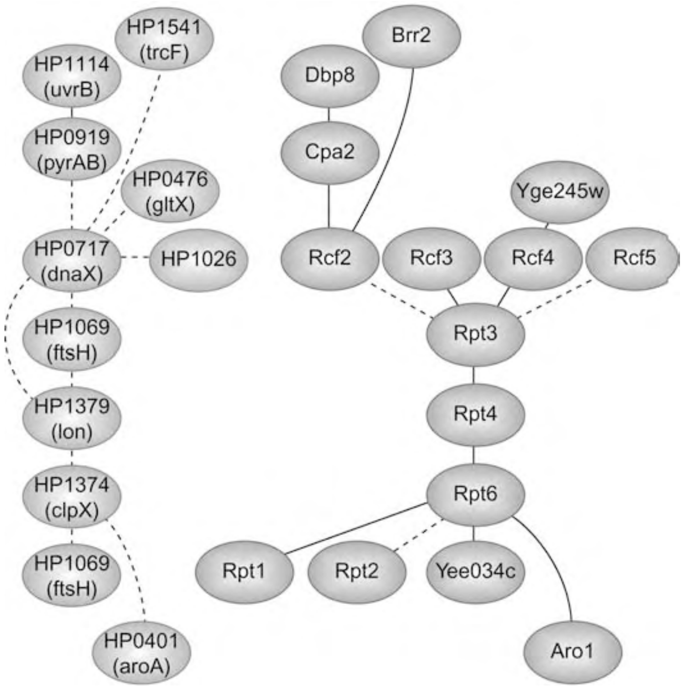

Figure 18 An example from Pathblast [71, 72]. The protein–protein interaction networks of *H. pylori* (left network) and *S. cerevisiae* (right network) were globally aligned to reveal conserved network regions. Proteins with above-threshold sequence similarity are placed on the same row of the pathway alignment (e.g. HP1114 and Dbp8). Direct protein interactions appear as solid links, and gaps or indirect interactions are dotted (From Ref. [71].)

information about expression, protein structure, localization, etc. Even previously uncharacterized proteins can be annotated fairly well from high-throughput data if all information is compiled and related [43, 129].

High-throughput data is also 1-D in the sense that it rarely provides information on the temporal and spatial dynamics and regulation of protein function. For example, in the endoplasmic reticulum so-called SREBP proteins form a complex with another membrane-embedded protein called SCAP, which escorts the SREBPs to the Golgi apparatus. Here, the SREBPs are sequentially cleaved by two Golgi-specific proteases. This releases a soluble fragment that travels to the nucleus where it interacts with other transcription factors to regulate its target genes (which are required for cholesterol synthesis). When cholesterol levels are low, SCAP escorts SREBPs to the Golgi, where processing takes place. When cholesterol levels are high, SCAP retains SREBP in the endoplasmic reticulum, processing is prevented and cholesterol synthesis is curtailed [96]. High-throughput studies (HTS) that analyze pro-

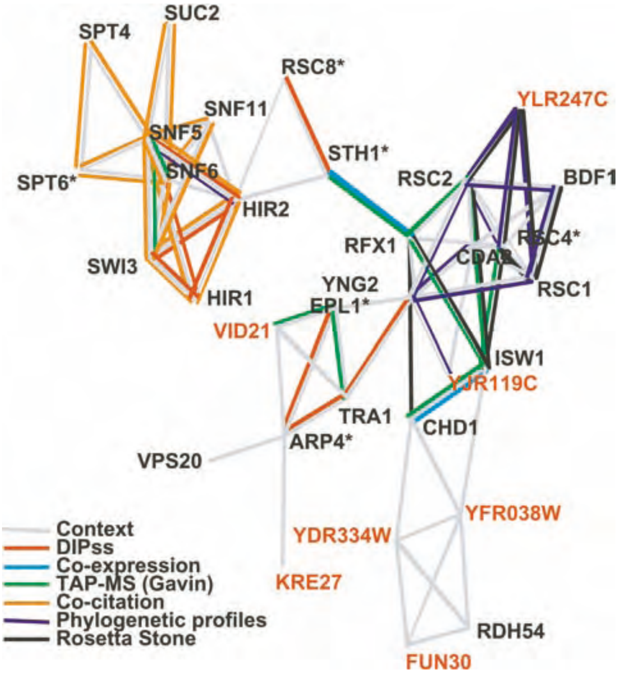

Figure 19 Integration of information. Shown are proteins involved in yeast chromatin remodeling, with several uncharacterized genes (red labels). This network was visualized with LGL (From Ref. [81], see Table 4).

tein interactions may only find nuclear interaction partners of SREBPs, HTS localization studies may only find their ER localization and expression studies may find that they are expressed at low levels – unless these assays are carried out under various cholesterol conditions.

Thus, high-throughput studies data will rarely give complete answers to biological problems. However, such data usually suggest further experiments and thus provide *hypotheses for hypothesis-driven research*. Protein interaction networks are particular informative because they often link proteins to other proteins whose function may suggest certain regulatory mechanisms. Even second-level protein interactions may be helpful, that is interactions of direct interactors.

Many studies integrated protein interaction data with other sources. Here we can present only a few examples:

- Lee and coworkers [81] reconstructed an extensive, high-quality functional gene network for yeast, consisting of 4681 (around 81%) of the known yeast genes linked by around 34 000 probabilistic linkages including expression data, gene linkage, phylogenetic profiles, cocitation and protein interaction data (Figure 19). The integrated linkages distinguish true- from false-positive interactions in earlier data sets; new interactions emerge from gene network contexts, as shown for genes in chromatin modification and ribosome biogenesis.

- Jansen and coworkers [65] used expression profiles, interaction data, and essentiality and localization information in order to predict protein complexes in yeast. Each of these data sources individually contains some weakly predictive information with respect to protein complexes, but Jansen and coworkers show how this prediction can be improved by combining all of them.

6.1 Protein Interactions and Gene Expression Data

Protein interactions and gene expression data have been correlated by a number of studies [15, 42, 50, 51, 128]. Although most of these studies found a correlation between interacting proteins and their gene expression levels, the correlation was not very strong. In fact, a few studies did not find a significant correlation or only did so when filtered data set were used [24,64]. Obviously, it is not necessary that expression levels are correlated in order to allow proteins to interact. See also Section 3.3.

6.2 Integration for Predicting Protein Function

Kemmeren and coworkers [75] analyzed 3.7 million yeast gene relationships (protein interactions, coexpression, colocalization, phenotypes, GO annotation) to predict the functions of yeast proteins or to improve their annotation. Integrated data were also used to cross-validate different interaction data sets which have different quality, different properties, etc. [74, 76]. See also Chapter 35 for further information on integrating heterogenous information to predict protein function.

7 Predicting Protein Functions from Protein Networks

Annotating uncharacterized proteins is still one of the most challenging problems of the post-genomic era [97]. However, assigning new functions to previously characterized proteins is equally important as hardly ever everything is known about a certain protein. Predicting protein function from sequence is discussed in Chapter 30. Inference of function from genomic context is described in Chapter 32 and predictions from structure in Chapter 33. Finally, Chapter 35 deals with information integration for protein function prediction.

We refer the reader to these chapters and only briefly discuss the role of protein interaction networks for protein function prediction.

Detecting a physical interaction between proteins is considered as one of the most powerful approaches for inferring the function of uncharacterized proteins [97].

Samanta and Liang [116] presented a network-based statistical algorithm that overcomes the presence of false positives in many interaction data sets and predicted functions of unannotated proteins from large-scale interaction data. Their algorithm uses the insight that if two proteins share a significantly larger number of common interaction partners than random, they have close functional associations. Analysis of publicly available data from *S. cerevisiae* revealed more than 2800 reliable functional associations, 29% of which involve at least one unannotated protein. By further analyzing these associations, Samanta and Liang derived functional predictions for 81 unannotated proteins with high certainty.

Vazquez and coworkers [135] presented an improved method for the assignment of protein functions based on global connectivity patterns of a protein network. In contrast to a simple majority rule [117], Vazquez and coworkers also used second-degree functional information, that is not only stemming from direct interactors but also from interactors of interactors.

Letovsky and Kasif [83] developed yet another method based on a probabilistic analysis of graph neighborhoods in a protein–protein interaction network to predict functions. The method exploits the fact that graph neighbors are more likely to share functions than nodes which are not neighbors. A binomial model of local neighbor function labeling probability was combined with a Markov random field propagation algorithm to assign function probabilities for proteins in the network.

8 Evolution of Protein–Protein Interactions

The evolution of protein networks can be studied from two different perspectives: (i) the network perspective where the loss and gain of interactions are counted for individual proteins, pathways or whole networks, and (ii) the protein sequence perspective, where the constraint of interactions on the rate of protein sequence evolution is measured. The former aspect is difficult to study because we do not have sufficient interaction data for different proteomes. Thus, most published studies concentrate on the sequence level.

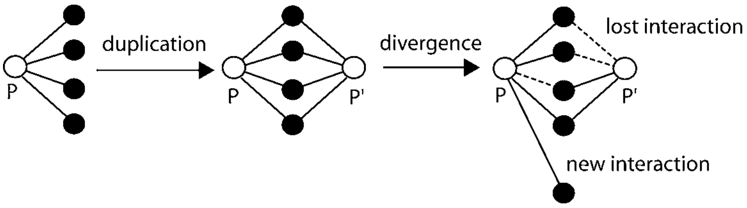

Figure 20 The effect of gene duplications on gene products that interact with proteins. Shortly after a gene duplication, the products P and P′ of the duplicate genes will interact with the same proteins. Eventually, some or all of the common interactions will be lost, and new interactions may be gained by either protein. In the rightmost panel, protein P has lost one interaction (dotted line) and gained a new interaction partner, whereas protein P′ has lost two interactions. If the number of common interaction partners is taken as a measure of functional overlap, then one of the functions of P is also covered by P′ and *vice versa*. (Redrawn after Ref. [138].)

8.1 The Network Level

Wagner [138] tried to estimate how fast the interaction network of yeast evolves, using gene duplicates (i.e. paralogs) in the yeast genome and the interaction partners of each duplicate (Figure 20).

Wagner found that genes with duplicates appeared slightly more highly connected. The reason is unclear. This difference in degree was not significant if more closely related duplicates were considered, i.e. duplicates with $K_s < 1$, where K_s is the fraction of synonymous (silent) substitutions per silent site.

More interestingly, Wagner's analysis indicated that duplicate gene products generally do not retain common interaction partners long after duplication. Only 57% (4/7) of the most closely related duplicate gene pairs ($0 < K_s < 0.5$) for which both genes interact with other proteins share any protein interaction partners. For all 380 gene pairs with $K_s > 0.5$, the fraction of duplicate partners with shared interactions is below 20%. For $K_s > 1.5$, it dwindles to a value close to the expected number of shared interactions between two proteins chosen at random from within the network.

Strikingly, already for $0.5 < K_s < 1$, only 20% of duplicate gene pairs share an interaction partner. That is, if one applies this criterion of functional overlap, 80% of genes have no functional overlap with their duplicates approximately 100 million years after the duplication (assuming a mutation rate of 10^{-8} per year per nucleotide).

8.1.1 The Rates of Interaction Loss and Gain

There are 127 duplicate gene pairs with $K_s < 2$ where both duplicates engage in protein–protein interactions. Assuming that all of the diversification observed between these duplicates is due to lost interactions, Wagner arrived at a total estimate of 920 interactions immediately after duplication, 429 of which have been lost since.

New interactions evolved at a rate of 2.88×10^{-6} per protein pair per million years according to Wagner. This may seem small. However, if extrapolated to all 1.97×10^{7}possible pairwise interactions in the yeast proteome, one arrives at an estimate of 57 newly evolving interactions per million years. Even when restricting oneself to the 985 proteins known to interact with other proteins, one arrives at an estimate of $(2.88 \times 10^{-6})(4.84 \times 10^{5}) \sim 1.4$ newly evolved interactions per million years. The true value is likely to lie somewhere in between.

Based on the assumption that the divergence in protein interactions after gene duplication is largely due to interaction loss, Wagner estimated the lower bound of the rate at which interactions get lost to be 2.2×10^{-3} per interaction per million years. If a comparable rate holds for interactions between single-copy genes, Wagner [138] estimated that 50% of all interactions may get lost every 300 million years.

8.2 Sequence and Interaction Divergence in Proteins

Interacting proteins have complementary surfaces that have evolved in a way that optimizes their affinity for the particular biological process they are involved in. Such interaction surfaces contain about 20 amino acids per partner (on average), although in most cases not all of these amino acids are involved in the interaction. Each protein loses about 800 Å^2 of contact area with the solvent when it is binding to its partner. It is intuitively obvious that the evolution of surface residues is constrained by protein–protein interactions, at least when the interaction is important for the cell. However, since the contact area comprises only a small fraction of the whole protein sequence, we will see an effect on the overall sequence only when the protein has many interactions with many different surface sites. Unfortunately, for most protein interactions we do not know their interaction sites. Thus, for simplification, the problem can be reduced to the question of how sequence conservation and the number of interactions are related.

Teichmann [126] found that proteins not known to be involved in interactions have an average sequence identity of 38% (between homologs of budding and fission yeast), while this value is 46% for proteins in stable complexes. Proteins that have transient interactions are intermediate between the two, with an average sequence identity of 41%. Thus, highly connected proteins (such as proteins in complexes) do appear to be more highly conserved than proteins with fewer connections. Indeed, Teichmann found that proteins belonging to small, medium and large complexes have average identities of

42, 44 and 51%, respectively (complexes were binned into groups with 1–14, 14–66 and 66–239 subunits).

8.2.1 Protein Evolution Rate and Protein–Protein Interactions

Fraser and coworkers [38] investigated the relationship between the evolutionary rate of protein sequence and the number of interactions these proteins have.

To estimate the evolutionary rates of these proteins, Fraser and coworkers compared putatively orthologous sequences between yeast and the nematode *C. elegans*. For each pair of orthologs, these authors estimated the evolutionary distance (K) that separates the two sequences, where K_a is defined as the number of substitutions per amino acid site that have taken place since the fungi–animal split. There were 164 yeast proteins for which the number of interactors and a well-conserved ortholog in the nematode was available.

If such coevolution is indeed an important mode of change in proteins constrained by interactions, then interacting proteins should evolve at similar rates. Fraser and coworkers tested this prediction by examining all 411 protein interactions in which each protein had a putative ortholog in *C. elegans* and showed no significant sequence similarity with its interaction partner. For each interaction, Fraser and coworkers calculated ΔK, which is the difference between the evolutionary distances separating the yeast proteins from their respective orthologs in the nematode. They then averaged these differences across all 411 interactions to find the mean difference in evolutionary rate between interacting proteins, $\Delta K^* = 1.3$ substitutions per site. To assess the significance of this difference, Fraser and coworkers repeatedly permuted the list of 411 interactions 10 000 times into random protein pairs and calculated the mean difference in evolutionary rate between arbitrarily paired proteins: In all but 44 of the 10 000 permutations, the observed averages of $\Delta K^* < \Delta K$, indicating that interacting proteins evolve at rates significantly closer than is expected to occur by chance ($p = 0.0044$).

A protein's fitness effect F, estimated as the reduction in relative growth rate of the organism due to deleting the gene that encodes the protein, is positively correlated with that protein's number of interactors I [38].

In summary, proteins with more interactors appear to evolve more slowly not because they are more important to the organism, but because a greater proportion of the protein is directly involved in its function. Interacting proteins evolve at similar rates.

The results by Fraser and coworkers [38] were not generally accepted. Jordan and coworkers [69] found only a very weak negative correlation between the number of interactions and evolutionary rate of a protein. In contrast to Fraser and coworkers, who used comparisons between yeast and worm proteins, Jordan and coworkers compared both budding and fission yeast as well as *H. pylori* and *Campylobacter jejuni*, both of which allow more reliable inference of homologous proteins than comparisons between yeast and worm. In addition, when the proteins from yeast were assorted into discrete bins according to the number of interactions, Jordan and coworkers found that only 6.5% of the proteins with the greatest number of interactions evolved, on average, significantly slower than the rest of the proteins.

While the correlation found by Fraser and coworkers was confirmed by Jordan and coworkers, even though it was weak, the result was dependent on the data set used: when only the most conserved (above 40% sequence identity), and thus most reliably identified, pairs of orthologous proteins were considered, the slope of the linear trend line decreased and the statistical significance disappeared.

As a conclusion, only a small fraction of yeast proteins with the largest number of interactions (the hubs of the interaction network) tend to evolve more slowly than the bulk of the proteins.

8.2.2 **Phylogenetic Relationships between Families of Interacting Proteins**

Goh and coworkers [46] and Goh and Cohen [47] reasoned that a ligand–receptor pair should occupy related positions in their phylogenetic trees if they coevolve. Previous results have shown that for ligand–receptor pairs that are part of large protein families, the correlation between their phylogenetic distance matrices is significantly greater than for unrelated protein families. An example of coevolving families is shown in Figure 21.

Following this logic, insulin sequences from different species should have a similar phylogenetic tree as the insulin receptor, because they coevolve.

As a consequence, the binding specificity of an uncharacterized protein may be inferred by comparing its phylogenetic tree to the trees of potential interaction partners. Results of the analysis show that binding partners can be quantitatively identified for proteins in diverse homologous protein families with approximately 58–100% sensitivity (predicted true binding pairs/all true binding pairs) and 82–100% specificity [1 – (predicted false binding pairs/all false binding pairs)] for a correlation score above 0.8 [47]. Similar results were obtained by Pazos and Valencia [101].

Hahn and coworkers [52] searched the genome of *S. cerevisiae* for the nearest paralog (if any) of each gene in the yeast protein-interaction network (that is an intragenome search) and used the ratio K_a/K_s, to measure selective constraint (K_a/K_s is the rate of amino acid replacement substitutions for each pair of orthologs divided by the rate of silent substitutions [77]). Furthermore, orthologous genes in the genomes of *Schizosaccharomyces pombe* and *Saccharomyces paradoxus* were identified.

Using the identified paralogs and orthologs, Hahn and coworkers calculated the correlation between evolutionary distance and the degree of protein

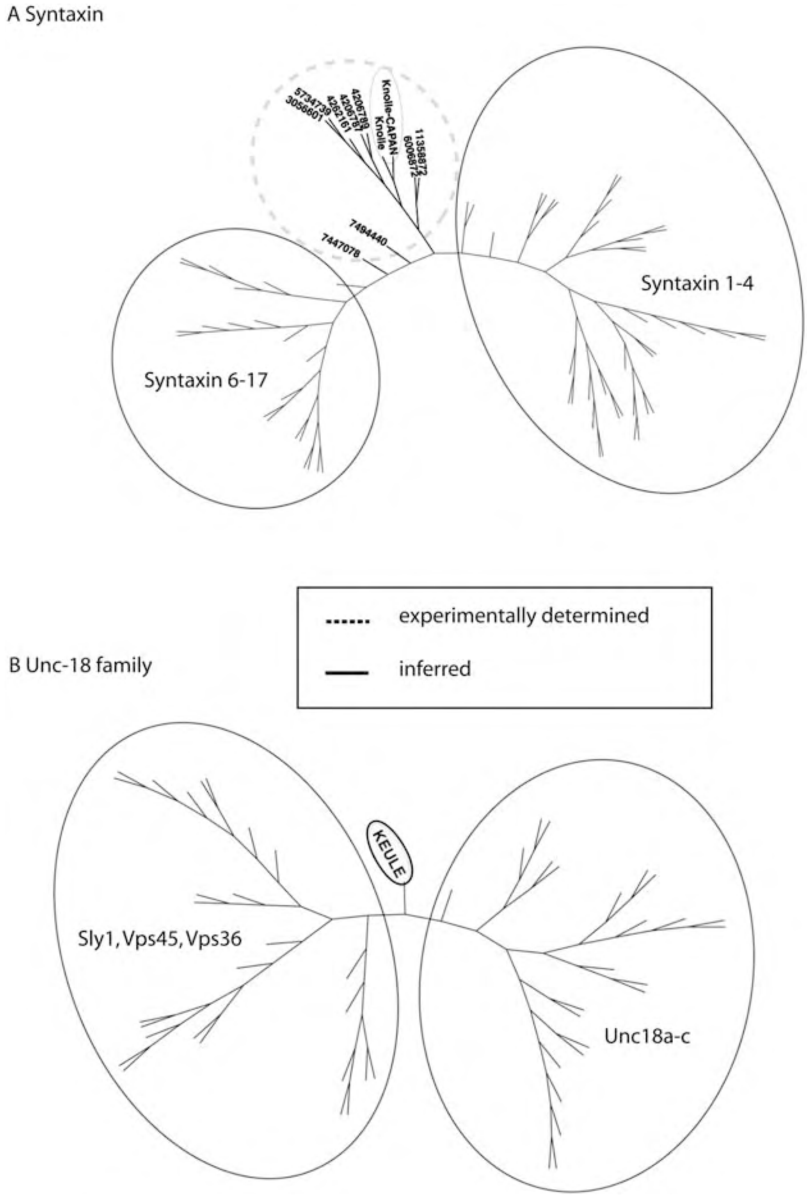

Figure 21 Coevolutionary analysis reveals insights into protein–protein interactions. Phylogenetic trees of the (a) syntaxin family and the (b) Unc-18 (Sec1) family. Members of the syntaxin family interact with members of the Unc-18 family and each family shows a similar tree structure. The area encompassed by the dotted circle indicates the search space for a potential KEULE binding partner. The filled circle outlines the known binding partner, Knolle, and an ortholog from *Capsicum anuum* (Knolle-CAPAN). (From Ref. [47].)

connectivity (D). For the *S. cerevisiae* paralogs and orthologs in *S. paradoxus*, they also calculated the correlation coefficients (both Pearson and Spearman) between K_a/K_s for the closest paralog and D using only unsaturated duplicate pairs with $K_s < 3$.

The study showed that there is a weakly significant Pearson's correlation between protein degree D and K_a/K_s, but no significant Spearman's correlation (Pearson's $r = -0.187$, $p = 0.047$; Spearman's $s = -0.151$, $p = 0.12$). There was a weak but highly significant correlation between D and the selective constraint (K_a/K_s) experienced by a gene.

Analyzing 1175 gene pairs from *S. cerevisiae* and *S. pombe* with this data set, Hahn and coworkers indeed found a correlation similar in magnitude to that obtained by Fraser and coauthors.

Hahn and coworkers were thus able to explain the discrepancy in results between Jordan and coauthors [69] and Fraser and coauthors [21,22] by using slightly different protein-interaction data sets. The reference taxon used by both of these groups, *S. pombe*, is less than ideal because it is only a distant relative of *S*. cerevisiae, with a most recent common ancestor 0.3–1.3 billion years ago. Thus, the analysis was repeated with the much more closely related *S. paradoxus* as the outgroup.

The relationship between the number of interacting partners and evolutionary constraint is highly dependent on a gene's function. Genes involved in metabolism, transport and the cytoskeleton show no significant relationship between D and K_a/K_s (always above 0.05). However, genes involved in the cell cycle and transcriptional processes show a significant, although weak, effect.

Pagel and coworkers [99] took a slightly different approach to investigate the relationship between interactions and evolution. They showed that interacting proteins in yeast have a much higher chance of possessing orthologs in other fungal genomes than randomly selected *S. cerevisiae* proteins. The number of species with orthologs was used here as a measure of conservation. This finding is compatible with the notion that highly connected nodes of the protein–protein interactions network are essential for survival.

Wuchty [143] also confirmed that there is a strong propensity of essential, highly connected proteins to be evolutionarily conserved, but he also found that this trend does not have an equivalent for nonessential proteins. Note the limitation to essential genes: only this subset of proteins shows correlation, not the complete set of interacting proteins. In order to guarantee balanced sampling for all connectivity (i.e. "k") values, Wuchty [143] used logarithmic binning of the k-axis, a procedure that corrects for the skewed nature of the scale-free distribution. In summary, Wuchty's results clearly indicate that highly connected proteins are far more likely to be essential and (simultaneously) conserved as orthologs in higher eukaryotes than are their less-connected counterparts.

Related studies have been published by Hurst and Smith [60], Hirsh and Fraser [57], Jordan and coworkers [68], and Fraser and coworkers [39].

8.3 Structural Aspects of Conserved Interactions

In addition to docking interacting proteins whose individual structure is known, one can study how interactions evolve on the structural level. For example, Aloy and coworkers [4] approached the problem by collecting all instances of the same domain pairs interacting in different complexes (from the SCOP database [7]), and then compared them with a simple geometric measure (interaction RMSD). When plotted against sequence similarity they found that close homologs (above 40% sequence identity) almost invariably interact the same way.

Aloy and coworkers defined contacting domains as those from the same Protein Data Bank (PDB) entry that had at least 10 C_α–C_α contacts smaller than 8 Å. The difference between domain orientations was described by the purely geometric interaction measure iRMSD. It does not require an interaction surface, interacting residues or residue equivalences to be assigned, and is thus readily applicable to remote similarities in sequence and over a wide range of differences in domain orientation. For identical domain interactions the expected iRMSD is 0, with values increasing with differences in domain orientations.

For some domain–domain interactions, interactions are preserved even at very low sequence identities, whereas for others the situation is reversed. For example, if one considers PID $< 20\%$ for the P-loop ATPase superfamily interacting with the ubiquitin-like superfamily, all four studied interactions are similar (iRMSD < 7 Å). In contrast, only two of the eight interactions between the P-loop ATPases and PH domains with PID $< 20\%$ have iRMSD < 10 Å, with the others showing great differences, their iRMSD being as high as 18 Å with clearly different binding surfaces.

This shows that interactions between weakly conserved proteins cannot always be predicted reliably (Figure 22). Additional experimental information may be required to construct realistic models in such cases.

9 Databases and Other Information Sources

Databases are critical for protein network analysis. A number of databases have been established over the past years. However, it is foreseeable that not all databases will continue to receive funding and thus we expect that

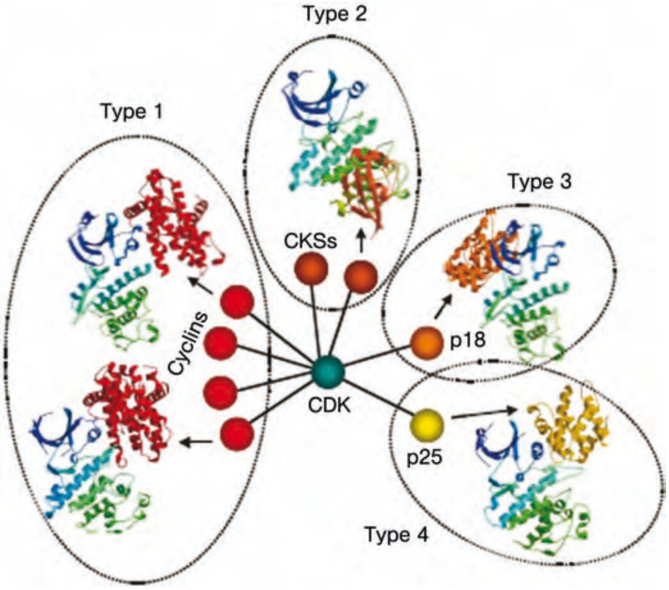

Figure 22 Homologous interactions are not always predictable. The same protein [here, cyclin-dependent kinase (CDK)] can have many different modes of interaction. This complicates both the prediction of homologous interactions and the relationship between connectivity and evolutionary constraint. See text for details. (From Ref. [5].)

some of theses databases will merge, while others may cease to exist. A list of databases is provided in Table 3.

10 Analysis and Visualization Tools

It is impossible to describe all available tools for protein network analysis and visualization in this chapter. In addition, new tools are constantly published and older tools improved or discontinued. We have collected some fairly widespread tools and their main features in Tables 4 and 5. Figure 23 shows a few screenshots from some of the packages we have used. We recommend visiting the websites of the academic or commercial suppliers for further information. New tools are regularly published in specialist journals.

11 Outlook/Perspectives

This chapter provides only a snapshot of a rapidly developing field in which many challenges remain. An increasing flood of data requires dynamic in-

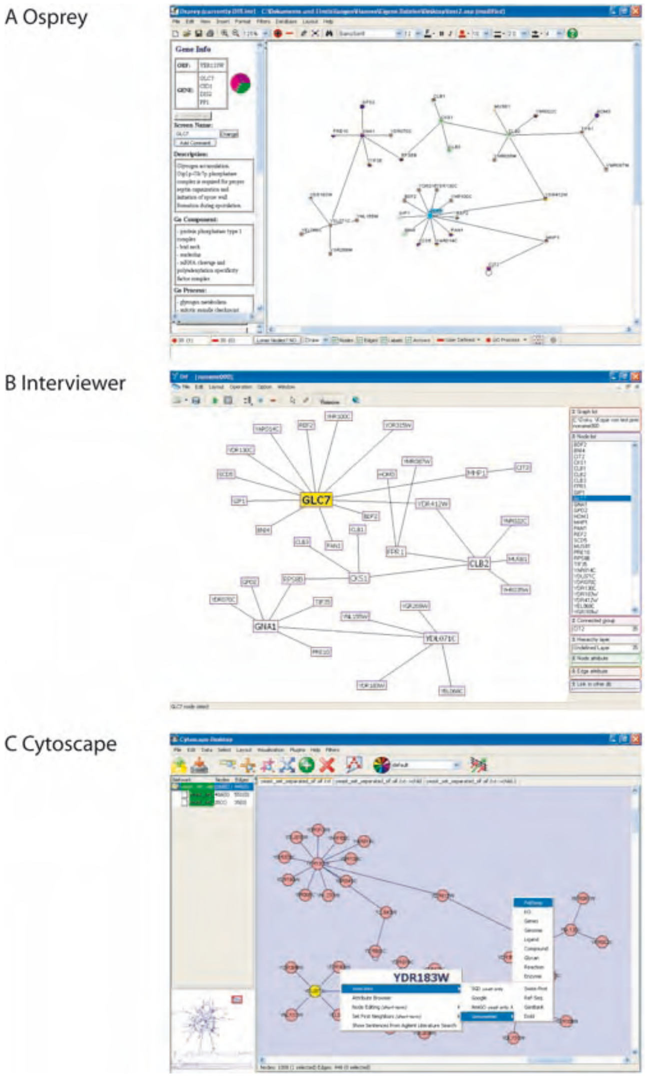

Figure 23 Protein–protein interaction network visualization tools. (A) Osprey 1.20 [18]. (B) WebInterViewer [54]. (C) Cytoscape 2.1 [118]. For details see Tables 4 and 5.

tegration into existing databases and constant re-evaluation of predictions and models. Integration of various data sources will be critical for biological interpretation. Some experimental approaches such as structural genomics are only now entering production levels and have barely been exploited for interactome analysis. Finally, comparative interactomics will only be possible with several completed interactomes. This is especially true for prokaryotic systems which are far more diverse than the few eukaryotes that can be

Disadvantages		slow layouting, low-resolution graphics	no filters, connection to dataserver failed
Documentation	detailed	detailed documentation	scarce

With increasing amounts of experimental data, analysis and visualization tools will be increasingly important. In particular, such tools need to be user-friendly enough to be used by experimental biologists. Eventually this will hopefully allow us to do “real” systems biology, i.e. representing and simulating biological systems in all their 4-D complexity *in silico* [125, 131].

Inferring Protein Function from Genomic Context

Christian von Mering

1 Introduction

1.1 Genomic Context – Genomes, Genes and Gene Arrangements

For function prediction, the most challenging proteins are those for which neither homology searches nor published experiments reveal any useful information. These functionally uncharacterized ("unknown") proteins are usually not known from actual observations, but instead merely inferred to exist based on sequence data from genome projects. They constitute a significant fraction of sequence databases today (uncharacterized open reading frames cover a large part of any given genome, ranging from about 20% in small, well-studied prokaryotes [17, 55] to more than 60% in large viruses [47]). While, in the future, homology searches with such uncharacterized sequences will increasingly recover at least some genes from related organisms (given the tremendous growth of genomic sequence data), these related genes will often lack functional annotation themselves.

In the absence of any other data, fully sequenced genomes remain the only useful source of information to begin characterizing such proteins (and the genes that encode them). Genome sequences can tell us a lot: which organisms do contain a gene from a particular family and which do not; how do the genes evolve; what sequences appear in physical proximity on the genomes, and much more. With genome sequences expected to be a widespread commodity soon, this information can often be remarkably useful for function prediction.

For example, the simple information on the presence or absence of similar sequences in other genomes may already narrow down the putative function of a gene to some extent: is gene X consistently found in any and all genomes queried? This may well mean that the gene performs an essential function, such as in information processing or central metabolism. Is gene Y found in a number of genomes, but never in more than a single copy per genome? This could be an indication that its function is sensitive to dosage effects. Gene Z has homologs, but its sequence appears to be changing faster than is the case

Bioinformatics - From Genomes to Therapies Vol. 3. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

for most other genes? This could be indicative of a function under changing selective pressures, such as in defense or reproduction.

Likewise, the immediate neighborhood of a gene within its chromosome can also be informative. Does a particular set of genes consistently appear next to gene W, even in phylogenetically quite distant organisms? This may indicate that the genes need to be coregulated, forming a jointly transcribed operon (in microbes), or that their consecutive order along the genome is somehow important for spatio-temporal expression regulation (as is the case for the *hox* gene cluster in eukaryotes). Regardless of the mechanisms responsible, a conserved neighborhood can often be taken as an indication that a group of genes are working together towards a common function.

Collectively, such purely genome-derived information forms the "genomic context" of a gene family. In its broadest sense, genomic context may be defined as any information on a gene that is contained in genome sequences, with respect to the occurrence and arrangement of the gene and its relatives in these genomes. Genomic context information implicitly reflects the past history of gene families and, as such, it has been shaped by a multitude of evolutionary events (mutation, selection and neutral drift). To make maximum use of genomic context for function prediction, it is essential to keep in mind that genomic context is of course relevant only when at least some aspect of its appearance can be assumed to have been under selection.

In the following, we will focus on the use of genomic context information to predict functional links ("associations") between genes; a conserved neighborhood of genes is one example for a genomic context link of this type. Predicted associations between genes are particularly useful in function prediction, because they are straightforward to interpret – if an uncharacterized gene is predicted to be associated with a better characterized gene, it is predicted to share (or contribute to) that gene's function.

It should be noted that genomic context analysis is of course not limited to function prediction of uncharacterized proteins – it can also be used to predict a functional role for proteins that do have at least a vague annotation (e.g. "likely methylase" or "transporter"), but still lack a clear functional context such as a pathway or process in which they might be involved.

1.2 Genome Comparisons Reveal Protein–Protein Associations

Three basic types of genomic context information are currently used for predicting functional associations between proteins (Table 1). They are all based on the assumption that functional partnership between proteins leaves detectable traces in the genomes during evolution. Several variations of these basic principles have been devised; these will be discussed in detail in the following sections.

Table 1

Type of genomic context	Basic principle	References
Genomic neighborhood	gene neighborhoods which are conserved, i.e. withstand the shuffling of genomes over time, are indicative of coregulation (often as operons) and may encode common functions	11, 42
Gene fusion analysis	genes that occasionally fuse to encode a single polypeptide chain (instead of two) may function together even in organisms in which they are not fused	14, 36
Gene co-occurrence	presence/absence analysis: genes that are consistently present in the same sequenced genomes (and absent together in others) may require each other for function	25, 45

The use of genomic context for predicting an association between genes can be generalized as follows. It should always begin with a systematic comparison of fully sequenced genomes, focused on the gene families of interest. One should then list all observations of the desired type (e.g. gene neighborhoods involving the families). The results should then be compared with those of other gene families (and with randomized data) in order to assess the relevance of the observation. As the three basic types of genomic context information are to some extent overlapping (shared function will often leave evolutionary traces of several types), the analysis should simultaneously employ several genomic context methods, if possible.

Generally, genomic context methods will increase in predictive power as more and more genomes become available, and they are applicable to any class of gene regardless of the type of proteins they encode (enzymes, structural proteins, regulators, etc.). Various implementations exist for each type of genomic context, and these differ significantly in technical and conceptual detail, and in computational cost.

1.3 Prerequisites for Genomic Context Analysis

Most proteins, but not all, are amenable to genomic context analysis. For a successful prediction, a number of prerequisites must be met: (i) the protein in question should be from an organism whose genome sequence is known, (ii) other sequenced genomes must be available (the more the better) at various phylogenetic distances relative to the query genome, (iii) all those genome sequences should ideally be finished, i.e. consist of high-quality contigs with little mis-assembly or gaps, and (iv) the gene in question must have counterparts in at least some of the other genomes (genomic context is not applicable to "molecular orphans", i.e. genes without any detectable relatives [18]).

Defining counterparts of a gene in other genomes is a key step for genomic context analysis. This is because it only makes sense to compare genomes if we can assign which part in one genome corresponds to which part in the other. What exactly is meant by a "counterpart" of a gene in another genome? Since genomic context analysis is based on detecting the long-term effects of shared function on genome evolution, the gene and its counterpart should be defined as having the same function. However, how can we know whether two genes have the same function – since function is what we aim to predict in the first place?

Luckily, we do not have to know the actual function of either gene to check whether they may be functionally equivalent; it is enough to test whether they are homologous or, better, orthologous. Generally, if two genes are homologous (i.e. of common descent), then they have a certain likelihood of performing the same function, especially if their sequence similarity is high (for low similarities, this is of course less certain – the actual percent identity cutoffs that should be applied are under debate [50, 56]). One particular subtype of homology, called *orthology* [15, 16], leads to the most reliable assignments of functional equivalence and it is often used in annotating newly sequenced genomes. Two sequences in two different organisms are defined to be orthologous if they trace back to a single sequence in the last common ancestor organism, as opposed to being paralogous for the case when they were already separate entities in the last common ancestor (see also Chapter 4). Because orthologs trace back to a single sequence at the time of speciation, they have a higher chance of having retained an identical function, even if their actual sequence similarity is low.

Orthology of two genes is always merely a hypothesis, and it can be difficult to decide which, if any, among the many homologs is the true ortholog. Fortunately, several databases exists that contain globally precomputed orthology predictions for a range of complete sequenced genomes [40, 55]; where such data is not available, homology can still be used instead (see Chapter 30).

1.4 How Specific are the Inferred Functions?

Genomic context analysis works by searching for putative effects of selection. A conserved gene arrangement, for example, may have been formed and retained because it provides a selective advantage for the organism to keep functional partners in close vicinity. Likewise, if one gene is lost from a genome because it is apparently no longer selected for, then many of its immediate functional partners may also be no longer under selection and they might be lost as well (the latter assumption forms the rationale behind the "gene co-occurrence" approach).

At the molecular level, the vast majority of large-scale genomic features are shuffled randomly, but those that are under selection can be made to stand out when enough genomes are being compared. As selection, ultimately, works at the level of the entire organism (or population), the specificity of the function prediction for any particular gene is inherently limited. A genomic context association prediction should always be thought of as "genes X and Y apparently share a common selection pressure". This is then translated into "genes X and Y participate in the same functional process". This translation is a leap of faith – it assumes that selection can indeed act on specific, separable functional processes and that these will somehow coincide with our definition of pathways or processes (or protein complexes, regulons, etc.). In some cases, the situation is pretty obvious, e.g. the biosynthesis of a complex organic molecule may involve several specific enzymes whose only purpose is catalyzing one step each of the reaction. The final pathway product is what is actually needed by the organism and is presumably what is being selected for – so that all enzymes needed to produce it share indeed a similar spectrum of selection during genome history. They form a unit and this may be detectable by inspecting genomes.

Of course, genomic context analysis will not normally be able to uncover the molecular detail of the actual enzymatic reactions. In other instances, it may not even be possible to identify clear functional units that could be selected for – some proteins may function in more than one pathway or may function autonomously without any direct partners. Nevertheless, the evolutionary approach taken in genomic context analysis has the great advantage of being independent of human classifications and biases – whatever evolution deems important enough to be selected for as a unit, will potentially be detectable as a group of genes, and can be interpreted as functional partners.

2 Gene Neighborhood

2.1 Conserved Neighborhood versus Simple Synteny

The physical proximity of genes in the genome (*gene neighborhood*) is the simplest form of genomic context information – it is routinely used in microbiology, even since long before the advent of the first complete genome sequences. In prokaryotes, gene neighbors often form operons [26]; operons represent the first recognized example of genes neighboring each other for functional reasons. In operons, several neighboring genes located on the same strand of the DNA form a polycistronic transcription unit (i.e. they are transcribed together as a single mRNA), presumably because they can be regulated more efficiently in this way. Usually, the genes in an operon will work together towards a common function – in microbiology, this has often been exploited for placing uncharacterized genes into their functional context (e.g. Ref. [22]).

However, not all genes that are found in physical proximity will be part of a polycistronic operon. Some genes may be neighbors simply because of a recent genome rearrangement which happened to place them next to each other. To some extent, the intergenic distance between genes can be used to distinguish true operon members from accidental neighbors, but this alone is not very reliable (having a roughly 20% error rate [38]). Fortunately, comparative genomics can help: true operons should have a higher chance of being observed in other genomes as well, whereas "chance" neighbors should be separated as fast as they are formed. Thus, any gene neighborhood that is observed in several genomes (a "conserved neighborhood"), leads to the prediction that its genes are forming a true coregulation unit and are thus likely to function together.

Unfortunately, the above is true only when the genomes in question are sufficiently distant phylogenetically – otherwise even chance neighbors can be observed repeatedly because of genome synteny. *Genome synteny* is defined as a broad similarity between homologous genome segments in two species, and it usually occurs simply because insufficient time has passed to shuffle the genomes and their gene arrangements through random events such as inversions or translocations. The timescale of genome synteny "decay" is an important factor for neighborhood analysis (because within that timescale, repeated observations of a neighborhood cannot be considered independent). For prokaryotes, synteny is usually restricted to species of at least the same phylogenetic order, e.g. within the Vibrionales, or the Enterobacteriales, but not between these two (Figure 1). For all types of gene neighborhood analysis, it is essential to determine and exclude the effects of genome synteny. Since synteny is usually assumed to evolve (and decay) neutrally with time, it can best be measured by tracking the fate of genes that lack any reasonable functional link – if they are neighbors, they are expected to be shuffled away at random. Such neutral neighbors could be, for example, well-characterized genes working in totally unrelated cellular functions, or gene neighbors arranged in a tail-to-tail orientation (Figure 1). Tail-to-tail arrangements are thought to be least likely coregulated, or functioning together, since they are transcribed from opposite strands and from distant promoters.

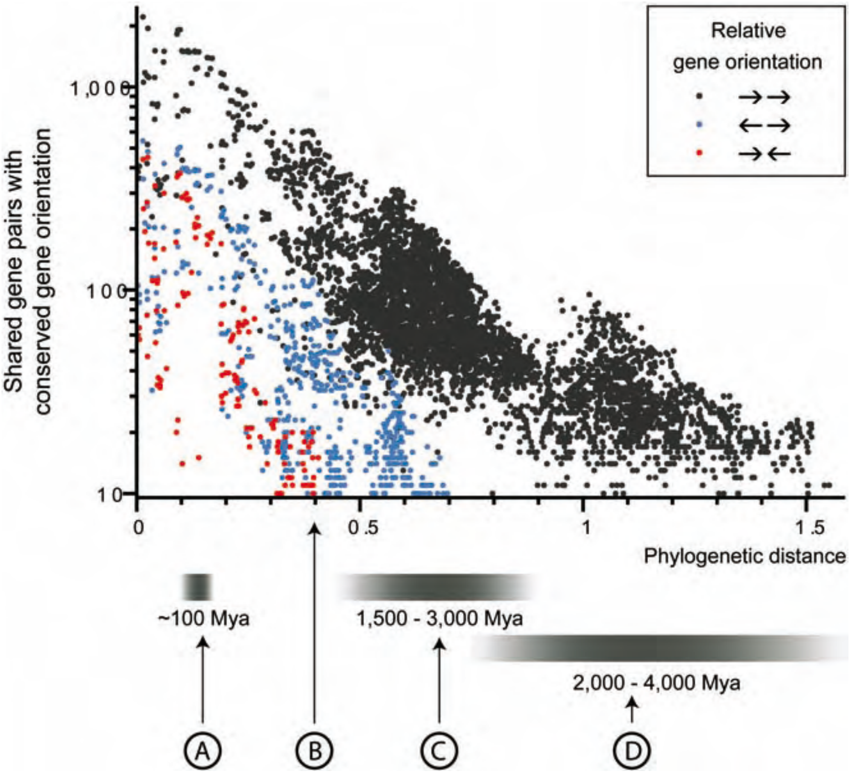

Figure 1 Decay of genome synteny with increased phylogenetic distance. Each dot in the graph represents a comparison between two fully sequenced prokaryotic genomes. The x-axis describes the phylogenetic distance between the two genomes [32] and the y-axis indicates how many gene neighborhoods are still detectable in both organisms (plotted separately for each of the three possible gene-to-gene orientations). The letters on the x-axis indicate the approximate time points of some representative evolutionary events (A: split between *Escherichia* and *Salmonella*; B: time point at which synteny is largely lost; C: split of main bacterial groups, such as Gram-positive or Gram-negative; D: Split of domains Bacteria and Archaea). The tail-to-tail orientation decays quickly with time (red dots); whereas in particular the codirectional neighbors (black dots) can be conserved over very large phylogenetic distances. This difference indicates that the three possible gene-to-gene arrangements are under different levels of purifying selection. If one assumes that tail-to-tail gene arrangements are not selected for at all, then these provide a background measure for the level of neighborhood that is expected simply due to genome synteny. (Modified from Ref. [31], with permission.)

2.2 Operons and "Über-Operons"

Operons are the most stable gene arrangements in prokaryotic genomes; however, even operons do occasionally break up, re-form or change the relative order of their constituent genes. Any given conserved gene neighborhood, therefore, even when found in a wide array of species and clearly selected for, can be "broken" in a particular species – the genes may be present in the genome, but in scattered locations, no longer forming a gene neighborhood. This does not necessarily mean that the genes are no longer sharing a function; it may simply be the result of an episode of extensive genome shuffling or of relaxed constraints on the regulation of the pathway. Over time, and with more and more genomes available, this leads to a situation in which only very few operons remain totally unchanged in all organisms studied. However, many of the changes in gene neighborhoods are conservative [34], i.e. operons are often re-formed (although possibly with differences in gene orientation or composition). For any given functional system, various partial or complete gene neighborhoods can be observed in fully sequenced genomes today; these can be thought of as variants of a prototypic, often larger, "über-operon" [34] (Figure 2). If each subpart of an über-operon is well-supported by repeated observations, then the entire über-operon can be assumed to encode functionally associated proteins.

This generalization is very valuable for function prediction – it means that, for any given species, a large number of functional links can be predicted, even for gene pairs that are not actually neighbors in the query species itself. For example, the arginine biosynthesis genes *argB* and *argC* are not neighbors in the genomes of cyanobacteria, yet they can be linked functionally, based on their recurring neighborhood – in various orientations – in many other bacterial clades.

The über-operon concept also implies that neighborhood analysis is not restricted to immediate neighbors: the two gene families *argJ* and *argF*, for example, are from a conserved neighborhood in most genomes, even though they are never direct neighbors (i.e. there is always at least one intervening gene between them in the genomes we know so far). In fact, if one assumes that neighborhood relations are fully transitive, this could even lead to association predictions for gene pairs that are never close to each other in any of the genomes: if gene A consistently forms a neighborhood with gene B and gene B with gene C, but genes A and C are never neighbors, then they could still be predicted as functional partners. Of course, as is the case with neighborhood analysis in general, any such observation needs to be carefully checked against two null-hypotheses: (i) that the observed scenario may have arisen by pure chance and (ii) that the observed scenario is merely due to genome synteny (see Section 2.1). Fortunately, both null-hypotheses can be tested: (i) gene arrangements can be randomized *in silico* to verify that it is unlikely to observe a given neighborhood by chance and (ii) the genomes to be analyzed can be made nonredundant, such that closely related genomes displaying remnants of synteny are considered as a single item only.

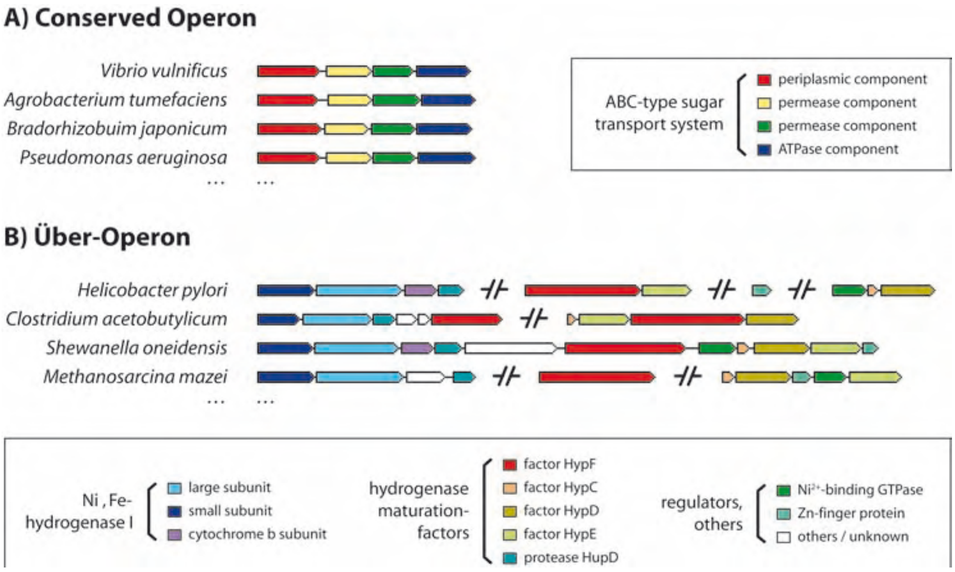

Figure 2 Typical genomic arrangements of functionally associated genes. Each colored section symbolizes one gene (i.e. an open reading frame) in a prokaryotic genome. Genes are shown as neighbors wherever they are encoded on the same DNA strand and are in close proximity (separated by fewer than 300 bp). Genes that are not neighbors are shown separated by break symbols, denoting a large area of intervening DNA that may contain many unrelated genes. The top panel shows the simplest case of informative neighborhood – a conserved neighborhood, found in identical composition and arrangement in many diverse bacterial genomes. These genes are likely to form a cotranscribed operon in many of the organisms. In contrast, the lower panel shows a more complex gene neighborhood, where the genes are neighbors in various different arrangements, forming one or several operons. This is more frequently observed than the ideal situation shown in the top panel; it is nonetheless indicative of a larger system of genes sharing a function (in this case, a Ni,Fe-hydrogenase is shown with its associated regulators and maturation factors).

2.3 Divergently Transcribed Gene Pairs

When scanning genome databases for repeatedly occurring gene neighborhoods, the most frequently observed arrangement is the collinear arrangement, in which the conserved neighbors are located on the same DNA strand and are transcribed in the same direction. This is not surprising – at least in prokaryotes, most genomes are enriched in stretches of consecutive genes transcribed in the same direction (partly because of operons, but also in part because of simple strand biases [49]). Thus, even a randomly selected gene pair has a higher chance of being observed repeatedly, if its arrangement is collinear. Apart from the collinear arrangement, two other arrangements of gene neighbors are possible: divergent (i.e. neighbors oriented in

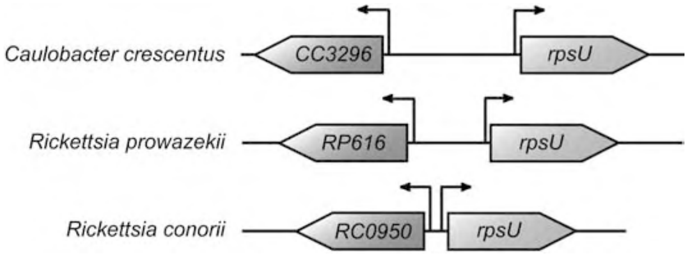

Figure 3 Example of a conserved, *divergently* arranged gene neighborhood. The two gene families (red, green) are found next to each other, in a divergent orientation, in three microbial genomes. The family shown in red contains previously uncharacterized genes weakly homologous to members of the TetR family of transcriptional regulators. The family shown in green contains genes encoding ribosomal proteins of the S2 type (rpsU). This observation leads to the suggestion that genes of the red gene family serve as regulators of ribosome production and of protein S2, in particular. The red gene family has orthologs in higher eukaryotes (including humans). These are not in any divergent gene neighborhood, but they may still perform the same function in humans (possibly in mitochondria, which are derived from prokaryotic ancestors). Thus, we have here an example of a genomic context prediction relevant to human biology, although the initial observation was made in prokaryotes. (Simplified from Ref. [31], with permission.)

a head-to-head fashion, transcribed away from each other) and convergent (i.e. neighbors orientated in a tail-to-tail fashion, transcribed towards each other). Interestingly, among repeatedly observed neighborhoods, the divergent arrangement is much more frequently seen than the convergent arrangement (Figure 1), although both are *per se* about equally frequent in any given genome. This suggests that, to some extent, even divergent gene neighbors are preferentially retained during genome evolution – presumably because some of them are functional partners maintained by selection. Indeed, this observation forms the basis for a recent extension [31] of the conserved neighborhood method: not only collinear neighbors, but also divergent neighbors are predicted to encode functional partners, if their arrangement is observed sufficiently often (see Figure 3 for an example).

It is not yet fully understood why divergent arrangements should provide a selective advantage, but one possibility is that they facilitate coordinated regulation, either through shared promoters or through mechanistic "cross-talk" between the neighboring loci [48]. Indeed, analysis of expression data for neighboring gene pairs suggests that divergent pairs have a higher chance of being coexpressed than convergent gene pairs [31]. Coregulation through a shared promoter might have the advantage of being very "immediate" (no intermediate steps are required for the regulation to take effect); tightly coupled coregulation might be particularly advantageous if one of the partners were a regulator itself, controlling the other partner (e.g. in a feedback loop). Korbel and coworkers have observed that the latter might indeed occur frequently: in many of the pairs, one gene encodes a transcription factor, regulating the other gene [31]. Divergent gene pairs may be a widespread phenomenon – they have been observed not only in prokaryotes, but also in higher eukaryotes such as humans [1].

2.4 Gene Neighborhood in Eukaryotes

Analyzing gene neighborhood has long been routine in prokaryotes – both in bacteria and in archaea. Prokaryotes have very compact genomes, thus their genes are naturally in very close proximity, and the known prevalence of operons shows that tight coregulation of neighboring genes is commonplace in prokaryotes. But what biological meaning does gene neighborhood have in eukaryotes?

In particular, multicellular eukaryotes can have a very low gene density, with noncoding sequences vastly outnumbering coding sequences (genes) in the genome. Eukaryotic genes are usually transcribed separately, each forming a single transcription unit, and not as longer, polycistronic transcripts covering several genes at once (operons). However, many unicellular eukaryotes do have quite high gene densities, and some basal eukaryotes, as well as nematodes, even have polycistronic transcripts [5,58]. Does this mean that neighborhood analysis can easily be extended to eukaryotes?

There are certainly some well-characterized examples of genes whose orientation and neighborhood on the genome is important, and presumably maintained by selection. A famous example is the "*hox* cluster", a set of homologous transcription factors usually found in a strict spatial ordering on the genome of animals. Each gene serves as a molecular switch for providing "identity" to a particular body part during development and the body parts in question are often arranged in the same spatial order as the genes on the genome. This gene arrangement bears all the hallmarks of a conserved gene neighborhood, potentially useful for genomic context analysis: the genes are present in a wide range of organisms (from insects to man), their neighborhood is consistently observed (with only a few exceptions) and the neighborhood is far more conserved than most other neighborhoods at equivalent phylogenetic distances. Indeed, had the *hox* cluster not already been appreciated through genetics experiments, genomic context analysis and the current availability of genomes would have easily revealed it as a special gene arrangement.

Unfortunately, only very few other examples seem to exist (in eukaryotes) of genes apparently maintained in each others' neighborhood. These include genes encoding histone subunits, as well as certain immunoglobulin gene clusters. In general, however, gene neighborhood in eukaryotes appears free to evolve, with few apparent evolutionary constraints. This is bad news for genomic context analysis: only when evolutionary constraints can be presumed to exist, does genomic context hold information about gene function. At least for higher eukaryotes, there seem to be too few constraints for neighborhood analysis to be useful at large – for basal eukaryotes, however, the jury is still out (because not many genomes have been analyzed so far).

That notwithstanding, neighborhood analysis can still be informative for eukaryotes, albeit indirectly – for all those eukaryotic genes for which clear orthologs can be identified in prokaryotes, any neighborhood that is observed in prokaryotes allows a prediction for the eukaryotic genes as well: functional partnerships are presumably maintained for much longer time than a particular gene neighborhood. A particular metabolic pathway, for example, might be recognizable through genomic context analysis in prokaryotes – then the genes will most likely form a pathway even in eukaryotes, although their mode of regulation may have changed. This can lead to the discovery of the function of hitherto uncharacterized genes, in higher eukaryotes and even in humans (e.g. Ref. [6]).

3 Gene Fusion

3.1 Gene Fusions and Gene Fissions

Among the many types of mutations that can affect genes and genomes, some are capable of changing where a gene starts or ends. A point mutation that introduces a stop codon, for example, might accidentally shorten a protein, whereas the inverse event (a stop codon changing to a valid codon) may lengthen it. Often, length changes will effectively destroy the gene, but in some instances the gene will remain functional. In extreme cases, a gene can even break up into two or more pieces that each remain functional (gene fission) or it may occur that two genes that have so far been separate become one entity, encoding a single polypeptide chain (gene fusion).

With respect to present-day genome sequences, successful gene fusions or fissions in the past led to very similar observations: two or more gene families that appear as separate genes in some of the genomes, but as longer, single genes in other genomes. Whether the underlying event was a gene fusion or gene fission is often difficult to discern and can sometimes only be inferred through careful phylogenetic analysis. Such analyses have been executed systematically [33, 51], and it has been observed that both events indeed occur during evolution and that fusions "survive" noticeably more often than fissions.

For genomic context analysis, both types of events hold information about protein function: in the case of the fission, the two separate gene families were once a single family (and thus were presumably part of the same function). In the case of the fusion, the two gene families apparently can occur together, i.e. they can tolerate being "tied" to each other; this means that the encoded proteins do not hinder each other sterically, are capable of working in the same cellular localization, and can function under the same transcriptional and translational regulation. This tolerance of course merely means that the fusion architecture is not selected against. However, a fused gene that lasts over long evolutionary time is probably not only neutral in the above sense, but may even be beneficial for the cell – otherwise it would have a high likelihood of breaking apart again into its constituents. Thus, whatever the underlying scenario, two separate gene families that are observed as a composite gene in some genomes can be predicted with some certainty to function in the same process or pathway. This basic observation was soon realized after the advent of the first complete genomes and is the basis for one of the three major genomic context techniques – the *gene fusion* method [14, 36].

For the gene fusion method, genomes are systematically scanned for open reading frames that seem to encompass more than one gene family. The gene families in question should be clearly defined as separate entities in other genomes, i.e. they should appear as distinct genes and they should not be homologous. If a candidate for a fused gene is found, it should be verified that the observation is not simply due to a sequencing error or a mistake in genome assembly. Next, it should be checked whether the fusion can be confirmed independently, i.e. rediscovered in another genome. This strengthens the case, because a single observation could be due to a chance event, such as a recent translocation or inversion (even when correctly sequenced). In addition, one should search for other fusion scenarios involving one of the two families: in real-world cases, a gene that undergoes fusions often will do so with more than one partner – usually all from the same pathway (e.g. Figure 4). Once a gene fusion (or fission) is observed and confirmed, a prediction ensues that the gene families in question have a functional relationship, even in all those genomes where they occur separately (not fused). This prediction is particularly strong when it can be demonstrated that the fused parts are orthologous to the distinct parts in the other genomes (as opposed to being merely homologous). This usually is the case when the fused parts are the only instances of the respective gene families in the genome containing the fusion gene.

3.2 Functional Implications

Gene fusions are distinct from all other types of gene context information, in that they entail a covalent link between two (or more) normally separate proteins. This implies a close, physical partnership between the proteins

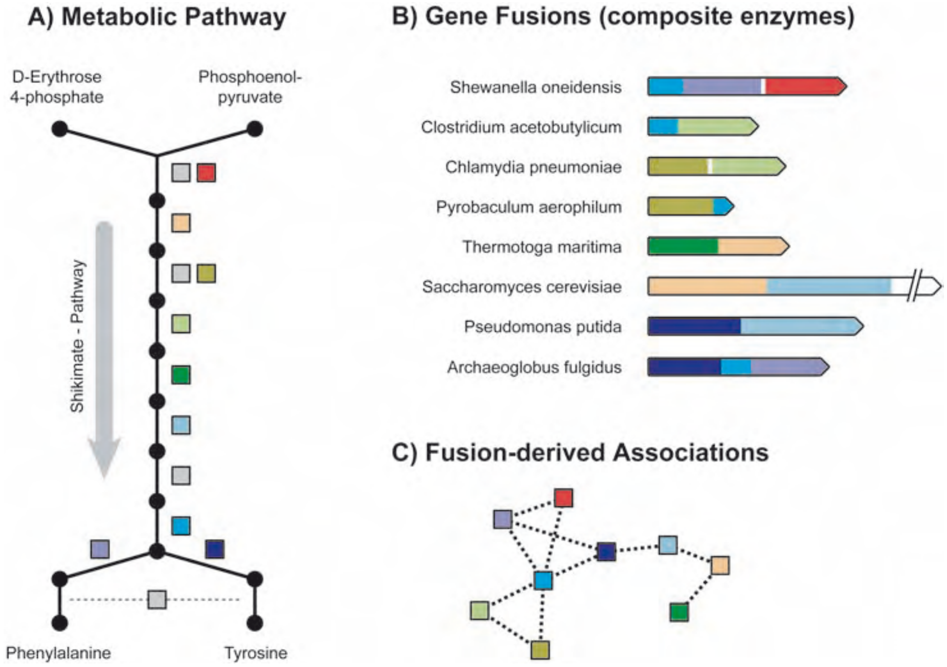

Figure 4 Gene fusion scenarios within a metabolic pathway. (A) The shikimate pathway is a biosynthetic metabolic pathway employed by plants and bacteria to generate aromatic amino acids (from precursors taken from carbohydrate metabolism). The colored symbols denote enzymes needed to perform the reactions in the pathway. (B) A selection of gene fusion scenarios observed for this pathway in completely sequenced genomes. Note that fusions occur in various combinations and do not necessarily involve direct pathway neighbors. (C) Association network derived from the fusion architectures. Note that the network connects all but four of the enzymes subunits of the pathway.

even when they are not part of a fusion; they possibly form part of a larger protein complex. In the cell, many important functions are performed by large complexes consisting of several tightly bound protein subunits (e.g. the ATP synthase complex, the fatty acid synthase complex or the pyruvate dehydrogenase complex). In many cases, the individual subunits of such complexes cannot function at all on their own – only the fully assembled complex is functional. In other cases, the individual subunits can to some extent fulfill their role in isolation, but do so more efficiently in a complex (where they may pass on substrates, akin to an assembly chain [61], or be more efficiently transported or integrated into a particular cellular location). For genes encoding the proteins in such macromolecular assemblies, it may be beneficial to fuse, enabling a tighter coupling and better coregulation. On the other hand, the synthesis of proteins may become costly and error prone when they become too large, especially in organisms under extreme conditions

[51], which may effectively limit the process. These balancing forces lead to a situation where many complexes or functional systems contain a certain number of fusion genes, but not necessarily the same fusion architectures in each organism (Figure 4).

Surprisingly, some protein complexes exhibit very few gene fusions (e.g. the ribosome) and it is unclear why this is the case. It could of course be due to special requirements in protein folding or complex assembly, or it may indicate that the complex is highly optimized and cannot tolerate many changes (consistent with this is the fact that the ribosome shows a very high level of sequence conservation). In general, gene fusion events are most often observed for metabolic enzymes, e.g. in *Escherichia coli* three-quarters of the total gene fusions affect metabolic genes [57].

3.3 Gene Fusions versus Domain Analysis

Some gene families are extremely prolific with respect to gene fusions. They participate in a large variety of fusion events, often with a diverse array of partners. Many of these promiscuous families are involved in signal transduction (e.g. histidine kinases or methyltransferases). Not only do they frequently participate in gene fusions, but they are also widespread in general, being present in several copies in most genomes. For the gene fusion method, these gene families pose a challenge. Due to their fast evolution and high copy number, it can be difficult to trace their phylogeny and to decide which of the genes within such a family are orthologous, for a given set of genomes. Without clear orthology information, however, a single fusion event involving such a gene family would lead to a prediction concerning all members of the family. For example, a fusion event involving a histidine kinase (such as the fusion of a certain histidine kinase to a likely Na^+/proline symporter in *Rhodopseudomonas palustris*) would lead to the prediction that all histidine kinases function in the respective process (proline import), which is clearly not the case.

In fact, these gene families are seldom seen in isolation, which is why they are sometimes not referred to as genes in their own right, but instead as fragments of larger genes; they often encode so-called *domains*. Domains are autonomously folding building blocks of proteins, which are frequently rearranged to form multi-domain proteins of significant architectural flexibility. They are frequently observed in areas such as signal transduction or immunity, in which novel proteins are quickly formed and changed during evolution.

Conceptually, the rearrangement of domains in order to form new proteins is of course simply a series of gene fusion and fission events – this is why the distinction between “domain analysis” and “gene fusion analysis” is not always clear. In general, the difference between both approaches lies in the precision of the phylogenetic information sought after: for gene fusions, we would like to know precisely, which genes (in which organisms) led to the fusion event; the goal is to be able to describe the phylogenetic relation of the various players. In contrast, for domain analysis this is usually not of interest, one does not ask what role the domains played before the fusion or where they came from. This is because domains are assumed to carry a certain basic molecular function, but are thought to take on a specific biological role only in conjunction with other domains, in a concrete protein.

4 Gene Co-occurrence

4.1 Phylogenetic Profiles

The gene complement in any given genome is subject to change over evolutionary timescales. Some genes may turn into pseudogenes and eventually be lost completely; others may newly enter the genome (for example through horizontal gene transfer from other species). Genes may also be invented de novo from previously non-coding genetic material; others may mutate beyond recognition and take on a new functional role, effectively becoming "new" genes. However, all of these changes are obviously constrained, and limited, by the effects of selection – leading to the general picture where changes in genome content are known to occur, but are not frequent enough to completely scramble genome identity [52].

As the gene complement is constrained by selection, changes in gene content are to some extent informative about changes in biological function. Any gene that is permanently lost, for example, indicates that a function may no longer be needed by an organism (such as the loss, in mammals, of genes to make a hard egg-shell; presumably this is a consequence of the internalization of their embryos [24]). The same is true for genes that are newly gained: many bacterial pathogens have recently acquired "new" antibiotics resistance genes, in a clear response to selection pressures mounted by humans. In the long run, the presence or absence of a gene in a genome thus appears to depend on, and reflect, its function.

As many genes work in teams, one would expect the same to be true for entire groups of genes – their presence should depend on their shared function and they should tend to be either present together or absent together in any given genome. Indeed, the presence of any particular gene increases the likelihood of finding its functional partners in the same genome: the presence/absence pattern of a gene among fully sequenced genomes (its *phylogenetic profile*) is often similar to the profile of its functional partners. This has been exploited as the basis of one of the major genomic context prediction methods: the *gene co-occurrence* approach. In this approach, phylogenetic profiles of all genes are compared, and if two or more genes show similar profiles, then they are said to "co-occur" and are predicted to be functional partners [25, 45]. This is a very powerful approach, because it does not depend on the actual genomic arrangement of genes or on their mode of transcriptional regulation – the simple presence of the gene anywhere in the genome provides the signal.

In real-world applications of this principle, it is important to take a close look at the phylogenetic profile of a gene family of interest before conducting a search, because not all profiles are equally "informative". For example, a gene family that is known to be present in all genomes has a profile of "full presence". Such a profile is not very specific; many other gene families have this profile. It presumably merely signifies that the gene family has an essential function needed by all organisms; however, because there are several essential functions (replication, transcription, translation, energy metabolism), it does not mean that all proteins with a "full presence" profile have the same function. Another pattern which is not very informative is the case that a gene occurs only in a single genome, i.e. it is a "molecular orphan". Usually, every genome has a number of such rare or fast-evolving genes, but this does not mean they are all functionally related. Another class of patterns that carry only little information encompasses those patterns that fully cover a single clade (or phylum) of organisms. For example, a gene that is present in all archaea, but nowhere else, has a phylogenetic profile that is neither "full presence" nor "molecular orphan". Yet, it is still not very informative, because many genes are known to have such a pattern (there is a significant length of evolution preceding the last common ancestor of extant archaea, during which a number of genes were invented that are now common to all archaea).

What, then, is an informative pattern for phylogenetic profile analysis? Basically, any pattern that appears "patchy". Ideally, the gene family should cover wide range of organisms, but it should not cover them completely, such that there are many instances in which the genes were presumably lost and/or transferred. In cases where such a "patchy" presence/absence pattern is matched by a second gene family, then a confident prediction for a functional link between the two families can be made, because the observation is unlikely to have arisen by chance (e.g. Figure 5). With more and more genome sequences known, the number of gene families that have a somewhat "patchy" profile is rising – fewer and fewer families show a "full presence" or otherwise entirely uninformative pattern.

Figure 5 Two proteins known to function together and the "phylogenetic profiles" of their genes. (Top) The two subunits of the tryptophan synthase enzyme are known to tightly bind each other and to jointly perform their function in tryptophan biosynthesis. (Bottom) The genes encoding these two proteins are usually either both present in a genome or both absent (i.e. their phylogenetic profiles are similar). Profiles can be either shown as discrete presence/absence profiles (left) or as continuous profiles (right, showing in this case the sequence similarity of the closest homolog in BLAST searches). Notice that the profiles of the two proteins are quite similar, even though the profiles are nontrivial ("patchy") and even though the proteins are not evolutionarily related.

4.2 Discrete versus Continuous Profiles

For the gene co-occurrence technique, it is particularly critical to have a reliable assignment of whether or not a gene family is present in a particular genome. Mistakes in this assignment will affect this method more than the gene-neighborhood or gene fusion methods, because the latter rely on gene-to-gene arrangements that are detectable even when the occasional gene copy is overlooked or erroneously included. In contrast, the co-occurrence technique relies on the gene presence itself as the signal and any error in assigning gene presence will introduce noise into the phylogenetic profiles.

Even when restricting the analysis to genomes that have been carefully finished and are of high quality, it can still be difficult to judge whether a functional counterpart of a gene is present or absent in a genome. As discussed in Section 1.3, the most reliable indicator for functional equivalence is "orthology", i.e. the situation that the genes in question presumably all trace back to a single ancestral sequence in the last common ancestor organism. However, orthology is always merely a hypothesis and can be difficult to assign in an automated fashion; possible errors are accidental oversight of true orthologs or unnecessary inclusion of paralogs (i.e. genes related through a gene duplication event, instead of a speciation).

An alternative measure of functional equivalence is simply the degree of sequence similarity between two genes – the higher the sequence similarity, the more likely the two genes have retained their function and are equivalent. While this measure clearly is not a good substitute for orthology, it is much easier to automate and just requires an arbitrary similarity cutoff below which a gene family is assigned as "absent".

Due to the general difficulties in reliably assigning gene presence, two types of phylogenetic profiles have been introduced: "discrete" profiles and "continuous" profiles. Discrete profiles are those that simply mark the presence or absence of a gene family in each genome; they essentially take the form of a vector with two types of elements: 0 (for absence) and 1 (for presence). Continuous profiles, in contrast, do not attempt to decide whether or not a gene is presence, but simply provide a measure that is thought to correlate with functional equivalence (e.g. sequence similarity). Continuous profiles take the form of a vector with values ranging from 0 to 1; a value of 0.8 might for example signify a sequence identity of 80% or any other quantitative measure pointing towards a high chance of functional equivalence.

4.3 Profile Distance Measures

With more and more genomes being sequenced, very few gene families are found to be present in exactly the same set of organisms (i.e. to have the same, discrete phylogenetic profile). This is true even for gene families known to be tightly associated functionally. In part, this lack of agreement can be attributed to technical limitations such as occasional gaps in genome sequences (or errors in orthology assignment), but it is also due to the stochastic nature of genome evolution itself: phylogenetic profiles are shaped by the inheritance, loss and/or horizontal transfer of genes in and between genomes. For genes sharing the same function, the overall outcome of this will be roughly similar (due to selection), but the individual evolutionary events are still stochastic.

A group of genes forming a metabolic pathway, for example, may become dispensable and will be eventually lost from a genome, but the loss takes time and may proceed in steps, and many of the genes may initially still be detectable as pseudogenes. Any phylogenetic profile observed at a given point in time thus contains a certain measure of biological and technical "noise".

This necessitates the use of distance measures in comparing profiles, in order to assess which profiles are most similar to a given query profile. A variety of different distance measures can and have been used, and since there is no formal and fully parameterized model of genome evolution, the choice of distance measure is determined empirically. The choice is guided mainly by the performance of the various distance measures in recovering known functional associations from the comparisons, and the choice may depend on the set of known reference associations, the number of genomes analyzed and the type of question asked.

For discrete profiles, a suitable distance measure is mutual information, a measure from information theory that describes the amount of information one profile contains about the other profile; two identical profiles have a large mutual information, whereas random, independent profiles will have a mutual information of zero. Another useful measure for discrete profiles is the hamming distance, i.e. the simple count of the positions in which the two profiles disagree. In the case of continuous profiles, useful distance measures are the Euclidian distance or the Pearson correlation coefficient and vectors may be normalized before the distance is assessed.

In any case, the distance measure will provide a ranking, for any given query profile, of other profiles that best resemble it. Among those, known and novel functional partners should be enriched. Distance measures in general also enable the design of a scoring system, because they provide a quantitative measure which can be benchmarked with regard to its predictive power, using previous knowledge. This predictive power can then be expressed as a *confidence estimate* – a certain distance is assigned a certain likelihood of corresponding to a useful prediction.

4.4 Tree-based Methods

Conceptually, any simple distance measure between two phylogenetic profiles is ignorant of the evolutionary relationships between the species. However, it is the evolution of species (and the ensuing changes in their genome content), that forms the conceptual basis for the gene co-occurrence method. Essentially, the "unusual" evolutionary events within the history of a gene family are what make its profile unique: gene loss, gene duplication and (horizontal) gene transfer.

Ideally, therefore, it should not be the phylogenetic profiles themselves that are compared, but the inferred evolutionary events that happened in the past of the two gene families: did these events have some influence on each other (preferentially happening in concert) or did they occur independently? Focusing on past evolutionary events would automatically provide a way to recognize "uninformative" profiles: uninformative profiles would be those that can be explained with very few evolutionary events. A "full presence" profile, for example, requires only a single event (a single gene birth before the last common ancestor). Apart from that event, the profile can be explained by standard vertical inheritance. A single event, however, is certainly not enough to propose a shared function for any other family sharing that event.

Unfortunately, it is difficult to infer with some certainty what happened during the evolution of a gene family, and when it happened. Usually, this involves the alignment of the sequences, and the generation of a phylogenetic sequence tree (see Chapter 4). This tree is then compared to the previously known organismal tree, and any deviation is taken as an indicator for an unusual evolutionary event. Parsimony analysis is then used to determine the minimum number of events necessary to explain the observed patterns. This whole process is difficult to automate, however, and unsupervised procedures are unlikely to result in accurate alignments and reliable evolutionary inferences. Nevertheless, including tree-based information represents a very promising avenue for analyzing gene co-occurrence and early attempts to do this are promising: trees can be used to reduce the bias and redundancy in completely sequenced genomes, before comparing profiles [59], or the trees can be compared directly to infer the interaction specificity for interactions involving large multigene families (such as receptors and their ligands [46]).

4.5 Anti-correlated Profiles

Remarkably, gene co-occurrence is not the only way in which functionally associated gene families can manifest themselves in terms of genome content. In some instances, functionally associated genes do not co-occur at all, but actually appear to avoid each other. This can happen when the two families in question are not merely functionally associated, but indeed have the very same, identical function. In this case, the reason for the apparent avoidance is simple: having the same function, the genes can effectively replace each other and a situation where both of them would be together in the same genome is of no evolutionary advantage, so usually only one of them is kept. Which family ends up in which genome is probably largely random, but the overall outcome is that the two families have phylogenetic profiles that are essentially complementary to each other.

In order to appear as two distinct families in the first place, the involved proteins should have distinct sequences, and display little or no sequence similarity. If the families are not similar in sequence, how can they still have the very same function? This is usually attributed to a process called *convergent evolution*, in which a certain molecular function has most likely evolved twice, independently, from unrelated sequences (or at least from sequences that have diverged significantly before converging again functionally).

Well-known examples of anti-correlated profiles have been described, such as the case of the complementary occurrence of class I and class II lysyl-tRNA synthase genes [19]. In principle, anti-correlations can provide a way to extend the usefulness of phylogenetic profiles: for any given query gene, one should not only search for the best-matching profile, but also for the profile that best complements it. In this way, gaps in metabolic pathways can be closed and new functions assigned to previously uncharacterized sequences acting as analogous enzymes (e.g. Ref. [39]). Overall, of course, convergent evolution and functional replacement are rare events, giving the exploit of anti-correlated profiles a low coverage.

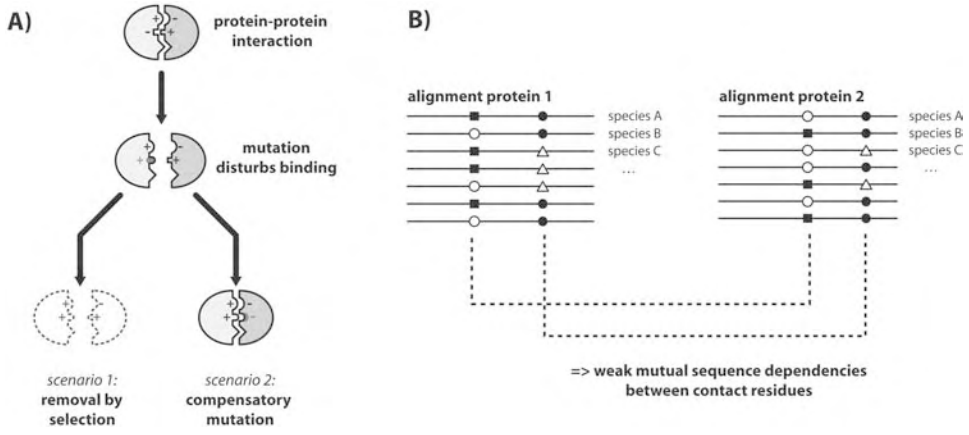
In general, anti-correlation in phylogenetic profiles is also more difficult to detect, because of one additional complication: while the genes may be nicely complementary in their occurrence and not be observed present together, they may very well be absent together. This is because the function they both represent may be entirely dispensable in some genomes, making both genes superfluous. The shared absences may to some extent mask the anti-correlation and usually need to be filtered away by only considering genomes known or suspected to encode the respective function [39].

5 Outlook

5.1 Methods based on Sequence Evolution

Interaction prediction based on genomic context is usually not concerned with the actual nucleotide sequences of the genes in question (or with the amino acid sequences of their encoded proteins). Sequences are only of interest inasmuch as they allow the delineation of orthology relations across genomes. Apart from that, mainly the arrangement and occurrence of the various genes relative to each other are of interest, as well as their presence in certain genome subsets.

However, at least in the case of proteins interacting directly through physical contact, the sequences themselves may also hold valuable information about the interaction. This is because of an effect termed *correlated mutations* [20, 44]. Correlated mutations may arise at the interaction interface between



A)
protein-protein interaction
mutation disturbs binding
scenario 1: removal by selection
scenario 2: compensatory mutation
B)
alignment protein 1
alignment protein 2
species A
species B
species C
...
=> weak mutual sequence dependencies between contact residues

Figure 6 Contact interfaces between proteins may lead to dependencies in their amino acid sequences. (A) Possible outcomes of a mutation that compromises/weakens a binding interface. Scenario 1 is by far the most frequent; the mutation is selected against and removed from the population. Scenario 2 happens only rarely; a second mutation, in the other protein, has compensated for the adverse effect of the initial mutation. (B) Multiple events of the latter type may lead to weak dependencies between some alignment columns of the proteins (physicochemical or sterical properties of the residues may have to remain compatible).

two proteins and are basically the result of mutations in one binding partner compensating the effects of mutations in the other binding partner. For example, if one residue at the interaction interface mutates from an amino acid with a small side-chain to an amino acid with a bulky side-chain, this may have negative effects on the strength and specificity of the binding: the bulky side-chain may cause a steric hindrance for the binding. In such a situation, two scenarios are conceivable: either the mutation causes a decrease in fitness, is thus selected against and eventually removed from the population, or it may occur that a second mutation (in the other protein) happens to have a compensatory effect in the binding surface and restores the quality of the binding (Figure 6). The first scenario is much more likely to happen, but even if events of the second type occur only occasionally, they have the potential to cause a weak correlation between the sequences of the two gene families. In principle, this "dependency" in sequence evolution can be detected and exploited for interaction prediction, using tools from information theory.

This approach may roughly qualify as a genomic context approach, because it relies on nothing more than protein sequences available from complete genomes, grouped into families according to orthology relations. It is potentially a very powerful approach: not only does it predict the exact type of a functional association (physical binding), but it may also predict binding interfaces and the topology of protein complexes.

Unfortunately, the correlated mutation signal in protein sequences is quite weak. Apart from correlated mutations, many other factors shape protein sequences: simple drift due to neutral mutations, selective constraints due to folding (folding often happens independently of a binding partner), as well as sequence conservation due to functional requirements such as active sites or substrate binding. The weak signal in correlated mutations means that a large number of sequences need to be analyzed and confounding signals/noise removed before a confident interaction prediction can be made. Currently, the method's power as an interaction prediction tool is still somewhat limited [44]; however, it is bound to improve with more genomes and, just like the other genomic context approaches, it is probably best used in combination with other prediction tools.

5.2 Web-based Implementations of Genomic Context Tools

Genomic context studies involve a considerable amount of work: hundreds of genomes need to be analyzed, orthology relations and gene families identified, and observations tested systematically for their relevance. Fortunately, much of this work recurs repeatedly for any type of genomic context analysis and most of it is well-suited for automation. For this reason, databases have been created that contain the results of many of the necessary computations and comparisons, and that hold large numbers of predicted protein–protein associations. These databases are periodically updated, to accommodate newly sequenced genomes. The predicted interactions may be available for download, and the databases often have web-accessible front-ends allowing the convenient browsing and comparison of prediction results (Table 2).

The last step in any genomic context analysis is the least amenable to automation. The predicted interactions need to be assessed for plausibility; they need to be integrated with expert knowledge and considered in the context of accessory information such as protein localization data or in-house experimental data. This last step needs to be done manually, but even for this task it is advantageous to have access to a database with a large number of predictions: The judgment on relevance is most useful when it is done globally – by ranking all the predictions for an organism according to score or "signal strength", then comparing them to previous knowledge and to reference data sets, and deciding which range of predictions is likely to be reliable. For this type of final judgment, a formal framework does not yet exist: no fully parameterized quantitative model for genome evolution is available, which would enable the estimation of an *a priori* likelihood or relevance of a certain observation. This means that any scoring system for ranking genomic context predictions is necessarily somewhat "*ad hoc*" and can provide only a rough estimate of the prediction accuracy. However, a scoring system is

Table 2 Genomic context databases and web tools (as of July 2005)

Name	Methods				Genomes (July 2005)	Comments	Ref.	URL
	N	F	P	O				
ERGO	√	√	√	√	330	a complex genome annotation and pathway discovery system, includes genomic context analysis modules; *only available commercially*	43	ergo.integratedgenomics.com
FusionDB		√			89	dedicated specifically to gene fusion analysis; for each fused gene, detailed evidence including alignments and phylogenetic trees of the protein sequences is displayed	54	igs-server.cnrs-mrs.fr/FusionDB
GeConT	√				238	focused on neighborhood analysis; compact and informative display of genomic situation; no scoring/ranking of predicted partners	9	www.ibt.unam.mx/biocomputo/gecont.html
Nebulon	√				229	specifically designed to allow "operon walking", i.e. to study the rearrangement of operon fragments in larger functional systems	27	http://tikal.cifn.unam.mx/nebulon
Phydbac	√		√		150	focused on the analysis of phylogenetic profiles; genes are not simply assigned as "present" or "absent", but represented by their score in similarity searches	13	igs-server.cnrs-mrs.fr/phydbac
PLEX	√	√	√		89	main focus is on analysis of phylogenetic profiles; genes are represented by their score in similarity searches; the neighborhood module only inspects one genome at a time	12	bioinformatics.icmb.utexas.edu/plex
Predictome	√	√	√		71	one of the earliest integrated genomic context analysis tools; cooperates with the VISANT network visualization tool; maps GO annotations to network	37	predictome.bu.edu
PROLINKS	√	√	√		163	Integrates genomic context predictions into a network of interactions; individual methods can be turned on and off; includes a text-mining module	8	dip.doe-mbi.ucla.edu/pronav
SEED	√	√		√	314	a comprehensive system for genome and pathway annotation, includes genomic context tools; complex user interface, can be installed and maintained locally by users	41	theseed.uchicago.edu/FIG/index.cgi
STRING	√	√	√	√	179	focused on scoring the predicted interactions and on inter-species knowledge transfer; apart from genomic context tools, includes text mining and imported experimental data, as well as coexpression information	60	string.embl.de

Available analysis methods are abbreviated as follows: N = conserved neighborhood; F = gene fusion analysis; P = phylogenetic profiles (gene co-occurrence analysis); O = other data and methods.

quite essential when dealing with genomic context predictions. A single query gene can have a multitude of predicted partners, especially when analyzing several types of genomic context simultaneously. Without a score providing the ranking of predictions, it can be very difficult to discern false positives from likely true positives.

Another advantage of globally precomputed databases is that they enable the presentation of a large number of predicted interactions in a graphical summary. Often, this is done in the form of an interaction network: nodes in the network represent proteins (or orthologous groups of proteins) and edges in the network represent predicted interactions. This enables the user to discover higher-order dependencies in the data, such as dense clusters of interactions that may represent functional subsystems (modules). Some web tools will also display associated information in the networks: experimental data, previous knowledge and detailed protein features such as their domain composition.

When using web tools and databases for genomic context analysis, it is generally prudent to have a look at the documentation. Each tool will follow its own philosophy and procedures, and results can therefore be quite different. The documentation should allow the user to understand what procedures were applied, and the user can then assess why differences may arise and how they can affect results in a particular area of interest. At the end of a genomic context analysis, the user might even want to follow-up with a manual, in-depth analysis – especially if initial results are promising. This may be needed because the databases and web tools are necessarily never quite up to date; there will usually be more data available in the form of newly sequenced genomes, which can be added to strengthen the analysis.

5.3 Scoring and Integration

As is the case with other bioinformatics prediction techniques, it is crucial in genomic context analysis to provide users with a score for each prediction, so that they can roughly judge its reliability. Scoring systems can take advantage of the fact that each genomic context technique produces a quantitative measure that its correlated with the "signal strength" of the predicted associations: in the case of gene neighborhood, for example, the quantitative measure lies in the number of genomes in which a particular gene neighborhood is found – the more genomes, the stronger the signal. For gene co-occurrence, the signal strength roughly corresponds to the degree of similarity between the phylogenetic profiles and for gene fusion it is the number of genomes that contain a given fusion architecture. To convert signal strength into an estimate of reliability, the predictions are usually benchmarked against a reference set of known functional associations or pathways. Such reference sets are typically based on externally provided expert annotations that group proteins into pathways, complexes, or otherwise similar functional “roles”. Reference sets that are frequently used include the pathway maps of the KEGG database [29], functional classification schemes such as the Gene Ontology [21] or the COGs database [55], or matches in Swiss-Prot keyword assignments [3]. Benchmarking itself is relatively straightforward: the predictions are binned according to genomic context signal strength, and the amount of false-positive and false-negative predictions is assessed for each bin. This leads to statements such as: “a gene neighborhood observed in more than three distinct bacterial phyla has a likelihood of above 95% of correctly indicating a functional link”.

It should be noted that such benchmarked scoring systems still provide only a rough approximation of the actual reliability of a prediction. This is due to the incomplete and possibly biased nature of the various reference sets. For example, a given reference set may be focused on a particular functional area only (e.g. metabolism in the case of KEGG); this may lead to overly confident predictions if a methods works particularly well in that area, but less well in other areas. Furthermore, some classes of genes may be lacking almost entirely from reference sets, for example fast-evolving or rarely occurring genes. Reference sets are often available for a limited number of model organisms only – providing scores for other organisms requires the assumption that a method works equally for these, which may or may not be true.

After scoring each individual prediction, it is often necessary to integrate the scores, e.g. when a particular interaction is supported by more than one type of prediction method or if there is additional experimental information to take into account. This type of integration across prediction methods and data sets is usually done in a probabilistic fashion, using Bayesian statistics [28,35]. In doing so, it is important to assess whether or not the different data sets are independent of each other. When full independence can be assumed, *naïve* Bayesian integration is sufficient – otherwise more sophisticated approaches are needed. It can be difficult to estimate the relative dependence (correlation) between the various data sets, so heuristic approaches are sometimes taken, in order to globally assign the relative weight of multiple evidence (e.g. Ref. [35]).

5.4 Genome Sequencing Strategies: Impact on Genomic Context Analysis

Genomic context techniques, like many other bioinformatics approaches, will become more and more powerful with the advent of further genome sequences [7]. Hopefully, genome sequencing will remain a mainstay of biology for some time to come – each newly completed genome has an intrinsic value that goes far beyond the initial applications foreseen at the time of sequencing. Only complete genomes can provide the molecular basis for a full understanding of organisms. For comparative genomics in particular (with all its applications in evolution and molecular function), a continued flux of genome sequences is essential.

However, given limited resources, there is always the question of how to prioritize sequencing, and at what level of precision and completeness to be satisfied in each individual sequencing project. Currently, there is an increasing trend for genome projects to be specifically designed for low coverage and precision – an approach termed "survey sequencing" (e.g. Refs. [30, 53]). While such projects provide valuable early characterizations of genomes (and give a welcome head start in the race to publication), they also run the danger of postponing indefinitely the necessary finishing work. In fact, many of the prominent animal genomes available today are still not finished, to the extent that some are not more than a large collection of incomplete fragments (e.g. Ref. [2]). To some extent, this de-values the initial investments – by effectively limiting the usefulness of genome data for studies in areas such as genome synteny, gene structure, duplication polymorphisms or gene content.

For genomic context techniques, it is important to be aware of the completion status of the genome sequences used. Phylogenetic profiles, for example, suffer a loss in resolution and predictive power when there are many sequencing gaps – any gene missed in sequencing will have the same effect as a gene loss, i.e. it will appear as an evolutionary event carrying a selective signal. This can lead to high levels of noise in phylogenetic profiles, especially for gene families that are rarely lost biologically, or for organisms in which gene loss constitutes a dominant part of the signal (such as higher eukaryotes). In addition, sequencing gaps can lead to problems when assigning orthology relations between species. Many orthology approaches rely on finding the "most similar" relative of a gene in the other organism, but this can lead to wrong results when the best relative has been missed in sequencing.

Another important issue is the selection of genomes to include in a genomic context analysis; with many more genome sequences expected, it may soon be no longer feasible to include all genomes for an analysis. In that case, it is important to select genomes that cover as widely as possible the known phylogenetic ranges of life. The goal should be to cover as much evolutionary time as possible, in order to maximize the cumulative impact of selection on the sequences studied. Formally, this can be achieved by maximizing the cumulative branch lengths of a whole-genome phylogeny, while at the same time minimizing the number of genomes considered. Effectively, one wishes to select against "redundant" (i.e. closely related) genomes, which do not provide much new signal in genomic context analysis. For comparative genomics in general, it would be desirable if genome sequencing projects were to follow this principle as well, trying to focus on deeply branching, underrepresented phyla. However, sequencing priorities of the scientific community are, necessarily, driven not only by phylogenetic considerations, but also by medical, economical and feasibility questions. This leads to a strong bias in available genomes: some parts of the tree of life are strongly underrepresented (certain bacterial phyla may be difficult to cultivate and do not have a single sequenced representative), whereas others are covered redundantly (of *E. coli* alone, several strains have been sequenced). Fortunately, future sequencing projects seem to be increasingly directed also by evolutionary and phylogenetic considerations [10], leading to a better representation of biodiversity and evolution.

5.5 Environmental Context

Each time a new genome is sequenced, we learn more about the metabolic and cellular capabilities of a particular organism. However, genomes also provide another type of information: they allow inferences about the environments in which the organisms live. For example, if a genome harbors photosynthesis genes, we can assume that the organism lives – at least occasionally – in an environment exposed to light; conversely, if a genome lacks certain genes (e.g. genes needed to produce an essential metabolite), we can assume that the metabolite in question is somehow available from the environment. Thus, genome sequences reflect environmental demands and opportunities – an assumption that is frequently the basis for interpreting novel genome sequences (e.g. Refs. [4,23]).

Taking this a step further, we may not even need fully sequenced genomes to learn something about an environment – instead, sequencing directly DNA that has been isolated from the environment should be almost as informative. Data of this type is increasingly becoming available through so-called *environmental genomics* or *metagenomics* projects, which are an alternative to traditional genome sequencing. In metagenomics, DNA is isolated directly and indiscriminately from an environment of interest (e.g. soil, water or even air), and is subjected to shotgun sequencing – irrespective of the complexity of the species mixture in the sample. Metagenomics data provide a very comprehensive and unbiased view on the coding potential of a biological community in an environment, much better than what can be achieved through traditional genome sequencing (traditional sequencing requires clonal growth of a single isolated organism in the lab, but a surprisingly large fraction of organisms in nature resist cultivation in a laboratory setting).

The increased availability of metagenomics data may soon enable an exciting extension to genomic context techniques – through an approach that might be termed "environmental context". Here, the presence and absence of a particular gene family in various environmental metagenomes (i.e. its "environmental profile") is assumed to depend on the gene's function – and this in turn means that functional partners should have similar environmental profiles. In the future, dedicated databases could hold such information (e.g. environmental presence/absence profiles) for all known gene families – updated with new information each time a novel metagenomics data set becomes available. Systematic searches in this database would then identify sets of genes that have higher-than-random similarities in their profiles and, thus, predict that they function together.

33 Inferring Protein Function from Protein Structure

Francisco S. Domingues and Thomas Lengauer

1 Introduction

It is well known that structure dictates function in many aspects of reality. This observation holds for the machines and buildings that we engineer. It also holds for the anatomy and physiology of the diverse types of organisms studied in biology, as well as to the molecular biology underlying the living processes of these organisms. Nevertheless, the determination of the protein function given its structure is not a trivial problem. The current chapter presents the recent developments in this field of structural bioinformatics.

So far, most of the investigation on the relationships between the structure and function of proteins has centred on the analysis of single case experimental results. Only recently have there been attempts to develop computational methods in order to find general rules behind these relationships and to generate predictions and testable hypotheses. There are two challenges at the center of these efforts: the localization of functional sites in proteins, and the identification of the molecular function of a protein. A considerable number of approaches have been proposed recently to address these challenges. Some of these approaches are still very new and untested, but others are more mature and have been successfully applied in the functional characterization of several proteins. This new field is now making its first contributions to the understanding of living processes at the molecular level, a necessary step along the path from genomes to therapies.

Structural models provide vital information as we seek to comprehend how proteins function at the molecular level. In this section we first address the different notions of protein function and the different kinds of functional information that is provided by the structure of a protein. We then focus on the structure–function relationships.

1.1 Different Levels of Protein Function

Function is not a simple concept. For a comprehensive definition, several levels have to be taken into account [13,97] (see also Chapter 29). The molecular or biochemical function pertains to the chemical interactions and reactions in which the protein participates. Function can also be defined on a broader level in terms of the biological processes in which the protein is involved, including its cellular and physiological roles.

In general, proteins bind to other molecules in order to perform their function. Therefore, binding can be regarded as a fundamental molecular function [97]. For example, proteins bind to other proteins to regulate their function or to transmit information along signal cascades, they bind to DNA in order to control gene expression, enzymes bind to the respective substrates as well as to cofactors and effectors in order to catalyze certain reactions, and transporters and receptors bind to the respective ligands in order to afford molecular transport or cellular communication.

1.2 Structural Models

Structural models can be determined experimentally by X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy or predicted using different computational approaches (see Chapters 10–12). Experimental models are much more reliable than predicted models, but in general the experimental approach is more costly and time consuming. Fortunately, over the past years there have been significant improvements both in the automation of experimental structure determination and in the quality of the predicted models.

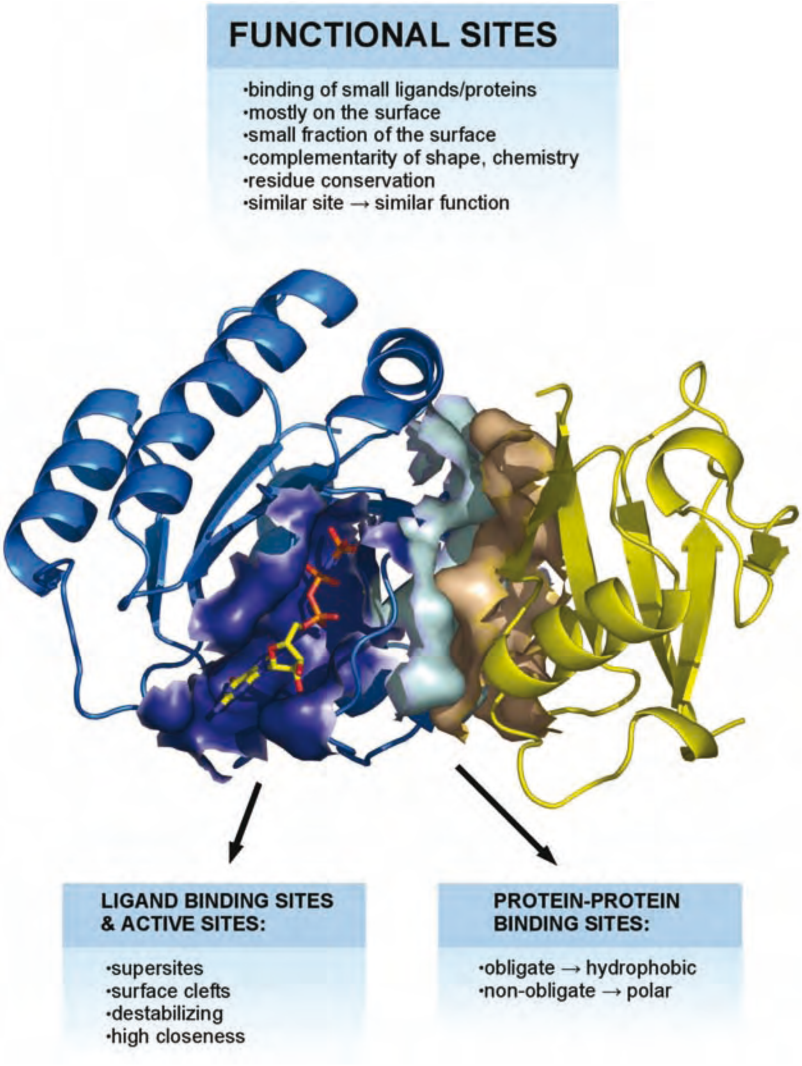
Structural models provide the three-dimensional (3-D) coordinates of the protein atoms. From these coordinates it is possible to characterize the protein in terms of geometry and chemistry. In particular, it is possible to identify the secondary structure elements and the organization of the polypeptide chain in 3-D (*fold*). Surface and buried atoms can also be identified, as well as the overall protein shape and surface chemistry. It is also possible to analyze the local arrangement of the atoms in any part of the model and characterize their local chemical environments. Many experimental models include several polypetide chains – from these models it is possible to identify and characterize the protein–protein interactions. Other models include small molecules bound to the proteins, either as natural substrates/ligands, or as artificial inhibitors or modified ligands. These protein–ligand complexes provide information regarding the location of the functional sites, the nature of the protein–ligand interactions and possibly even the molecular mechanisms underlying the protein function. Obviously, these structural models provide valuable information regarding molecular function [120]. Nevertheless, it is not trivial, at least with current methods, to infer the biological, cellular or physiological role of a protein based on structure data.

1.3 Homology and Function

Searching for homology has been a predominant approach in bioinformatics. This is understandable given that sequences are easily determined, and that the resulting data are suited quite well for a wide range of computational and statistical approaches for homology detection. This has produced important evolutionary insights and also provided functional information indirectly (see Chapters 3, 4, 11, 30 and 37).

An evolutionary relationship between two proteins indicates a possible function relationship, where the confidence for functional relationship increases with the percentage of sequence identity. It has been found that function is conserved between two enzymes when they share more than 40% of sequence identity (close homology) [121, 134]. Structure is more conserved in evolution than sequence. Therefore, methods for backbone structure comparison have been applied to detect remote homology between proteins, where the sequence similarity is not significant. Nevertheless, fold similarity does not necessarily imply homology, as proteins can share similar folds in the absence of homology. Backbone structure comparison methods are usually combined with other approaches (including functional information) in order to predict remote homology [35]. Functional variation is significant in the case of remote homology [121, 134], therefore inferring function relationship between remote homologous proteins is even more challenging than in the case of close homology. In addition, proteins can share similar molecular function in the absence of homology [42].

Despite these difficulties, methods for the comparison of protein structures in terms of backbone geometries are now routinely used in the functional characterization of newly determined structures. The process is not automated and relies extensively on human expertise for the interpretation of results. Usually a query structure is compared to all the structures in the Protein Data Bank (PDB) [16], and the entries with the most similar backbone structure to the query are identified. In general, most similar structures correspond to the homologous proteins (if any). Most of these methods also generate a structural alignment between the two proteins compared. Detailed analysis of this structure alignment, particularly of the aligned functional sites, is of great value for inferring functional relationships. The success of this approach is demonstrated by the considerable list of proteins functionally characterized using backbone structural comparison [136]. Severall backbone structure comparison methods are available and have been recently reviewed [66, 111].



FUNCTIONAL SITES
•binding of small ligands/proteins
•mostly on the surface
•small fraction of the surface
•complementarity of shape, chemistry
•residue conservation
•similar site → similar function
LIGAND BINDING SITES & ACTIVE SITES:
•supersites
•surface clefts
•destabilizing
•high closeness
PROTEIN-PROTEIN BINDING SITES:
•obligate → hydrophobic
•non-obligate → polar

Figure 1 General properties of functional sites. Complex of Ras (blue) with RalGDS (yellow), PDB code 1lfd [51]. Protein–protein binding sites in light blue and orange. Substrate-binding site in dark blue, with bound substrate analog. Graphics produced with PyMOL (http://www.pymol.org).

1.4 Structure and Function

Functional sites share geometric and physicochemical properties [97], (Figure 1). These properties provide the basis for different computational methods for function prediction.

As mentioned before, binding is a common theme in protein function. Binding usually takes place in a localized region at the protein surface, which typically corresponds to a relatively small fraction of the total surface. It consists of several key chemical groups from some residues that cluster at the protein surface independent of the position along the sequence. The rest of the protein serves as a structural framework that provides both the stability and flexibility necessary for shaping the functional region. Complementarity of shape and chemistry contributes to specific binding (lock-and-key model). However, proteins are flexible, so this complementarity is not always evident before binding, as proteins can adjust their conformation upon ligand binding (induced-fit model).

In general, the binding sites at the protein–protein interfaces display a high degree of complementarity with respect to shape and chemistry. This complementarity is achieved with different shapes, varying from flat surfaces to interfaces consisting of a protruding surface binding a cavity. Different physicochemical environments are also observed in different types of protein–protein interactions [86]. Hydrophobic residues tend to cluster at the interfaces of obligate interactions. These obligate interactions are required for the stability of the proteins that form the complex. In non-obligate interactions, the participating proteins can fold and form stable structures independently. These interfaces tend to include polar residues.

If the ligand is a small molecule, the interactions are usually located at surface clefts. These clefts provide easy accessibility for the ligand. In addition, high complementarity and increased binding specificity can be achieved by enveloping the ligand. These are general rules, but it is not difficult to find exceptions – a common theme in biological systems. For example, some ligands are found deeply buried inside the protein, requiring large conformational changes for the ligand to move in and out.

Functional sites are subjected to selective pressure different from the rest of the protein surface, as their structural and chemical integrity is required in order to preserve molecular function. In particular, functional-site residues are less tolerant to mutations than the rest of the surface residues. If the molecular function is preserved in two homologous proteins, the functional sites tend to display higher sequence conservation than the rest of the protein surface. Functional sites have also been found to be destabilizing (energetically unfavorable) [107,108]. The rest of the protein structure has to compensate for this effect in order to guarantee overall stability. In addition, analysis of residue interaction graphs, where protein residues are the nodes and interactions are edges, has revealed that active-site residues tend to have a relatively low average distance to all other residues in the graph (high closeness) [3].

Functional sites of different proteins exhibiting similar molecular function have also been found to share conserved geometry and chemistry. This property is quite relevant for the prediction of protein function. If two proteins have similar functional sites, it is likely that they have similar molecular function. This is valid independently of the overall fold or sequence similarity, or whether the proteins are homologous or not. The conserved ATP recognition in different types of enzymes is one such example [34]. Defining function similarity in this respect is not trivial. For example, enzyme similarity can be observed at the level of the substrate or cofactor binding site, the catalytic site, or the mechanism of catalysis.

Finally, it has been observed that the locations of small-molecule ligand-binding sites are conserved among some protein folds [101]. This conservation of binding sites can be observed even between nonhomologous proteins with the same fold.

1.5 Why Predict Function from Structure

The current motivation for function prediction based on structure information involves several factors. (i) The increasing availability of structural data results in many opportunities for computational analysis. (ii) The many hypothetical proteins whose structures are becoming available via structural genomics projects need to be characterized functionally. (iii) Improving the understanding of protein function based on available structural information is expected to generate deep biological insight. (iv) A rising interest in more direct approaches for characterizing proteins functionally.

Over the past 20 years the improvements in the techniques for protein structure determination have resulted in increasing numbers of experimental models being made publicly available in the PDB [16]. The amount of structural data achieved a certain level of critical mass, in the sense that it is now possible to train and test statistical learning and computational methods for characterizing structures and generating predictions in an automated fashion. Knowledge-based approaches and statistical learning methods are at the center of the new field of structural bioinformatics.

The current structural genomic initiatives (Chapter 13) are another factor. As an outcome of these initiatives we now have many structures available for proteins with uncharacterized function and many more are to be expected. This creates a demand for computational tools for functional characterization that make use of the available structural information.

We should not assume that these tools are only applicable to the structural models of hypothetical proteins. When applied to already annotated proteins, such methods can provide additional functional information. In particular, many proteins are known to have multiple functions [32, 55]. It is reasonable to think that this is the case for many more proteins which are yet to be identified. New and exciting functional insights can be expected, as these tools are applied to structures of partially characterized proteins.

Finally, one can observe a growing interest in more direct approaches for function characterization than the traditional homology detection methods. An important development has been Gene Ontology (GO), a systematic ontology for gene function [9]. An example of this new focus on functional characterization was the development of genomic context methods to predict which proteins participate in common biological processes. These methods are based on the comparison between genomes of different species (see Chapter 32). Approaches to functionally characterize proteins based on structural information are also part of this trend.

1.6 The Challenges of Automatic Prediction of Function from Structure

The two main challenges in prediction of function from structure are the localization of functional sites and the characterization of molecular function. Different approaches have been proposed in order to locate functional sites: structure comparison, quantification of structural features, and a combination of structural information and evolutionary conservation. They will be described in the Section 2. Characterization of molecular function is the other great challenge and is described in Section 3. The field is still in a highly experimental stage, and many different approaches are being proposed and tested. Among these alternative approaches we find several based on local structure comparison. Their goal is to find similar local structures (*motifs*) in different proteins. If these structural motifs correspond to functional sites, the functional information can be transferred between the matching proteins independent of the evolutionary relationships. An important element in the search for structural motifs is the availability of a database of functional sites.

1.7 Structure of the Chapter

It is possible to describe bioinformatics approaches from either the methodological or the application point of view. In this chapter we try to cover both. The two main sections of the chapter address each of the two main challenges (application): site localization (Section 2) and function characterization (Section 3). Each of these sections is subdivided according to the different approaches (*methodology*). We then mention preliminary efforts to address both challenges (Section 4). We also provide a list with the main tools currently available (Section 5) and apply them to a concrete example. We then describe some of recent successes in structure-based functional characterization (Section 6). We complete the chapter with a look at the future developments (Section 7).

2 Localization of Functional Sites

As described above (Section 1.4), functional sites have several unique features. These are explored by different approaches to locating functional sites in the protein structure.

2.1 Supersites

Structure comparison and structure classification are well-established fields of structural bioinformatics. Superfolds correspond to frequently observed folds which are shared by different nonhomologous proteins [89]. Russell and coworkers have investigated the localization of ligand-binding sites among proteins with the same fold [101]. They have identified supersites, which correspond to conserved structural regions within different superfolds with a significant tendency to bind ligands. Different supersites have been identified, each associated with a different superfold. If the fold of a given protein corresponds to one of these superfolds, the ligand-binding site is likely to match the corresponding supersite.

2.2 Electrostatics

Functional sites are quite unique in terms of local structure [96] – they are generally strained and destabilizing. This strain can become apparent in theoretical estimates of stability based on continuum electrostatics calculations. Two methods have been proposed based on this principle. One of the methods identifies the location of general functional sites [37], while the other focuses on the identification of active sites of enzymes [15]. A related approach uses computed titration curves for the same purpose [64, 88].

Nucleic acid-binding sites are a special case of protein functional sites, in which charge complementarity plays an important role. Two methods have been proposed for the identification of nucleic acid-binding sites. They are based on the identification of positively charged patches with electrostatic potentials [57, 118].

2.3 Surface Geometry

The shape of a site binding a small ligand has unique features in comparison to the remaining protein surface. It has been observed that ligands tend to bind to the largest surface cleft [70]. The SURFNET program locates protein surface clefts or pockets and computes their volume [74]. SURFNET can be used to locate functional sites by identification of the largest surface clefts. To locate these surface clefts, "gap spheres" of a certain radius (4 Å) are placed midway between each pair of atoms and the size of the sphere is reduced until all clashes to other nearby atoms are removed. The sphere is retained if the radius is larger than 1 Å. A contour surface is generated around the clusters of overlapping spheres, which represent the surface clefts and cavities in the protein. The volume of each surface cleft is calculated and the cleft with largest volume is predicted to be the ligand binding site.

Other approaches rely on the α shape algorithm to detect protein surface clefts. The α shape is derived from the weighted Delaunay triangulation of the point coodinates of the atom centers, where Voronoi edges and vertices outside the protein define empty tetrahedra and are excluded. In the APROPOS [95] method, α shapes are used to describe the protein surface at two different resolutions. The higher-resolution α shape includes surface details like cavities and the lower resolution just provides the global shape of the protein. The surface pockets or clefts are identified by determining the regions with the largest differences between the two representations. A single α shape representation is used in the CASTp [75] method and pockets are identified from the collection of empty tetrahedra. CASTp is an analytic method and, in comparison to other methods, has the advantage that it does not depend on discretization, iterations or any heuristic parameters. Nevertheless, unlike SURFNET or APROPOS, CASTp cannot identify clefts corresponding to shallow depressions where the openings are wider than any cross section of the interior. CASTp is available as a web service [20]

SURFNET, APROPOS and CASTp are not the only methods for finding surface clefts. Other methods such as LIGSITE [49] and PASS [25] have been proposed.

2.4 Structure and Evolutionary Information

Several methods have been proposed for the localization of functional sites based on the principle that these sites are subject to a different selective pressure than the rest of the protein along the evolutionary process. The approach has its origins in methods based purely on sequence [31]. More recently, several methods have been proposed that combine evolutionary and structural information in different ways.

2.4.1 Evolutionary Trace (ET)

The ET method was one of the first approaches combining evolutionary and structural information for the purpose of localizing functional regions in proteins [78]. The method is based on several hypotheses. (i) If function is conserved between an ancestral and its descendant proteins, the respective functional sites retain their localization. (ii) If the function is conserved within a subgroup of homologous proteins, the sequence of that functional site will be also be conserved in that subgroup. (iii) If the functions diverge between two subgroups of homologous proteins, one can expect that the functional divergence arises mostly from substitutions at the functional sites. (iv) The functional residues (binding or catalytic sites) are expected to cluster, forming patches along the protein surface.

The ET method consists of several steps. First, given a query protein with known structure, a set of homologous sequences is collected by pairwise sequence comparison. Then, a multiple sequence alignment is generated and a corresponding phylogenetic tree is constructed. The tree is used as a guide to partitioning the set into subgroups of homologous proteins at a certain evolutionary distance. Different partitions can be made at different evolutionary distances. For a given partition, the consensus sequences are determined for each subgroup, describing conserved and nonconserved positions. The evolutionary trace of the entire partition is obtained by aligning the consensus sequences. A position in the trace is neutral if it is nonconserved in any of the consensus sequences. The position is conserved in the trace if it is invariant over all consensus sequences. The position can also be class specific in the trace if it varies between the different subgroups, but is constant within each subgroup. The rank of a residue is the minimum number of subgroups into which the tree has to be divided in order for a residue to be class specific. Residues with low rank number are conserved over most of the tree and residues with high rank number tend to vary even between the most related proteins. Finally, the residues can be mapped into the structure and labeled according to the trace: neutral, conserved or class specific. Functional sites are expected to correspond to conserved and class specific trace residues clustering on the surface of the protein.

Some improvements have been proposed more recently in order to facilitate the use of the method at a large scale. In particular, the method now implicitly takes gaps into account, and calculates a statistical estimate of the significance of the spatial clusters of trace predictions [79, 137]. The method has been applied successfully to the regulators of G-protein signaling (RGS) family of proteins (see Section 6).

2.4.2 **ConSurf**

Several approaches related to the ET method have been proposed. The ConSurf [7,68,100] method tries to improve over ET by weighting amino acid substitutions according to differences in physicochemical properties and by calculating residue conservation scores based on maximum likelihood or empirical Bayesian algorithms. These residue conservation scores are then mapped onto the corresponding structural models. In general, the functional sites correspond to surface patches with high conservation scores (Figure 2). The initial implementation did not provide an objective criterion for defining

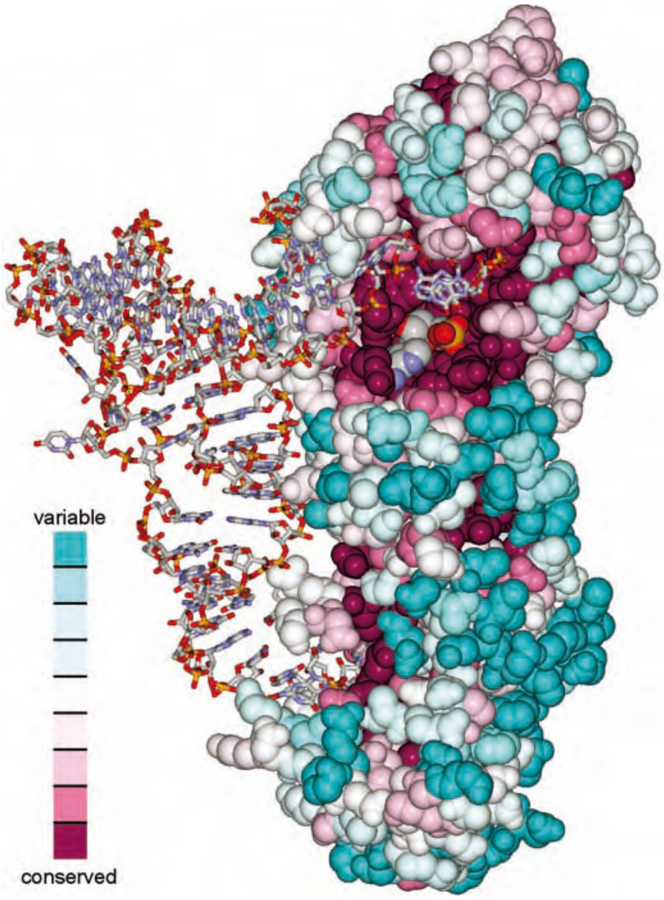


Figure 2 ConSurf results for glutaminyl-tRNA synthetase from *Escherichia coli* complexed with tRNA, PDB code 1gts [94]. Most conserved surface regions match the activation site (top) and the anticodon recognition site (bottom). Graphics produced with RasMol [17, 104] based on a script generated by ConSurf.

the functional region. The authors have now implemented a complementary method (PatchFinder) to automatically identify functional regions [85]. The predicted functional sites correspond to statistically significant clusters of conserved surface residues.

2.4.3 Residue Conservation and Structural Information

Other methods are based on more simplistic models for the conservation of residues while making direct use of structural information [1,22,69]. Sternberg and coworkers proposed a method based on the identification of C^{β} spatial clusters of conserved polar residues [1]. The predicted functional site residues are defined within a sphere centred at the geometric centroid of the conserved spatial cluster. The radius of the sphere is the distance between the centroid and the most distant C^{β} atom of the clustered residues. The approach is only applicable to functional sites with conserved polar residues. This is expected to be the case in most enzyme active sites and in many protein–protein interaction sites.

Landgraf and coworkers have proposed a method for locating functional sites based on two principles [69]. (i) Between functionally conserved proteins the residue conservation of the structural neighbors of a residue at a functional site is larger than the global residue conservation. This is measured by the regional conservation score of a residue. (ii) The global sequence similarities between functionally conserved proteins changes significantly when the same type of analysis is restricted to the structural neighbors of functional site residues. The authors proposed a so-called similarity deviation score of a residue to measure this effect. These scores are calculated from a multiple sequence alignment that includes a protein with known structure and a number of corresponding homologous sequences. From this alignment, two matrices are calculated – the global similarity matrix and the residue-specific regional similarity matrix. The first matrix consists of the pairwise sequence similarity scores between all homologous proteins. The regional similarity matrix includes the same of type of data as the global similarity matrix, but is restricted to the similarity scores of the structural neighbors of the residue. The regional conservation score of a residue amounts to the magnitude of the differences between the two matrices. The similarity deviation score is the correlation between the two matrices.

2.5 Network Centrality

Protein structures have been represented as networks, where nodes correspond to amino acid residues and edges represent interactions. Each residue in the protein can then be characterized in terms of network centrality (closeness centrality), as measured by the inverse of the mean geodesic distance (shortest path) between the node and all other nodes. Amitai and coworkers have shown that enzyme active-site residues tend to have high closeness values [3], which means such residues interact with the other residues directly or by relatively few intermediates. Based on this observation, they proposed SARIG (Structural Analysis of Residue Interaction Graphs) – a method to predict active site residues using closeness and relative solvent accessability. A SARIG web server has been implemented to predict the active site residues and to visualize the distribution of closeness values on the protein structure.

2.6 Combined Approaches

Several methods combine these different approaches in order to locate functional sites. In particular, combined methods have been proposed to identify active sites of enzymes and protein–protein interaction sites.

2.6.1 Catalytic Sites in Enzymes

Catalytic residues constitute a special group of functional residues. They are generally conserved, they tend to be found in the largest clefts, but at the same time, they tend to be buried (low relative solvent accessibility). They tend to be located in coil regions and usually are charged or polar [14]. Based on these observations, Gutteridge and coworkers devised a method for locating active site residues [46]. The following parameters were used to train a neural network: residue conservation, solvent accessibility, localization on a surface cleft and relative size of the cleft, type of secondary structure, and residue type. The neural network score obtained for each residue is used to define a list of possible active-site residues. Then, spatial clustering is performed and the cluster with the best scoring residues is predicted to be the catalytic site. Ota and coworkers addressed the same problem with a related method, based on identification of conserved residues, estimation of destabilization effect and location (cleft versus surface or buried) [90].

2.6.2 Protein–protein Interactions

Protein–protein interactions can be classified into different types, regarding composition (homo-oligomers, hetero-oligomers), autonomy of the protomers (obligate, non-obligate) or lifetime (permanent, transient) [86]. Protein–protein binding interfaces have been characterized regarding different properties: solvation potential (preference for being buried or exposed to solvent), surface residue propensity, hydrophobicity or protrusion. Different trends were observed for the different types of interactions (homodimer, large or small heteroligomers, or antibody–antigens). These observations were the basis for devising different scoring functions for the identification of certain types of interactions [58, 59]. More recently, Neuvirth and coworkers [84] tested the combination of different measures in order to predict transient protein–protein binding sites. The authors found that the most successful combination includes secondary structure, atom distribution, patterns of neighboring amino acids, residue conservation, chemical character of surface atoms (charge, aromaticity, hydrophobicity), position of water in crystal structures, sequence distance and hydrophobic patches. This problem has now been addressed in the PPI-Pred method, using statistical learning approaches in order to find the best combination of properties for each type of interaction [23].

A related problem is to distinguish the native protein–protein interactions (so-called biological interactions) from crystal contacts in structural models determined by X-ray crystallography. The latter contacts are a result of the crystallization process and do not occur natively in solution. This problem has been addressed in the Protein Quaternary Structure database (PQS) [50]. PQS is based on a method that empirically combines different interface physical measures, particularly the contact area, in order to discriminate biological from nonbiological contacts. It provides as a result the predicted quarternary state for each PDB entry. Other approaches have combined interaction size and residue conservation with a neural network predictor [124]. More recently, the NOXclass classification method has been proposed (NOXclass: non-obligate, obligate and crystal-packing classification). Different interface features have been combined in NOXclass with a support vector machine (SVM) implementation to classify a given protein–protein interface into crystal contacts, non-obligate or obligate interactions [140].

3 Characterization of Molecular Function

Characterization of molecular function based on protein structure is a considerable challenge. Direct comparison of functional sites provides a more direct approach to function prediction than methods based on homology detection (Section 1.3). The general strategy is to identify similarities between a query, an uncharacterized functional site and a functional site corresponding to a protein of characterized molecular function. The similarities are measured in terms of geometry or physicochemical environment. Based on this similarity, an attempt is made to infer aspects of the molecular function of the query protein.

We start this section by presenting some general concepts regarding functional characterization based on structure and then we describe several methods. First, we focus on the approaches based on comparison of atom coordinates, and then we describe methods that take into account surface shape and the local chemical environment. Finally, we briefly mention different databases of functional sites.

3.1 General Principles

3.1.1 Homology versus Nonhomology

There are different application scenarios in the prediction of function based on structure. A possible application is the identification of homologous proteins with similar function and, therefore, with conserved functional site. As described in Section 1.3, homology can be identified by sequence-based methods and by backbone structure comparison. The sequence-based methods have been combined with rule-based approaches for automated functional annotation of uncharacterized proteins [21, 41]. In addition, an automated method for functional prediction of homologous proteins has been proposed, which combines measures of backbone structural similarity and sequence conservation in the structural alignment [98]. Sequence-based methods lack information regarding the geometry and the distances between the functional groups, and methods based on backbone structural comparison do not center on the functional site. In contrast, methods for function prediction based on local structure similarity take into consideration the particular chemistry and geometry of the functional sites. One can expect that applying such methods to compare the functional sites of homologous proteins will further improve the quality of the functional annotations.

In another application scenario, the goal is to identify common function independent of homology. It is known for some cases that function and functional sites can be conserved regarding chemistry and geometry even in the absence of homology. A classical example is the Ser–His–Asp catalytic triad, found in peptidases with different folds (trypsin-like and subtilisins) [127]. Another example is provided by the similar ATP-binding sites in different ATP-dependent enzymes [34]. The comparison of functional sites can help in the characterization of molecular function, even if the query protein and characterized protein are not homologous.

3.1.2 Uncertainty and Flexibility in the Structural Models

When comparing functional sites one has to take into account that similar molecular functions can correspond to similar functional sites, but one can only expect similarity, not exact conservation of geometries and chemistry. In this respect, uncertainties in the coordinate values should be taken into account first. They correspond to atom vibrations, disorder in the crystal or errors in the structure determination process. Experimental methods always have a certain degree of uncertainty associated with the resulting coordinates, although the actual error estimates might not always be easy to obtain. The resolution and the free R factor (R_{free}) are common indicators for the quality of the crystallographic models. The RMSD across the ensemble of solutions has been used as a measure of quality for NMR structures, but other measures have also been proposed [73]. The quality of predicted structural models has been improving over time, but they still cannot compete with experimental models.

Apart from the flexibility resulting from atom vibrations, proteins are also flexible as a result of collective motions of atoms and residues. One can often observe considerable differences between backbone conformations in alternative structural models of the same protein [36]. Often, the changes comprise the functional sites, as structural changes are generally associated with function. Binding of a ligand, nucleic acid or protein is often associated with structural changes in the functional site.

Ultimately, one can always expect some degree of dissimilarity between different proteins with similar functional sites and molecular function. The challenge is to define a similarity measure and a threshold that can be used to identify the sites with similar molecular function.

3.1.3 **Functional Descriptors, Comparison and Scoring**

Within the set of known protein structures, one can observe conserved regions regarding structure and chemical environment. These recurrent structural/chemical environments correspond to structural or spatial motifs or structural patterns. Some of these motifs are purely structural; others correspond to functional sites.

In order to characterize functional sites, a descriptor is often used that encapsulates the corresponding conserved geometry and/or chemical environment. A comparison between two sites or between a site and a structure is carried out using these descriptors. A functional relationship is then inferred if the sites are significantly similar.

An algorithm for comparing the descriptors is required that identifies geometrical/chemical similarities. Generally, this involves finding equivalent regions in the functional sites (alignment) and scoring the similarities. Finally, a measure of statistical significance is needed in order to identify relevant hits.

There are different possibilities to compare functional sites. The query structure can be either a functional site or a complete protein. This query is compared to each entry in a database, consisting of functional sites or alternatively of complete structures. Databases of functional sites can be defined either manually (more reliable, slow, not reproducible) or with automated methods (faster, reproducible, not restricted to functional sites, problematic data quality).

Different types of descriptors have been proposed. Some are purely geometric, including the atom coordinates, or pseudo-atom coordinates representing the side-chain position, or a surface representation. Others include a description of the chemical environment, either indirectly by considering the amino acid types or, more directly, by considering the chemical functional groups. There are many possible ways to classify these different descriptors. For convenience we define two types; descriptors based on atom coordinates, and descriptors based on chemical environment and surface. Other classifications would be equally valid.

Different applications require different types of descriptors. For example, if side-chain atoms are considered for each residue, the comparison is more specific for a given functional site than if only the coordinates of the C^{α} atoms are used. On the other hand, the former is less robust regarding structural flexibility, vibration, disorder or model quality. When searching for functional similarity between homologous proteins, sequence similarity restricted to the functional site should be taken into account. If the identification of functional similarity on nonhomologous proteins is the goal, then the method should be independent of sequence similarity and the match should rely on the equivalences of chemical functional groups.

When the descriptors are based on atom coordinates, a simple measure like RMSD after optimal rigid-body superposition of the local structures can provide a similarity score for sites with the same size (same number of atoms). Nevertheless, a threshold for the identification of the significant hits is still required. In addition, if the results correspond to matches of different sizes, a measure of statistical significance (p-value or E-value) is necessary in order to compare the results. This is the case when comparison results include partial matches to a descriptor or when they include matches to different descriptors.

3.2 Descriptors based on Atom Coordinates

The most obvious way to represent a functional site is by the coordinates of atoms that constitute the residues making up the functional site. The descriptors vary in terms of whether they use atoms or pseudo-atoms and with respect to the type of chemical information considered. In addition, different search algorithms have been proposed for this type of descriptors.

3.2.1 **ASSAM**

The Willett group was among the early pioneers in the field when they proposed ASSAM in 1994 [8]. The descriptor consists of two or three pseudo-atoms per residue, representing both ends and the midpoint of the side-chain. The query descriptor is searched against a structural database using a standard subgraph-isomorphism algorithm [123]. In the implementation of ASSAM, the pseudo-atoms correspond to nodes in the graph and the distances between the coordinates of these pseudo-atoms correspond to the edges. The method has been successfully applied in the identification of enzymes that include the classical catalytic triad. The triad consist of a conserved serine, histidine and aspartate in the active site of some hydrolases (peptidases and lipases) in different families (nonhomologous, parallel/convergent evolution) [12,26].

A new version of ASSAM has been proposed that features several improvements [113]. In particular, the amino acids have been grouped into different classes according to their chemical properties and matches are allowed between different amino acids of the same class. Secondary structure information has also been added, as well as solvent accessibility, disulfide bridge information and distances to known binding sites.

3.2.2 SPASM

Kleywegt has proposed a related descriptor for the structural comparison of structural motifs [63, 81]. The descriptor is used in SPASM (Spatial Arrangements of Side-chains and Main-chain) to search for matches of a given structural motif in a protein structure database. Each residue is represented by the coordinates of the C^{α} atom and by the pseudo-atom coordinates corresponding to the side-chain center of mass. The method is flexible with respect to the matching of amino acid types. Several options are available; all amino acid substitutions can be allowed, or only some types of substitutions can be allowed, or the substitutions can be scored with a substitution matrix and selected according to a certain cutoff. Additional restrains can be used regarding conservation of sequence directionality, residue neighboring and conservation of gap size.

To search for a functional site in a protein structure, a recursive depth-first search algorithm is used. The candidate residues that match the correct residue type or the allowed substitutions are identified. Then the possible combinations of residues are generated and the distance between atoms (or pseudo-atoms) are compared to the the distances in the query site. If the distances match (differ less than a given cutoff) then the atoms (and pseudo-atoms) are superimposed and the RMSD value is calculated. Results are reported for matches bellow a given RMSD threshold. SPASM reports the possible matches of a query descriptor in a given structural database. RIGOR is a related program that performs the reverse type of search, comparing a query structure to a database of sites.

3.2.3 PINTS

The methods above require that a putative functional site definition is available for the query protein (ASSAM, SPASM) or that a database of characterized functional sites is available (RIGOR). Russell proposed a method for identifying common functional sites between two proteins, without requiring a previous localization of the functional site [102]. He addresses both challenges: localization and characterization. The putative functional site residues are selected according to the established principle of residue conservation and by selection of interacting residues (small inter-atomic distances). In addition, the comparisons are restricted to nonhydrophobic residues and disulfide bridges are ignored. A depth-first search algorithm is used and inter-atomic distances are compared. Unlike SPASM, the proposed method enforces a match of residue types. C^{α}, C^{β} atoms and a single functional atom (predefined according to the residue type) are used in the distance comparison. The matching residues are superimposed and the RMSD calculated. The method also includes a measure of statistical significance (p-values) for the RMSD values. The p-values are calculated based on RMSD values for random matches of side-chain patterns.

An improved model for the statistical significance of RMSD values for local structure comparison has been proposed more recently [116]. The model takes into account the geometry of a match for a given RMSD value, as well as the frequency of residue types and the dependency of the covalently linked atoms in the different side-chains. The derived cumulative distribution functions were shown to fit the observed distribution of the RMSD values for matches between random structural motifs and a background structural database. This model has been included into the search method PINTS (Patterns in Nonhomologous Tertiary Structures). PINTS compares a query site to a structural database, or a protein structure to a database of functional sites [117]. The current limitations of this method are the restrictions to nonhydrophobic residues and the enforcement of exact matches of residue types. Despite these restrictions, PINTS constitutes a reference tool for local structure comparisons and for functional site characterization.

3.2.4 **SuMo**

The SuMo method has been proposed to compare a given query structure to a structural database in order to find similar substructures [53]. The method relies on matching triples of chemical groups. In the comparison of two structures (A, B), a graph of triplets is defined for each structure (S^{A}, S^{B}), where triplets T_1^{A}, T_2^{A} with two common functional groups form connected vertices in the graph. To compare sites in different proteins, the triples are first matched according to the relative postion, local atomic density and type of the chemical groups, resulting in pairs of matching triplets (T_1^{A}, T_1^{B}). Then a comparison graph is defined (G^{AB}), where vertices correspond to pairs of matching triplets (T_1^{A}, T_1^{B}) and edges connect two consistent pairs of triplets $[(T_1^{A}, T_1^{B}), (T_2^{A}, T_2^{B})]$. For the pair of triplets to be consistent, T_1^{A} must be connected by an edge to T_2^{A} in S^{A} and T_1^{B} must be connected by an edge to T_2^{B} in S^{B}, and the angles between the planes of T_1^{A} and T_2^{A} must be similar to the angle between T_1^{B} and T_2^{B}. The independent subgraphs in G^{AB} correspond to similar substructures. As the structure graphs S for all structures in the PDB can be precomplied, it is possible to perform a fast search for all common substructures between a given query and all entries in the PDB. Given a query structure, or a ligand-binding site, the SuMo server [54] can search for all common substructures in the PDB or in a database of ligand-binding sites. Results are sorted by the number of matching functional groups or by RMSD. SuMo does not provide (yet) an estimate of significance of a match. One should also keep in mind that SuMo is a purely structural method; therefore, a match of two substructures does not necessarily imply that they are functional sites, but one can expect that functional sites with significant structural similarity will be detected. The great advantage of SuMo is that it does not require a predefined definition of sites in the query or in the structure database and that the results are provided within seconds or minutes. SuMo relies on matching chemical functional groups, instead of amino acid residues, and does not depend on fold or sequence similarity; therefore, it is suitable to find similar functional sites in the absence of homology.

3.2.5 TESS and Jess

The Thornton group has proposed a method for deriving consensus structural motif descriptors, called templates [127]. The approach was exemplified in the derivation of a template for the classical Ser–His–Asp catalytic triad found in different hydrolases. The template was derived using the coordinates of a known functional site as seed. In particular, the side-chain atoms of the histidine residue were used as reference, and the relative position of the functional oxygens Asp $O^{\delta2}$ and Ser O^{γ} were considered. Then candidate enzymes (serine proteases, subtilisin-like serine proteases, serine carboxypeptidases and lipases) were selected. Interacting Ser, His and Asp were collected and superimposed to the seed. Matching triples (RMSD < 2.0 Å) were used to derive a new consensus functional template. The outcome is a consensus descriptor for the functional site. The method requires some human intervention for the selection of seed structure, the reference and the functional atoms, and the RMSD cutoff for the match. The derived Ser–His–Asp template describes the conserved catalytic triad in the three different types of nonhomologous hydrolases. An additional template that includes the orientation of all side-chain atoms of aspartate and serine (and not only the functional oxygen atoms) was derived for each type of enzyme. The relative orientation of the functional oxygen atoms are conserved across these different enzyme types, but not the overall conformation of the relevant side-chains. Therefore, it was not possible to obtain a consensus template for all enzyme types using all side-chain atoms.

The authors have subsequently proposed TESS – a faster geometric hashing algorithm for the comparison of a functional site template to a structure [126]. To derive a TESS template, a grid is placed around a set of reference residue atoms and the relative positions of the functional atoms are mapped to the grid. In addition, a TESS hash table is obtained for a structural database. This table includes for each occurrence of the reference atoms in the database, the relative positions of the neighboring atoms. The comparison between the query template and the TESS table just requires matching the relevant grid positions, atom types and residue types. If a hit is identified, the coordinates are extracted, and the RMSD of the superimposition is calculated. The method was applied in the identification of different types of catalytic triads involving histidine (including the Ser–His–Asp). TESS allows some flexibility regarding the matching of atom and residue types. The new improved search method, Jess [11], is very flexible regarding the type of descriptor that can be used.

The group has also been compiling a new set of templates for enzyme catalytic residues in the Catalytic Site Atlas (CSA) [99,122] (see also Section 3.4.3). A CSA family has been defined for each group of homologous proteins with a conserved active site. Two different templates were created for each protein family – one based on C^{α}/C^{β} atoms and another based on the functional atoms (that play an active role in the catalysis). The templates allow for matching of chemically similar residues or atoms. The representative template for a family corresponds to the catalytic site with the lowest mean RMSD from all other members of the family. The authors analyzed the diversity of templates within these families. They found that the templates within the homologous families tend to differ by less than 1 Å RMSD and this effect was independent of sequence similarity. The authors also found that templates based on C^{α}/C^{β} atoms tend to be more discriminating than those based on the functional side-chain atoms in the identification of similar catalytic sites within protein families. This is an indication that C^{α}/C^{β} templates are more strongly conserved over homologous families and more robust with respect to structural flexibility than templates based on functional side-chain atoms. Different results might be have been obtained if the analysis had been performed over nonhomologous proteins.

More recently, the authors have derived additional sets of templates in an automated way [71]. Ligand- and DNA-binding templates have been generated from PDB based on the interactions between amino acid residues and small ligands or nucleic acids. In addition, an alternative template search strategy has been implemented. Instead of comparing a query structure to a template library, three-residue templates are extracted from the query structure and compared to a set of representative structures from PDB. This reverse template strategy provides a much higher coverage for matching functional sites than is possible with CSA templates of ligand/nucleic acid templates. The disadvantage is that not all matches correspond to functional sites. The authors have also proposed a new estimate of significance of a match that takes into account the relative positions of the matching residues in protein sequences. This measure is expected to identify similar functional sites in homologous proteins, but is not applicable to compare functional sites in nonhomologous proteins.

3.3 Descriptors based on Chemical Environment and Surface

So far we have described methods that define functional sites in terms of atom or pseudo-atom geometries. An alternative approach is to view the functional site as an environment with certain chemical and physical properties, and with a certain shape. After all, binding is the basis for the molecular function of proteins, and binding specificity is determined by complementarity in terms of shape and chemistry. If the atom coordinates are not taken into account directly, one can expect the descriptors to be more robust with respect to local structural changes and to structural flexibility, and better suited for describing the general molecular function independently of homology.

3.3.1 FEATURE

FEATURE is a method for characterizing the micro-environments surrounding the functional sites in terms of chemical and physical properties [10, 131, 132]. Typical properties are atom types, hydrophobicity, charge, residue types, chemical groups, secondary structure or solvent accessibility. A 3-D grid is used as reference in each protein structure. Each protein atom is mapped to the grid and the values of the corresponding physicochemical properties are stored for each grid cell. Then the spatial distribution of the properties over a certain site can be calculated by summing the property values of all gird cells within a certain radial distance from the center of the site. In this way, a collection of adjacent grid cells is united to a radial shell. The properties pertaining to certain types of sites can then be compared to background properties. If a certain property has a significantly different radial shell distribution in the given site type than in the background (to be determined by a rank-sum test), then this property is considered to be characteristic of that given type of site. In this way the set of property distributions for different radial shells can be identified that are characteristic of a certain type of functional site. These characteristic property distributions can be used as a descriptor in the identification of similar sites in query proteins. In order to compare a query site to a descriptor, a Bayesian scoring function is used to score the likelihood that the property value for a given radial shell in the query site matches the distribution in the site descriptor. The probability values calculated for each property can be combined to give an overall likelihood that the query site matches the site descriptor. A web site is available (WEBFEATURE) to scan a query protein for the occurrence of severall precompiled functional site descriptors. Particularly interesting is the availability of RNA magnesium-binding site descriptors.

A promising development is the use of established sequence motifs as seeds for the definition of the structural-based FEATURE descriptors [76]. In this way it is possible to generate a large number of FEATURE descriptors that are expected to correspond to functionally relevant sites.

3.3.2 CavBase and SiteEngine

The Klebe group has proposed a descriptor for ligand-binding sites that combines physicochemical interaction properties and the surface geometry of the binding site [106]. The ligand-binding sites are extracted using LIGSITE [49], in combination with Relibase, a structural database of protein–ligand interactions [48] (see Section 3.4.1). The physicochemical properties of the binding site are represented as a set of pseudocenters (pseudo-atoms) defined in terms of the atom coordinates of the different chemical functional groups on the protein side-chains and backbone. Five properties are considered: hydrogen-bond donor, hydrogen-bond acceptor, mixed donor/acceptor, aliphatic and aromatic. The binding site descriptor consists of the set of pseudocenters and a grid surface representation. In this surface representation, each grid point is associated with the physicochemical property of the adjacent pseudocenter.

A graph-based approach is used for the comparison of two sites. The problem is reduced to the detection of a maximum common subgraph of the pseudocenters in the two descriptors and solved by a clique detection algorithm [27, 65]. The spatial arrangement of the pseudocenter is viewed as a graph with nodes corresponding to the pseudocenters and edges corresponding to the distances between them. Given two descriptors represented by two graphs, *A* and *B*, all pairs of nodes from *A* and *B* are collected into a product graph *G*. In this product graph the nodes correspond to pairs of pseudocenters with compatible properties. In the product graph *G*, the edges join nodes that correspond to pairs with similar pseudocenter distances in *A* and *B* (difference less than 2 Å). In *G*, the maximum cliques (completely connected subgraphs) are enumerated. Each clique corresponds to a choice of equivalent pseudocenters from both sites with compatible properties and a similar geometry. The size of the clique (number of nodes) is the number of equivalent pseudocenters in each site. The clique solutions are then ranked according to the surface similarity in both descriptors, as measured by the superposition of the surface representation (surface grid points). For each clique, the superposition minimizing the RMSD between the equivalent pseudocenters is calculated. The resulting transformation is applied to the surface grid points and the overlap of surface patches with compatible properties is calculated. Nonoverlapping surface patches and corresponding pseudocenters are filtered out. A new transformation is calculated and the final overlap of compatible surfaces is used to rank the comparisons solutions between two sites. The process is repeated each time a query site descriptor is compared to each entry in a database of binding sites descriptors (CavBase). The surface overlap score and an additional measure are used to compare the search results of different sites. This additional measure takes into account not only the overlap of compatible surface grid points, but also the RMSD of the final superposition of the surface grid.

This group has recently proposed a more efficient similarity search method [133] combining geometric hashing with clique detection. In particular, the method uses a modified product graph in which the nodes correspond to larger matches of local subsets of pseudocenters. This reduces the graph size and the possibility of false matches. The implementation results in considerable speed up of detection with a small sacrifice in coverage.

SiteEngine is a related method developed by the Wolfson group [109, 110]. They also use pseudocenters corresponding to different physicochemical properties and a surface representation. For the comparison they do not use a clique detection algorithm, instead they rely on an efficient geometric hashing implementation. Figure 3 show a comparison of two similar nucleotide binding sites in proteins with different folds. The group also implemented I2I-SiteEngine – a related method for the comparison of protein–protein interfaces [110]. The implementation is similar to SiteEngine, but it additionally relies on predefined patterns of pseudocenters. These patterns correspond to the different types of noncovalent interactions that are expected to be found in protein–protein interfaces.

3.3.3 **eF-site**

The Nakamura group developed the eF-site database, consisting of surface descriptors for different functional sites. The descriptors consist of representations of surface geometry and electrostatics [60–62]. The group also proposed a graph-theoretic based approach for site comparison. Each site is represented as a graph in which each node corresponds to a vertex in the triangular mesh of the molecular surface representation. The product graph corresponds to pairs of nodes from the two sites with similar values for surface curvatures and electrostatic potential. Edges in the product graph represent vertices at similar distances in both functional sites (differing by less than 1.5 Å). A clique detection algorithm [27] is applied to find the similar surface regions.

3.3.4 **pvSOAR**

The pvSOAR (pocket and void surfaces of amino acid residues) method compares protein pockets or cavities regarding sequence, spatial arrangement and orientation [18]. Pockets and cavities are detected by CASTp [75] (see Section 2.3). For each pocket residue, the geometric center of the atoms that contribute to the walls of the pocket is selected. The statistical significance of a match of two pockets or cavities is assessed by aligning the patterns of amino acid pocket residues. The sequence similarity score is

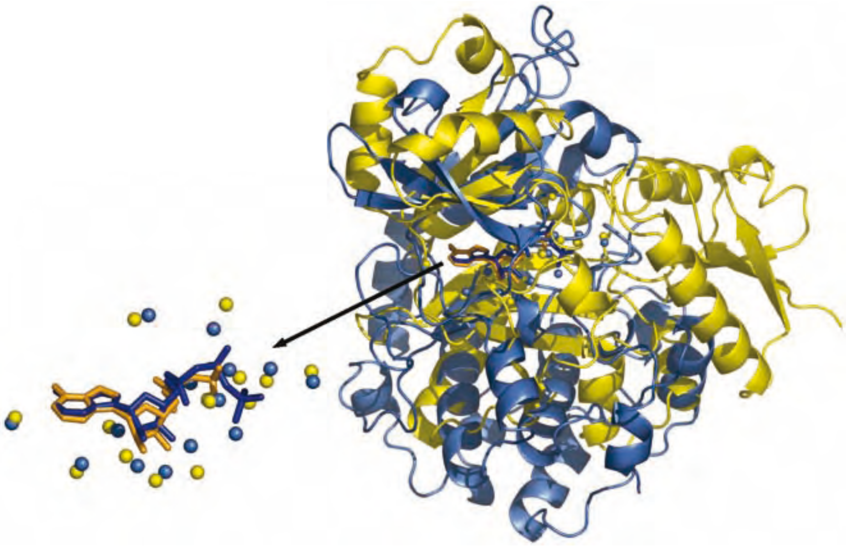

Figure 3 Finding similar small-ligand-binding sites with SiteEngine. The cAMP-dependent protein kinase (blue, PDB code 1atp [139]), and the D-Ala–D-Ala ligase (yellow, PDB code 1iow [39]) have different folds. The kinase binds to ATP (blue) and the ligase binds to ADP (orange). The bound ligands have similar conformations. SiteEngine identified 14 equivalent pseudocenters at the ligand-binding sites. The ligands and pseudocenters are shown enlarged on the left, with the kinase pseudocenters in blue and ligase pseudocenters in yellow. The two structures are shown superimposed according to the transformation from the SiteEngine solution. Graphics produced with PyMOL.

used to compute an *E*-value using a background distribution of similarity scores of randomly shuffled pocket sequences. Two additional measures of significance of match are computed based on the geometry of the matching pockets/cavities. One measure is based on the calculation of the atom coordinate RMSD (cRMSD) after optimal superposition of the atoms in the pocket according to the alignment of the sequence patterns. The second measure is based on the orientation RMSD (oRMSD), which is less sensitive to outliers. The oRMSD is calculated after optimal superposition of coordinate unit vectors defined along the direction of the pocket geometric center. To evaluate the significance of the structural match, *p*-values are computed for both cRMSD and oRMSD, using matches of randomly generated pockets as a background distribution. The amino acid type and position in the sequence is used to compute the sequence-based *E*-value and to define the equivalent residues in the superposition. As the method depends on sequence similarity of the pocket residues, it is expected to perform better in identifying similar functional sites between homologous proteins than between functional sites in nonhomologous proteins. A pvSOAR web server is available [19], where users can compare a given structure to the database of pockets and cavities extracted from the PDB structures. Results can be sorted by sequence based E-value, and by cRMSD or oRMSD p-values, and the aligned pockets are visualized interactively with Jmol (www.jmol.org).

3.3.5 Enzyme Classifier

The development of an enzyme classifier based on self-organizing maps (SOMs) trained with surface cleft properties [114] is an application of statistical learning methods to function prediction based on structural information. Surface clefts were detected with a grid-based method and solvent-accessible surfaces were computed for each cleft. Each surface point was assigned to a chemical type according to the nature and direction of the closest chemical group. Five types were considered: aliphatic, hydrogen-bond donor, hydrogen-bond acceptor, aromatic face and aromatic edge. A set of surface cleft points was used for the generation of topological correlation vectors. Each vector consists of 150 elements; each element corresponds to a certain type of interaction between two chemical types (15 possible interactions), within a certain distance interval (10 equal distance bins of 1.5 Å). Each vector element stores the sum of occurrences of pairs of surface points of the corresponding chemical types and within the corresponding distance. A SOM was then trained using the topological correlation vector and applied in the classification of different types of metalloproteinases.

3.3.6 3D Shape Descriptors

An efficient approach based on spherical harmonics has been proposed for the description of ligand and binding site shape, and for their comparison. The method was applied to virtual drug screening [28] (see Chapter 18). More recently, a similar approach has been proposed for the comparison of ligand-binding sites [82]. The surface is treated as a linear combination of real spherical harmonics. The corresponding expansion coefficients can be used as a description of the shape of the surface cleft and the Euclidean distance metric is used as a measure of similarity between the shapes of the sites. The computation of the expansion coefficients is very fast. Sets of sites can be clustered according to shape similarity using this metric. The approach is quite promising, but there are some limitations. In particular, performance is poor for flat or solvent-exposed binding sites and local matches, where the similarity is restricted to a subregion, cannot be detected. Structural flexibility is not taken into account directly, but it is possible to generate descriptors and perform comparisons for all alternative site conformations given the efficiency of the implementation. Currently, the method is restricted to shape comparison and does not take into account physicochemical properties, but the authors proposed the future inclusion of electrostatic potentials in the descriptor.

3.4 Databases of Functional Sites

Data tend to accumulate dramatically during the process of discovery. Large data volumes can be reached as a result and then it becomes difficult to capture the underling principles from the detailed analysis of single cases. At this point annotated databases and classification methods become valuable, allowing the extraction of the relevant information in a systematic and organized way.

Databases for classification of protein structures [4, 93] fulfilled that important role for the structural data available in the PDB [16]. They provide structural and evolutionary classifications of the known protein structures. However, structures can also be classified based on other principles. A functional classification of protein structures is under way by linking the structural models to functional terms [30, 125]. As mentioned in Section 1.4, molecular function can usually be mapped to a set of localized functional sites. An additional classification database is desirable in this respect, which groups the different types of functional sites according to the underlying molecular function. This will provide a basis for the better understanding of the structure–function relationships and for the development of prediction methods.

Most of the methods for functional characterization described here provide a match between a query protein and a characterized protein. The comparison can be performed between a query structure or site descriptor and a structural database or a database of functional sites. For performance and methodological reasons, it is usually necessary to use a precompiled database of site descriptors, particularly if the query is a complete protein structure. This creates a need for a database of classified functional sites, from which a set of functional descriptors can be compiled. In addition, a database of functional sites can be used to extract the characteristic properties of different functional sites in order to develop new strategies and methods for function prediction. It also affords training, testing and comparing of different methods.

3.4.1 **Relibase**

Relibase is a database of binding sites, ligands and protein–ligand interactions [48]. Structural motifs can be defined and searched for, which is especially interesting in the search for particular protein–ligand interactions motifs. CavBase (see Section 3.3.2) has been integrated into Relibase. The database has been specially targeted to drug design, but it also constitutes a useful resource for general-purpose structural analysis of ligand-binding sites.

3.4.2 **MSDsite**

The Macromolecular Structure Database Group (MSD) at the European Bioinformatics Institute (EBI) provides the community with different types information services for macromolecular structures. One such database is MSDsite [44], an alternative database to Relibase, for the analysis of ligands and ligand-binding sites. Each ligand-binding site in the PDB is extracted and extensively characterized regarding chemistry of the ligand, interacting atoms and residues, and types of interactions. This information is provided for any given PDB structure and the results can be displayed within a molecular viewer. All PDB entries with a given ligand can be easily retrieved. More elaborate queries are also possible, where a given ligand-binding environment is specified and all matching PDB entries retrieved. The environment can be defined by the interacting residue or atom and by the type of interaction (bind length and bond type). In addition to MSDsite, the MSD group provides an extensive set of resources for protein structure analysis [45]. For example, MSDmotif provides extensive search capabilities for structural motifs given sequence patterns, secondary structure patterns or by ϕ, ψ angles and MSDChem allows to search for ligands in the PDB according to given chemical properties.

3.4.3 **CSA**

Enzyme catalytic sites are a particularly relevant type of functional sites. The CSA provides a set of manually curated enzyme catalytic sites, and a set of computed annotations inferred by sequence homology and alignment [99]. CSA includes Jess descriptors (see Section 3.2.5) for some of the homologous families.

3.4.4 **SURFACE**

The SURFACE database (Surface Residues and Functions Annotated Compared and Evaluated) [40] lists the surface clefts on each structure from a nonredundant PDB subset. The clefts are determined with SURFNET [74] (see Section 2.3). Interactions between residues and any bound ligands are identified. The proteins are also annotated with GO terms [29] and with matches to PROSITE [38] sequence motifs. In addition, the authors performed an all-against-all structure comparison of the cleft residues from the different representative structures. Matches are identified according to the residue similarity given by a substitution matrix, as well as according to the Z-score of the RMSD of structural superposition of the clefts. The C^{α} atoms and the average coordinate of the side-chain atoms was used in the superposition. Each PDB structure is associated with the closest representative in the nonredundant set. Users can query the database giving a PDB code, and the information on surface clefts, cleft compassion results, ligand interactions, GO and PROSITE annotation is provided for the representative structure.

3.4.5 Databases of Structural Motifs

Ligand-binding sites can be extracted automatically from the PDB if the ligand is present in the protein structure, as in Relibase or MSDsite, and active sites have been manually compiled in CSA. However, these databases will not include the sites which do not include the ligand in the structural model or which are not yet annotated. Additional databases and approaches are needed to cover these functional sites. A possible strategy is to automatically extract conserved structural motifs from the PDB [24, 47, 53, 87, 128]. The resulting structural motif database is then used to search for similarities to a given query protein structure. It is expected that some (but not all) resulting matches will correspond to functional sites that are not yet included in Relibase, MSDsite or CSA, therefore extending the coverage of functional sites. The disadvantage is that many matches will correspond to purely conserved substructures, without a direct relationship to function. Another possible strategy is the reverse template search [71] described in Section 3.2.5. In this case, structural motifs are extracted directly from the query, therefore avoiding having to define a database of functional/structural sites.

3.4.6 Protein–protein Binding Sites

Apart from ligand-binding sites and the active sites of enzymes, protein–protein binding sites constitute the other major type of functional sites. SCOPPI [135] is a database for protein–protein binding sites and interfaces. In this context, interfaces correspond to the interacting surface regions found on each protein in the complex. Proteins are modular entities composed of domain units. Therefore, the interfaces are characterized at the domain level. Structures are obtained from PDB [16]. The structure of the biologically relevant protein complex is derived from PQS [50] (Section 2.6.2) and domain definitions are obtained from SCOP [4]. SCOPPI classifies the different binding sites within SCOP families into different types (face types). PIBASE and 3did are related protein–protein interaction databases [33, 119].

4 Integration Efforts

As described above, different tools and databases are currently available for locating and characterizing functional sites. Thus, it is natural to ask at this point for the best strategy/protocol to apply given the structure of an uncharacterized protein. Recently, two groups have addressed this question and proposed pipelines for protein function prediction: ProKnow [91] and ProFunc [72].

ProKnow [91] is a pipeline for the annotation of query protein structures with GO [9] functional terms. At the center of the method is the ProKnow knowledgebase which associates protein features with GO terms. Different types of features are extracted from a given query structure: homologous sequences, homologous structures, sequence motifs, interacting proteins and structural motifs (using RIGOR [63], see Section 3.2.2). Then weights for different functional terms are computed using the knowledgebase, by mapping the identified features in the query to functional likelihoods.

The ProFunc pipeline [72] performs three types of analysis for a given query structure: sequence scans, structural features and template searches. In the first type of analysis different sequence-based methods are applied to characterize the query protein. Homologous proteins in UniProt [5] and the PDB are collected based on sequence similarity using BLAST [2]. The resulting alignments are combined to generate a multiple sequence alignment which is used to compute residue conservation scores [124]. The target sequence is also scanned for the occurrence of sequence motifs with InterProScan [138] and for matches in SCOP [4] structural superfamilies with SUPERFAMILY [80]. Gene neighborhood analysis is also performed in order to identify genes functionally related to the target (see Chapter 32). Different structural features are analyzed in parallel. Secondary structure matching (SSM) [67] is used to identify similar folds in the PDB. Surface pockets are located using SURFNET [74] (see Section 2.3). The results from SURFNET together with the residue conservation scores are mapped onto the protein structure for visualization and identification of putative functional sites. A nest search is also performed on the query structure. Nests correspond to a certain type of structural motif associated with anion-binding sites and found often at functional sites [129]. In order to characterize the possible functional sites, Jess [11] is applied to detect matches to different types of templates [71], as described previously in Section 3.2.5. The sets of templates correspond to the manually derived catalytic site descriptors from CSA [99], and to the automatically generated sets of templates for ligand- and nucleic acid-binding sites. A reverse template search is also performed, where the templates are automatically extracted from the target structure and compare to a representative set of PDB structures. Most of the ProFunc computations run in parallel, so that results from the different methods are made available as soon as they are finished.

5 Resources for Structural Characterization

5.1 Available Tools and Databases

Table 1 lists some of the available methods for predicting protein function based on structural information. The methods are freely available, either as software for download or as web services.

Table 1 Tools and databases for structure-based function prediction

5.2 Characterizing a Protein

In order to demonstrate how these different methods can be used for functional characterization, we applied them to the structure of protein MJ0882. Protein MJ0882 from *Methanococcus jannaschii* has been functionally characterized based on the analysis of the structural model (PDB code 1dus) [52]. Backbone structure comparison revealed that 1dus is structurally similar to several *S*-adenosylmethionine (AdoMet)-dependent methyltransferases, although there was no significant sequence similarity. Manual comparison of the cofactor AdoMet-binding site in methyltransferases and the equivalent region in 1dus revealed considerable similarities. In particular, 1dus displayed the conserved four motifs (motifs I–IV), characteristic of the AdoMet-binding sites. The binding of MJ0882 to AdoMet was then experimentally confirmed, indicating that MJ0882 is an AdoMet-dependent methyltransferase.

First, we applied several methods for functional localization to the 1dus structure. In particular, CASTp identified the AdoMet-binding site as the largest surface cleft. Consurf and SARIG also identified the the cofactor-binding pocket residues. All these web resources for functional site localization provided results within seconds.

Then 1dus was compared to a database of ligand-binding sites with PINTS and the results were also obtained within seconds. The three top ranking hits (lowest *E*-value) are all AdoMet-dependent methyltransferases with significant *E*-values < 0.01 (see Figure 4 for the result with lowest *E*-value). The matching residues correspond to the conserved motifs in the AdoMet-binding site. The fourth-best hit is not a methyltransferase, but its *E*-value (0.02) does not indicate high significance. SuMo rovided results within a few minutes, but does not provide a measure of statistical significance for the hits; therefore, results were not as easy to interpret as with PINTS. When the results are ranked by the number of residues or by volume of the match, among the top three ranking hits there is a match to an AdoMet-dependent methyltransferase. In this solution the AdoMet-binding motifs II and III are aligned. The other hits seem to be false positives. The SiteEngine web service allows the comparison of a structure to a ligand-binding site. 1dus was compared to the AdoMet-binding site of the TaqI DAN methyltransferase, PDB code 2adm chain A [105]. SiteEngine correctly aligned the four motifs in the cofactor-binding site. The entry in the CSA database for 1dus listed residues in motifs I, II and IV, based on homology to the functionals site of another AdoMet-dependent methyltransferase. Within a few hours ProFunc provided a large array of results for the functional characterization of 1dus. Matches to methyltransferases were reported in InterPro [83] and Superfamily [80] using sequence-based methods and by SSM (backbone structure comparison). The nest search method identified the AdoMet-binding motif I, and the AdoMet-

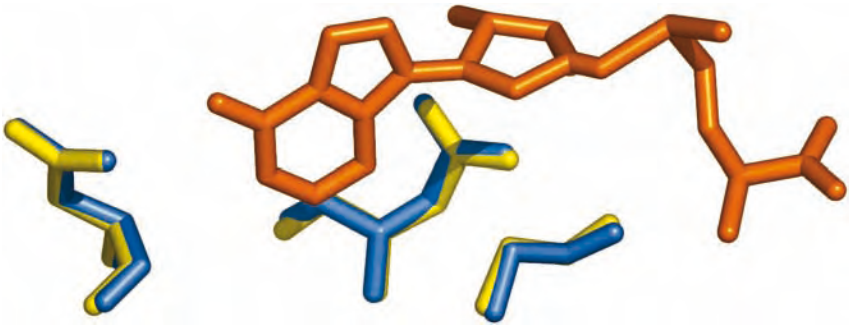

Figure 4 Comparsion of protein MJ0882 (PDB 1dus) with a database of ligand-binding sites with PINTS gives isoflavone *O*-methyltransferase (PDB code 1fpx) as the best result (E-value 3.1×10^{-5}). The side-chains of the three matching residues in 1dus (blue) and 1fpx (yellow) are shown superimposed. The three residues correspond to the conserved AdoMet-binding motifs I, II and III. The cofactor AdoMet from 1fpx is represented in orange.

binding pocket was identified by the residue conservation analysis and by SURFNET.

To summarize, the methods for functional site localization correctly identified the cofactor-binding site. In addition, both PINTS and (less clearly) SuMo results indicate that the protein has a functional site typical of AdoMet-dependent methyltransferases. This was further confirmed by the comparison of 1dus to the TaqI methyltransferase with SiteEngine and by the combined results from ProFunc.

6 Current Applications

There are now documented examples for the application of structure-based function prediction methods in generating valuable hypotheses for function assignment. Some of these results have been used to guide further experiments, which eventually confirmed the original predictions.

The application of the ET method to the RGS signaling family constitutes an early documented success of function prediction. The predicted functional site location was later confirmed by targeted mutagenesis and by structure determination of the protein in a complex [112].

Another example is the functional characterization of the *E. coli* BioH protein [103]. The crystal structure of the uncharacterized protein was determined by X-ray crystallography. Backbone structural comparison results revealed similarities to proteins with different enzymatic functions. TESS was used to compare the structure to catalytic site descriptors compiled from

CSA, resulting in a significant hit to the lipase catalytic triad and indicating hydrolase activity. The protein was subjected to different enzymatic assays in order to test for different types of hydrolase activity. The results indicated that BioH is a carboxylesterase.

PINTS has been applied to structural genomics models, for which sequence-based methods failed to identify any homology to known proteins [115]. The authors compared 157 uncharacterized structures to a database of descriptors corresponding to ligand-binding sites and PDB SITE records. For 17 cases with significant overall fold similarity to a characterized protein, PINTS confirmed the backbone structure comparison result with significant structural matches to functional sites. For 12 query structures corresponding to new folds, new functional hypothesis were suggested. The process is fully automated and can be reproduced as more uncharacterized structures become available.

7 Future Perspectives

In this chapter, we have reviewed a rather young and exciting field in bioinformatics, as can be demonstrated by the fact that more than two-thirds of the references have been published within the last 5 years. The methods available are rather diverse and the approaches quite exploratory. One can expect that as function prediction tools based on structure are more routinely applied and more thoroughly tested, a set of mature procedures will start to emerge. The newly proposed pipelines ProFunc and ProKnow constitute a promising start.

We can also expect that standard test sets and evaluation procedures will be introduced, analogously to the developments in the structure prediction field (see Chapters 10–12). Particularly important in this respect is the further development of databases of functional sites. They are essential for method development, training, testing and application. As we have seen, several functional site databases are already available but, in general, they include a subset of functional site types: catalytic residues (CSA), ligand binding sites (Relibase) or protein–protein interfaces (PIBASE, 3did). There is still a real need for a comprehensive and accurate database of functional sites. In principle, such a database could be implemented manually, but it would be desirable to rely on automated approaches as much as possible in order to reduce the time of data processing, increase coverage and guarantee consistency. In this respect some promising strategies have been proposed to extract conserved structural motifs [24, 47, 53, 87, 128]. The difficulty is then is to distinguish between functional sites and nonfunctional/structural motifs.

A particularly important development is the integration of established sequence-based approaches (Chapter 30) with structure-based methods. These methods go one step further than the identification of homology and directly associate functional terms to the query protein [92, 98].

One can also expect that developments in the fields of structural genomics and structure prediction will boost the range of targets for function prediction. In this respect it is particularly relevant to ask how useful are predicted structural models for functional annotation. The perspective some years ago was not very optimistic [130], but the situation is changing [6]. It is noticeable that predicted models are now being used together with other types of information for the functional annotation of different genomes (see Chapter 12).

It is also reasonable to expect significant contributions to drug design and, conversely, that methods developed for drug discovery to be applied in functional characterization. As an example for the interplay between the two fields, we start to see that application of virtual screening methods (Chapter 18) to the identification of potential natural ligands in functional characterization [56]. Better methods for characterization of protein functional sites will have an impact in the development of new drugs, and in the better understanding and prediction of side-effects.

Acknowledgments

We thank Gerard Kleywegt, Ingolf Sommer, Oliver Sander and Andreas Kämper for their helpfull comments and suggestions. F. S. D. is supported by the BioSapiens project. The BioSapiens project is funded by the European Commission within its FP6 Programme, under the thematic area "Life sciences, genomics and biotechnology for health" (LSHG-CT-2003-503265).

34 Mining Information on Protein Function from Text

Martin Krallinger and Alfonso Valencia

1 Introduction

In general, research discoveries made by means of experiments are commonly published in the form of free text in peer-reviewed articles. These articles, stored in scientific literature repositories, are a fundamental data resource for research in molecular biology and biomedicine, and most current research projects start with an extensive trawl through the literature. The scientific literature is consulted by database curators to extract functional annotations, by biologists to obtain information relevant to planning, set-up and interpretation of experiments, and by pharmaceutical companies to aid in the selection of new drug targets. In addition, most current knowledge about the functional aspects of proteins was either directly (by manual annotation during study of the literature) or indirectly (using electronic annotation, i.e. based on sequence similarity to previously annotated proteins) derived from the biomedical literature. Therefore, most bioinformatics tools using functional annotations stored in databases depend on prior extraction of functional descriptions from the literature.

The rapid growth of entries and abstracts in biomedical literature databases such as PubMed (Figure 1), the rapid discovery and analysis of new genes and proteins, and the development and extension of biological ontologies (Chapter 29) have increased interest in ways of extracting functional descriptions automatically from text. Pointers from protein database entries to their corresponding literature, linking sequence information to textual descriptions, are needed. The increasing number of characterized genes together with the growth and accumulation of published biomedical articles makes it difficult for biological databases to cope with the current flow of data.

Additionally the process of populating and updating annotations with information manually extracted from the literature implies considerable delay between the publication and the entering of the annotations in biological databases. Moreover, the curation process is itself very time consuming and costly, requiring highly qualified domain experts.

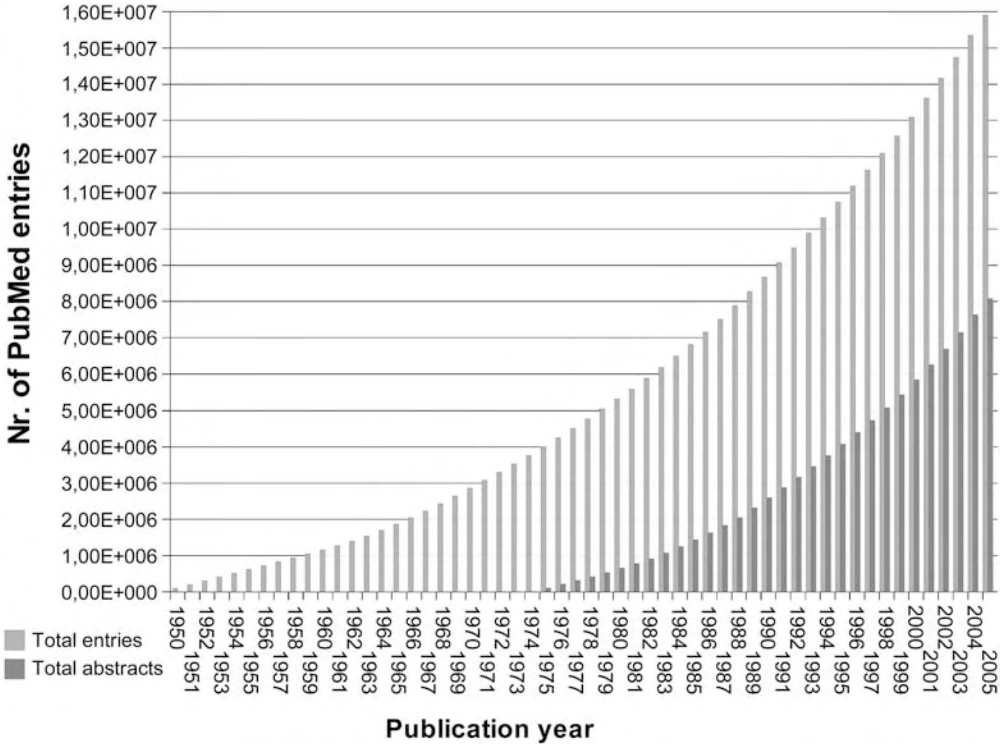

Figure 1 PubMed growth. Growth of the biomedical literature database PubMed in terms of number of total accumulated entries and abstracts for each year retrieved from PubMed using Entrez.

In model organisms such as the mouse genome, a more focused effort is being made to keep existing annotations as complete and up to date as possible (especially for disease-related genes and in some systems such as the immune system), while for other organisms resources are insufficient to keep annotations to the same level, even in cases in which articles providing functional characterizations have been published.

Functional descriptions deposited in the form of database entries therefore represent only a small fraction of existing functional information provided in scientific publications.

Due to the existence of large collections of electronically available articles, computational techniques such as text mining and information extraction (IE) offer the possibility to not only speed-up database curation, helping in the task of converting textual information into structured database entries, but also to provide biologists with better access to functional descriptions extracted from scientific publications. The use of IE techniques during the annotation process can be very useful for maintaining the links between facts stored in databases and the underlying information extracted from the literature, which in turn provide information on the experimental conditions supporting those descriptions, which is usually not incorporated in database annotations.

Text mining and Natural Language Processing (NLP) systems are used for target selection in the case of genomics projects, e.g. FungalWeb [14], and drug discovery [56], complementing traditional bioinformatics strategies to extract those enzymes which are potentially interesting for commercial purposes, for example. In the case of commercial applications in the pharmaceutical industry, text mining has additionally been used in the context of competitive intelligence to monitor competitor information, mine patents, newswire and scientific articles relative to information on drugs, diseases, gene products and chemical compounds, as well as their respective associations. A range of text mining and NLP systems have been recently developed, specifically adapted to the demands and characteristics of biomedical literature, for a review see [56].

This chapter covers basic aspects of data in the form of free text, the most relevant features of information retrieval (IR), text mining and NLP systems designed to provide functional information for proteins and genes. The automatic extraction of different types of text-based functional information is discussed, such as extraction of protein annotations, interactions and subcellular locations from the literature. The most significant resources and methods are introduced briefly. Some of the evaluation metrics and performance assessments currently in use to estimate the performance of existing applications are also introduced.

2 Information Types of Protein Function Descriptions

Different types of biological information can be linked directly or indirectly to protein function. A range of diverse experimental data served to determine protein functions – a considerable number of them are related with the more traditional biochemical and molecular genetics techniques. More recently a full range of technologies in genomics and proteomics (e.g. gene mutation/knockout, coimmunoprecipitation of protein complexes, yeast two-hybrid experiments, gene expression studies with DNA arrays and Chip-on-Chip experiments) have become able to provide additional information on protein function of a substantially different nature. The interpretation and combination of all this information related with protein function can greatly benefit from the use of IE techniques. Information on basically all kinds of experimental results relevant to characterizing protein function is contained in the literature.

Most of the approaches are centered on the analysis of protein sequences and structures (Chapters 30 and 33), and, more recently, on the analysis of gene expression data obtained by microarray experiments (see Chapters 24–27).

Database curators extract annotations supported by experimental evidence from the literature. In the case of Gene Ontology (GO) annotation entries, annotators extract functional information from the literature, providing for each record also the type of experimental information supporting the functional annotation [15]. They thus convert information in the form of free text into entries in structured databases [21]. To populate those database entries it is crucial for annotators to retrieve and extract functional descriptions efficiently from the vast amount of free text. IR, text mining and IE are becoming crucial to save time and effort in manual human curation by providing better access to functional information in biology. For this reason, the GOA database recently included text mining as one of their evidence types for annotation (see also Chapter 29 for more information on biological ontologies).

Humans transmit information by means of natural language expressions to define, communicate and exchange descriptions of functional properties. The way these expressions are formulated often depends on their context, e.g. whether they are designed for annotation records or are embedded in scientific literature. Textual data types often used to describe protein function are basically free-text descriptions, functional keywords and concepts contained in ontologies.

3 Literature Databases in Biomedicine

In order to carry out computational processing of textual data, as is done by NLP, text mining and IR approaches, it is necessary to obtain free text available in a digitally encoded format which can be read by electronic means. One of the first efforts to construct a library of resources available in a machine-readable format was Project Gutenberg. It is still one of the most successful digital library projects, carried out by volunteers who digitize, archive and distribute full-text data, mostly public domain books. Digital libraries are closely associated with the Internet, often being accessed remotely via computer networks. It was, in fact, the introduction of the world wide web and the Internet, where users navigate hyperspace searching for information of interest, which pointed out the importance of efficient IR and web and text mining strategies. Efforts have been made to develop search engines which deal with textual data specifically for academic literature (e.g. books, reports and articles). In this context Google has made an important effort developing

Google Scholar, which allows searching the scholarly literature for relevant research articles, theses or books [13].

Digital libraries have also been constructed for life sciences, especially for the biological and biomedical domain. The most significant of them is the National Library of Medicine (NLM) from the US National Institutes of Health (NIH), consisting of bibliographic databases covering the fields of life sciences, biomedicine as well as other health care and preclinical sciences-related fields.

In life sciences, common knowledge, in contrast to the latest scientific discoveries, is stored in books. The National Center for Biotechnology Information (NCBI), a division of the NLM offers Bookshelf – a collection of biomedical books available online (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi ?db=Books). In addition to books related to medical and clinical subjects, this collection also includes standard biochemistry, molecular and cell biology, developmental biology and immunology books.

The main attention has been paid to processing articles which contain new scientific discoveries (at the time of publication). Citation entries of scientific articles are stored in the PubMed/Medline database developed at the NCBI. This digital library contains more than 15 million citations from over 4800 biomedical journals, most of them (over 12 000 000) articles in English (April 2005). Each entry is characterized by a unique identifier, the PMID. For more than half of them (over 7 000 000), abstracts are available (Figure 1) and often links to the full-text articles are displayed. In the case of old records (before 1975), only relatively few abstracts have been digitized and are provided by PubMed. The PubMed abstracts are currently the most important data source for text mining applications in Biomedicine [53]. According to our estimations over million entries with abstracts contain information relevant to describe important aspects of gene products, such as their function, expression or relationships to diseases. Among the other elements contained in PubMed records are author, journal and title information of the publication. For a (small) number of records gene symbols and molecular sequence databank numbers such as GenBank accession numbers are provided.

In order to characterize articles contained in PubMed, entries have been associated to terms contained in a controlled vocabulary thesaurus with a hierarchical structure – the Medical Subject Headings (MeSH) – allowing searches with those terms at various levels of specificity [71]. There are over 20 thousand descriptors in MeSH and it is used by the NLM to index the entries in PubMed. The use of MeSH terms for text mining purposes is a relevant subject of study in the medical informatics community, as they provide associations of articles to a set of biomedical terms which characterize them.

The PubMed database can be accessed online using a text-based search query system called Entrez and offers additional programming utilities, the

Entrez Programming Utilities (eUtils), to provide a stable interface to this query system. The NLM also leases the content of the PubMed/Medline database on a yearly basis, enabling download of the PubMed records in eXtensible Markup Language (XML) formatted form.

Although some attempts have been made to process full-text biomedical articles [22], the limitations imposed by accessibility and formatting have so far prevented extended processing. Nevertheless, new initiatives related to free and open access of scientific publications are increasing interest in the mining of full-text articles. To provide free access of life science full-text articles, the NIH launched the PubMed Central (PMC) archive in 2000. It contains a few hundred thousand full-text articles as well as book reviews. Efforts are being made by the NIH to digitize older articles, to include new electronic full-text articles and to develop a common format for archiving diverse content provided by different journals in the form of a Journal Archiving and Interchange XML document type definition (DTD). Future developments of PMC will allow searches using the entire body of full-text articles, promoting integration of literature data with other resources such as sequence databases.

4 NLP

NLP methods are being used to handle large collections of electronic articles contained in biomedical literature repositories. NLP is an interdisciplinary research field concerned with the analysis, processing, understanding, modeling and retrieval of natural language. The overall aim of NLP strategies is, despite the complexity of human language, to explore the grammatical, morphological, syntactical and semantic features of well-structured language, in order to process, understand and model natural language by means of computational tools [35].

The statistical analysis of large text collections regarding those features is generally the basic approach used by NLP techniques. Those features are inter-related and often combinations of different features are explored by NLP strategies.

4.1 Grammatical Features

In NLP, grammar refers to the exploration of rules governing a particular language, often referring to those rules which (by convention) are considered to determine the correct formulation of a specific language, such as English. Among the grammatical features studied in NLP is the part of speech (POS) of a word in a given sentence, the role it has in the context of this sentence, whether it is for instance a noun, verb, adjective, adverb or preposition. Programs which automatically label words with their corresponding part of speech in a sentence are called POS taggers. A sample output of a POS tagger corresponds to: *Caspase-3* <Proper noun, sing.> *was* <Verb, past tense> *partially* <Adverb> *activated* <Verb, past part.> *by* <Prep. or subord. Conjunction> *IFN-gamma* <Proper noun, sing.>. [PMID 12700631], where each word in the sentence has been assigned automatically to its corresponding POS label.

POS taggers are usually based on machine learning strategies previously trained using a set of manually POS-tagged sentences. POS information has been shown to be relevant for the identification of gene symbols, which often correspond to nouns or for the extraction of protein interactions from text, where proteins are often associated through a set of interaction-describing verbs.

In order to account for differences in the use of POS for a given word in the case of biomedical texts when compared to generic literature, the Medpost [88] tool has been developed. It is a freely available POS tagger program specifically adapted to biomedical texts. The Medpost authors claim that this system reaches an accuracy of 97% when applied to labeling the corresponding part of speech of words from PubMed abstracts (compared to 86.8% when using a POS tagger trained using generic texts), increasing accuracy over 10%.

4.2 Morphological Features

In the case of morphological features of natural language, word structures are analyzed and rules of how words relate to each other are derived. Those rules include, for instance, plural formation rules (e.g. *gene* and *genes* or *caspase* and *caspases* are singular–plural pairs or the same entity) or verb inflection rules (e.g. *phosphorylate*, *phosphorylates* and *phosphorylating* all refer to the same verb root). Stemmer algorithms are used in this context to normalize word forms to a common stem (word root), providing a way to link different words to the same entity. After applying a stemmer algorithm [78], in the case of the plural formation example, both word forms would map to the same stem, i.e. ‘caspas’.

A common problem associated with stemming algorithms is that they sometimes collapse two words which are semantically different into the same stem (e.g. for gallery and gall).

4.3 Syntactic Features

In order to understand the meaning of a sentence it is necessary to previously identify the relationships between its words, i.e. its syntactic structure. Programs known as shallow parsers analyze such relations at a coarse level, focusing on the identification of phrases (groups of words which function as a syntactic unit) [1]. A sample output using the commercial Connexor shallow parser of the previous example sentence would be:

Caspase-3 <nominal head, noun, single-word noun phrase> *was* <auxiliary verb, indicative past> *partially* <adverbial head, adverb> *activated* <main verb, participle perfect> *by* <preposed marker, preposition> *IFN-* <premodifier, noun, noun phrase begins> *gamma* <nominal head, noun, noun phrase ends>.

Each word is hence labeled according to its corresponding phrase. In particular, phrases where the head is a noun [noun phrases (NP)], "Caspase-3" and "IFN-gamma" in the case of the example, and where the head is a verb [verbal phrases (VP)] are often relevant for NLP applications.

Other useful features include the identification of subject–object relationships from sentences [52]. A sample sentence of this approach, of sentence type NP-VP-NP was: 'Smith and Mitchell (1989) found that [overexpression of <Gene>IMEl</gene>] induced [an <GO>early meiotic event (recombination)</GO> in rich medium], but later meiotic events did not occur (i.e., they detected [no spore formation])'. In this case the subject is represented by the 'IMEl' gene and the object by the Gene Ontology term 'early meiotic event'.

Needless to say, any incorrect identification by the taggers tends to produce a chain of errors during the posterior identification of the syntactic relations.

4.4 Semantic Features

An important issue for NLP strategies is the discovery of associations of words with their corresponding meaning in a given context. To know the semantics (meanings) of a word is a prerequisite to understanding the overall meaning of a sentence. Dictionaries and thesauri provide such associations of words with their corresponding meanings. In the case of the biomedical domain, GO [32] (see Chapter 29) provides a set of concepts which are useful to describe relevant biological aspects of gene products. Also, the collections of gene names and symbols contained in SwissProt and other databases are useful to discover whether in a given sentence a symbol might correspond to a gene or protein. In the case of the following sentence:

Caspase-3 <GENE PRODUCT> was partially *activated* <INTERACTION VERB> by *IFN-gamma* <GENE PRODUCT>.

the associations of words to their corresponding meanings are labeled. Caspase-3 and IFN-gamma are identified as being gene products, and the verb activated in this context refers to a verb which is used to express a certain type of interaction between those two gene products. Gene dictionaries together with the context of occurrence are often indicative of whether a given word or symbol corresponds actually to a gene.

4.5 Contextual Features

When words cooccur significantly often together within a certain textual context (e.g. within the same document, abstract or sentence), they usually display some kind of association. For instance, the cooccurrence of Caspase-3 and IFN-gamma within the same sentence indicates that there is some relationship between them.

To determine whether two documents are similar or whether two proteins are mentioned in texts which are overall similar, the list of words (bag of words) which build up those documents and their associated frequencies (how often they occur within those documents and within the whole set of documents) can be used. The statistical analysis of word frequencies or patterns of word frequencies using large text collections is the base of learning statistical properties of natural language, and characterizing lexical and structural preferences.

As discussed previously, these features are clearly inter-related and the NLP analysis tends to explore the potential of these relations. For example, words which were POS tagged as verbs and which often occur between (connect) gene symbols with functional terms in sentences can indicate a protein description. Similar approaches are commonly used to build patterns of language expression that combine features at different levels. A sample of such language expressions indicating a protein functional description is "protein is involved in".

5 Main NLP Tasks

NLP strategies have been applied to many different tasks, ranging from machine translation (automatic translation of texts from one language into another) to the detection of typing errors in documents. Among the main tasks addressed in NLP as applied to biomedical literature are IR, IE, question answering (QA) and natural language generation (NLG), which will be presented in this section. General techniques and basic terminology used in NLP are described in Table 1.

5.1 IR

To obtain documents related to a certain biological information, such as the interaction between the caspase-3 protein and IFN-gamma, usually in a first step literature databases are consulted to retrieve all the documents which describe this interaction. Thus, all documents which are relevant to this information demand should be retrieved. This is actually the overall aim of

Table 1 General NLP terms and techniques

Corpus: collection of textual data or documents

Indexing: providing terms in textual documents with indices to allow formulation of queries using those terms

Information extraction (IE): analysis of texts to identify entities, relationships and facts in text

Information Retrieval (IR): return relevant documents from a collection of documents according to a predefined information need

Part of speech (POS) tagging: providing each word given a sentence with its corresponding POS label, e.g. whether it is a noun, verb, preposition, article, etc

Question answering (QA): application of computational techniques to generate automatically answers from text collections in response to user queries

Shallow parsing: process of identifying phrasal chunks in sentences like noun phrases, but without providing a deeper grammatical structure

Stemming: process of removing affixes of words transforming them to their corresponding morphological base form or root

Syntax parsing: process of returning the grammatical structure for a given sentence, often in the form of a syntax tree

Tokenization: process of dividing a given text into predefined units, such as words or sentences

Vector space model (VSM): model to calculate the similarity between documents and queries based on the weighted word vectors for terms comprised in the documents

Word sense disambiguation (WSD): process of determining the sense for a word given its context, e.g ATM can refer to the ataxia telangiectasia disorder or the ATM gene, depending on the context used

text IR systems – to retrieve from large documents collections as many relevant documents as possible while retrieving as few as possible nonrelevant ones. To provide relevant documents, those that satisfy a given information demand must be previously identified. In practice, the information demand is formalized or defined in the form of a query. Queries in IR are basically formulations of user demands in the form of words or regular expressions which contain semantic information related to the information need [6]. For instance in our example, a sample query would contain the words "caspase-3" and "IFN-gamma", but it is easy to imagine that users would ideally like to formulate more sophisticated queries such as: "all the documents about capase-3 and IFN-gamma that describes an experimental interaction done *in vivo*".

To know which documents contain the words matching a given query it is necessary to know previously which words build up each document. One of the first steps towards building up an efficient IR system is indexing a collection of documents, locating terms in text [101] and extracting documents in which each term appears. Several strategies exist for locating these terms. The steps common to most of them are:

- Word tokenization (splitting the text into words, e.g. using white spaces for splitting).

- Stop word removal (removing high-frequency words with low information content, e.g. *the*, *a* or *it*).
- Case folding (transforming all upper-case letters to lower-case letters).
- Stemming (transforming words into their basic form by removing affixes).
- Term weighting (assigning a weight to each term according to its relative importance, often based on term frequencies).

These steps help to reduce the vocabulary of terms and the number of query formulations: e.g. the queries *Glycogenin* AND *binding*, as well as *bind* AND *glycogenin*, would retrieve the same documents. The most common strategy used when building the index is based on *inverted file indexing*, in which an index structure that comprises for each term a list of references to documents which contain this term is created [101].

The most widespread information retrieval models are the Boolean model and the vector space model (VSM) – a detailed discussion of different IR models including some probabilistic IR models can be found in Ref. [6]. In the case of the Boolean model, the query is based on the combination of terms using Boolean operators (e.g. AND, OR and NOT). A sample Boolean query would be "caspase-3 AND IFN-gamma", which should retrieve all the documents containing both query words. These query terms are matched against the terms comprised in the inverted file index and a list of documents that satisfy the query expression is returned. The IR system used in PubMed allows such query types [85]. Nevertheless, this type of query usually returns large collections of documents, a considerable number of which are not relevant to the information requested. In addition, relevant documents that do not satisfy exactly the query expression will be absent.

To retrieve documents that are similar to a given list of query terms or that are similar to a given query document, methods based on the VSM are commonly used. In the VSM approach, each document is represented by a vector of terms derived from the document. Each term is weighted according to its relative importance (frequency) within the document and/or within the whole document collection [60]. In addition, the query is represented as a vector of weighted terms. Several different weighting schemes for terms have been developed, but the most widespread are the *tf* × *idf* strategies, which include information on term and document frequencies. The term frequency, $tf_{i,j}$, is the frequency of occurrence of the term j in the document i, whereas the document frequency df_j is the frequency of occurrence of that term in the whole collection of documents. The resulting weight $w_{i,j}$ of term j in document i, given N documents, is obtained by:

$$w_{i,j} = tf_{i,j} \times idf_j \,, \tag{1}$$

where idf_j is the inverse document frequency:

$$idf_j = \log\left(\frac{N}{df_j}\right). \tag{2}$$

As in the case of term weighting, different ways of calculating similarity measures for the term document vectors have been proposed [60]. The cosine measurement is often used to calculate the similarity between the term vector obtained for the query Q and the term vector obtained for each document D in the document collection. Most of them include a normalization factor to avoid the influence of document length. In the cosine measurement, the similarity $\mathrm{sim}(Q, D)$ between the query and a given document is:

$$\mathrm{sim}(Q, D) = \frac{\sum_{j=1}^{V} w_{Q,j} \times w_{i,j}}{\sqrt{\sum_{j=1}^{V} w_{Q,j} \times \sum_{j=1}^{V} w_{i,j}^2}}. \tag{3}$$

The query and the document vectors are represented in a V-dimensional Euclidean space, with V being the number of all terms.

The retrieval strategy behind the *related article search* in PubMed is based on the idea behind the VSM [100], i.e. to provide for a given query document a list of documents ranked according to their similarity to the query document. It allows PubMed document-based queries, returning those records which share relevant terms (words) with the query document on the basis of the frequency of those terms in the whole document (PubMed) collection. The eTBLAST search engine [97] carries out similarity searches using user-provided input text, e.g. paragraphs, whole articles or even proposals, and retrieves similar ones from PubMed.

In practice, not only the calculation of similarities between a single document and each of the documents in the document repository might be of interest. It is also possible, given a set of documents which mention proteins belonging to the same protein family [3] or genes sharing the same cluster derived from a microarray experiment [75], for instance, to automatically extract relevant keywords for this set of documents when compared to the background frequencies of these terms (in the whole document collection).

The performance of IR systems is usually evaluated by means of two relevant feedback parameters, precision and recall. Precision amounts to the number of relevant documents retrieved divided by the total number of documents returned, while recall is the proportion of relevant documents returned by the system divided by the total number of relevant documents. IR performance is often expressed in terms of precision–recall curves. In addition, the f-score, the harmonic mean of precision and recall, is sometimes used to score IR performance [6].

5.2 IE

Although retrieval of relevant articles is one of the first steps to obtain relevant information, these methods do not provide fine-grained identification of specific entities such as genes and proteins, and their respective functional descriptions. For instance, when searching for articles mentioning functional aspects of a specific gene such as *the Drosophila* gene *peanut* [74] using IR systems, many nonrelevant articles are usually retrieved which are related to other topics such as peanut allergy. This is due to the fact that IR techniques do not disambiguate the meaning of words – they are centered merely on the presence or absence (i.e. frequencies) of words and terms. Moreover, most of the genes have a range of synonyms or can be mentioned using the full name or one of their corresponding gene symbols [19]. Therefore, to retrieve all the articles describing functional aspects of genes would imply first searching using all the different combinations of gene names, symbols and typographical variants of these gene symbols, and then selecting those documents which actually are related to the gene of interest. IE methods are useful to avoid this time-consuming process and automatically mine sentences or text segments containing specific entities of interest (e.g. proteins, genes, drugs). For instance, an efficient IE system would identify that the first of the following sentences mentions the peanut gene, while in the second sentence the peanut plant (*Arachis hypogaea*) is mentioned:

(i) *The* Drosophila peanut *gene is required for cytokinesis and encodes a protein similar to yeast putative bud neck filament proteins* [PMID 8181057].
(ii) *In this study, we identified a novel PLD gene in peanut (*Arachis hypogaea*), encoding a putative phospholipase D (PLD, EC 3.1.4.4)* [PMID 16200410].

IE refers to the automatic identification of entities [named entity recognition (NER)] of relationships between those entities, as well as facts and events from unstructured text. IE methods applied to generic or newswire texts have been used to identify company names, persons, locations or events such as terrorist attacks from text. In fact, the identification of entities (NER) in text has been addressed by IE systems for years [39]. In the pharmaceutical industry, IE systems are being used not only to identify textual passages referring to gene names and drugs, but also extract information relative to competitor companies and their current research interests from scientific articles, newswire texts and patents.

In the case of academic IE applications developed for the life science literature, they are mainly related to the identification of biological entities such as genes, proteins, cell lines and chemical compounds, as well as the extraction of protein interactions and protein functional annotations [9].

IE strategies exploit all kinds of features of natural language, including syntactical, lexical and contextual features to identify and characterize relevant biological information. Among the most frequently used NLP techniques in IE are POS tagging, shallow parsing and stemming (Table 1).

Often, certain additional features (e.g. use of capital letters and hyphens) are explored by IE systems designed to identify entities such as gene names [39]. Some IE strategies use rule-based approaches to detect certain word patterns which are often encountered within gene names [34], or language expressions indicating protein interactions [76], phosphorylation [46] or protein functions [25].

Although some strategies generate rules automatically [92], most of them rely on rules generated manually by domain experts [10,52].

Domain-specific knowledge is used by IE systems to account for linguistic properties that are characteristic of the scientific literature. Many IE procedures take advantage of knowledge representations such as ontologies (e.g. GO) for the extraction of functional descriptions or annotations of proteins from texts [80,91].

In the case of the identification of gene names, IE methods can rely on the availability of gene lists provided by biological databases [34] or use machine learning techniques (trained on manually gene-tagged texts) such as support vector machines (SVMs) [67] (see also Chapter 26) or hidden Markov models (HMMs) [50] (see also Chapter 3), identifying also gene names which are not yet included in existing biological databases.

A more detailed discussion of different applications of IE systems is provided in Section 6.

5.3 QA

To obtain information, humans formulate questions using natural language expressions such as: "(i) *What are the molecular functions of Glycogenin ?*" or "(2) *Which organisms express glycogenin?*". The field of QA addresses the automatic generation of answers to specific user queries formulated as natural language expressions to large document collections [31]. Most of the existing QA techniques are limited to general literature or newswire texts and have not yet been tailored to the biology-specific literature. In the best of the cases they are only effective for questions that can be answered with few words derived directly from text passages. The development of QA systems in biomedicine and molecular biology is especially cumbersome because these are poorly formalized, very heterogeneous domains and new scientific terms are constantly created. *Question parsing* is one of the steps used by QA systems, consisting of the analysis of the query sentence with respect to its semantic structure (semantic representation). In the first example question, two elements are significant, i.e. the entity glycogenin (protein) and its molecular function. The next step would involve question analysis of the input question to obtain the relevant content words to perform IR, e.g. the words *glycogenin* and *functions*. In this step, the words or tokens to be used for IR searches are determined. Then, the actual document retrieval using those words is carried out, yielding a (ranked) list of relevant documents. In this case, the actual query could consist of *glycogenin* AND *function*. The retrieved documents are then split into segments or passages to avoid processing of long documents and to operate by using only the relevant segments (document segmentation step). To extract those segments which might contain the desired answer (which contain the query entities), the segments are ranked and each segment is further processed at the sentence level to identify relevant entities. Then, the question and the potential answer segments are compared (word overlap) and ranked according to their word usage similarity to the input question. Words can also be weighted taking into account their background frequency within the whole document collection. Finally, the potential answers are ranked, visualized and presented to the user. In the case of the used example, the following PubMed abstract sentence could be presented: *Glycogenin is a glycosyltransferase that functions as the autocatalytic initiator for the synthesis of glycogen in eukaryotic organisms* [PMID 15849187].

One of the few QA systems in the biomedical domain was developed by Galitsky [30]. This system is based on the use of semantic skeletons (SSK), which consist of matching the semantic representations of a given question to that of the set of potential answers. It thus tries to match the formal representation of a question with the formal representation of an answer. By introducing logical programming strategies it was also able to handle semantic rules.

Many of the existing QA systems for the genomics domain were developed in the context of the Text REtrieval Conference (TREC) Genomics track – a contest to evaluate information retrieval and QA techniques applied to the biology literature. The Genomics track is one of the areas addressed at TREC – a periodically organized workshop where previously posed tasks of IR and QA for different areas (including spam filtering and IR at a terabyte level) are evaluated. At the *ad hoc retrieval task* of the TREC Genomics Track 2005 [37], a collection of sample topics containing a topic title, information need and topic context (formulated as natural language expressions) was given to the participating systems, which had to return the PubMed documents relevant to this information need. For instance, one of the topic titles was: "Find information about base sequences or restriction maps in plasmids that are used as gene vectors".

5.4 NLG

The output of QA systems consists of those sentences in text collections that hold relevant information to the question formulated. There is increasing interest in the construction of natural language texts as output of QA systems, to facilitate to the end user with the interpretation of the information provided. Displaying database contents or the results of gene annotation efforts as automatically generated reports or summaries is also attracting some attention.

NLG is concerned with the development of natural language texts by computer programs based on a semantic input, i.e. providing a computer-internal representation of the information [24]. NLG systems show different degrees of complexity, ranging from *canned text systems*, which return unaltered sentences without any change, to complex *feature-based systems*. NLG has also importance for automatic generation of summaries. Kang and Park developed a system for automatically constructing gene summaries from articles by selecting and ordering those sentences which contain gene related facts [48a]. Therefore they also took into account aspects related to the arrangement of sentences to provide a coherent discourse of the summary. Currently, NLG tools are only efficient in the case of very specific applications. In the case of biology-related texts, the additional difficulty of modeling domain language has to be considered.

Only a limited number of NLG systems have been applied in the biological domain. The Simpathica/XSSYS trace analysis tool combines a natural language query system and a story generation system in a bioinformatics tool devoted to the analysis of biological data such as those resulting from microarray time course experiments [4]. It uses prepositional temporal logic and generates sentences of biologically relevant facts using a set of heuristics.

6 Difficulties when Processing Biological Texts

Computer programming languages are aimed at providing a standardized way of unambiguously expressing instructions to a computer using well-defined syntactic and semantic rules. In contrast, human language is characterized by complex grammatical constructions, and both semantic and syntactic ambiguity. In the case of semantic ambiguity, a given word can have different meanings (polysemy) depending on the context it is used in or even on the background knowledge of the person who is interpreting it. An example would be the previously mentioned case of the word “peanut”, which depending on the context could refer to a *Drosophila* gene, a plant or a plant seed. To automatically identify the correct meaning of words (word sense disambiguation) is especially cumbersome in cases where these words are used in a similar contexts (e.g. protein symbol and the associated disease name). There is also a significant semantic variability in natural language, meaning that two different words (synonyms) or even text fragments (textual entailment) can have the same meaning. The words *apopain* and *Yama* correspond to synonyms of the same human gene, i.e. *CASP-3*. For the identification of gene synonyms most methods rely on the synonym lists provided by biological databases, which are often incomplete. Also, novel names and terms are constantly created and used in the literature which are not included in any of the existing dictionaries.

Human language allows us to express the same meaning in a range of different ways. To infer (entail) that one text fragment has the same meaning as another text fragment is especially cumbersome [23]. This scenario is one of the main challenges for systems which try to associate proteins to functional terms such as GO terms, as a variety of different language expressions may display the same meaning of a single GO term. The following two sentences illustrate this difficulty:

(i) *Fim1 is involved in cell division*.
(ii) *Fim-1 function in cytokinesis*.

In this case both sentences have essentially the same meaning, but only in the second case is the standard GO term *cytokinesis* used.

Another difficulty is syntactic ambiguity, i.e. sentences can be interpreted in different ways depending on how the reader interprets the syntactic connections between words and arranges them into sentences. The sentence "*We analyzed the protein with a functional complementation*" could be interpreted as:

(i) *The protein was studied using the functional complementation technique*, or
(ii) *The protein which displays functional complementation was studied*

To avoid repetitions and to improve writing style, pronouns are commonly used to refer to previously mentioned nouns. For instance the word "*These*" refers to the proteins Bax and Bad in:

(i) Bcl-2 and Bcl-x_L expressions were down-regulated after paclitaxel treatment in FHIT-expressing cells, whereas Bax and Bad expressions were up-regulated.
(ii) These were reversed by siRNA treatment.

To identify those relationships between pronouns and nouns, known as anaphora resolution, can be arduous, especially in long and complex sentences, and when the noun and pronouns are located far from each other within the text. Authors of anaphora resolution systems developed for biomedical literature claim that they reached a precision of 77% and recall of 71% [16].

Another difficulty arises because most words in texts occur extremely infrequently (data sparseness) and have an uneven distribution. Only a small number of words, known as *function words*, like prepositions, appear with high frequency and are very common. Zipf's law describes this characteristic of frequency distribution of words in human language, where a few words appear very often, a middling number corresponds to medium frequency words and the majority are low-frequency words [63, 82]. It is difficult to make predictions of word behavior when relevant words are rare or often not picked up in the data set used to derive the statistical language models, but do appear in data used to test the model. Word frequency distributions are not only affected by the size of the dataset used, but also by the corresponding domain language.

Most of the currently available NLP technologies were developed using generic texts and word frequency distributions differ depending on the domain. Thus, the performance of generic tools is lower when used for biomedical literature.

The majority of life science articles published since the 1950s are in English, but more than half of the corresponding authors have a different native language. The writing style of authors has been shown to depend upon their native language, resulting in variations of word and phrase usage as well as writing style and average sentence lengths. In some cases, this lack of a standard scientific English can reduce the understanding and processing of scientific communications [73].

Mining of biology literature is especially challenging, as it is a rapidly evolving, poorly formalized domain with ambiguous and flexible naming of entities. Often, new gene names are created which are not contained in gene lists of any biological database. The domain is characterized by a great deal of domain-specific terminology (over 12% consists of domain-specific terms) [89], but existing dictionaries are incomplete and standard terminology is rarely used. Some systems tried to circumvent this drawback by developing automatic term recognition systems [72]. NLP tools, which process biomedical literature, have to be adapted taking into account knowledge and features which characterize texts of this domain.

Low-level processing, even tokenization, i.e. dividing texts into units such as words or sentences, is cumbersome in scientific texts due to the heavy use of punctuation marks and special characters. Anyhow, an increasing number of strategies are being developed to solve the important task of extracting functional information from life science texts. Performance of such systems is increasing not only due to adoption of more sophisticated approaches, but also due to the availability of new textual training data which allows the training and comparison of alternative methods. The following section provides an overview of the different applications which have been developed in this field.

7 Strategies of Extracting Functional Information from Text

A variety of strategies have been devised to associate proteins with functional information derived from scientific text elements which can be processed by computational tools.

There are two basic types of text mining approaches supplying functional information through literature analysis. The first comprises direct function extraction methods that identify functional annotations from text, i.e. associations of proteins with functional expressions (keywords, concepts, phrases) using IE, heuristics, statistical and machine learning techniques and rule-based strategies. The second type of approach comprises indirect function extraction methods that discover characteristics of proteins related to the biological context in the whole cell. These indirect methods include the text-based discovery of protein interaction partners and networks, the cellular localization of proteins [90] and the extraction of kinetic parameters [33]. Both methods, as well as the previous tagging of proteins in text, are discussed here.

7.1 NER and Protein Tagging

After retrieval of an initial set of documents that might hold relevant information for proteins, it is crucial to precisely identify those entities within the articles and to link them to entries in biological databases. The second step is called NER. While the first step of name identification is generic, i.e. basically the same in a wide variety of domains, the second step differs between domains. In biology it requires the precise identification of the individual gene (and not the generic name of a family) and the corresponding organism.

NER has been studied by the IE community for years. In the case of entities such as corporate names and locations, NER techniques achieve an f-score of over 0.9 [105]. The recognition of biological entities is far more complex and the results in protein tagging are clearly worse than in the identification of other entities like corporate names.

Difficulties in identifying correctly protein names in texts are of various types. Authors who refer to genes and proteins in articles often do not use the official gene symbols, but express those entities using synonyms or full gene names instead [19, 41]. The disambiguation of gene names that correspond to medical terms or common English words, such as many fly genes, e.g. *18-*

wheeler or *amnesiac*, and the existence of alternative typographical variants of gene names constitute additional hurdles. Even associating genes with the corresponding source organism is cumbersome, as 14% of genes are estimated to display inter-species ambiguity [19]. Finally, the ambiguity between distinct protein names and their protein family names lowers the performance of NER systems in the biology domain [56] [e.g. protein kinase C (PKC) family and individual members such as PKC-α, -βI or ζ]. Also new gene names appear in texts which are still not contained in any biological database – to identify those novel gene symbols is only possible using methods which are able to use inference from the context.

The performance of top-scoring NER systems that tag protein and gene names ranges from f-scores of 0.7 to 0.9 depending on the organism source of the gene names [38], the method used as well as if distinction between identification of proteins, DNA and RNA was made [50]. Nevertheless, this performance was reached using documents which had been previously filtered and were known to be associated to certain model organism genes. Therefore, when randomly selecting a document from the PubMed database and tagging gene and protein names, the overall performance of these systems would be lower.

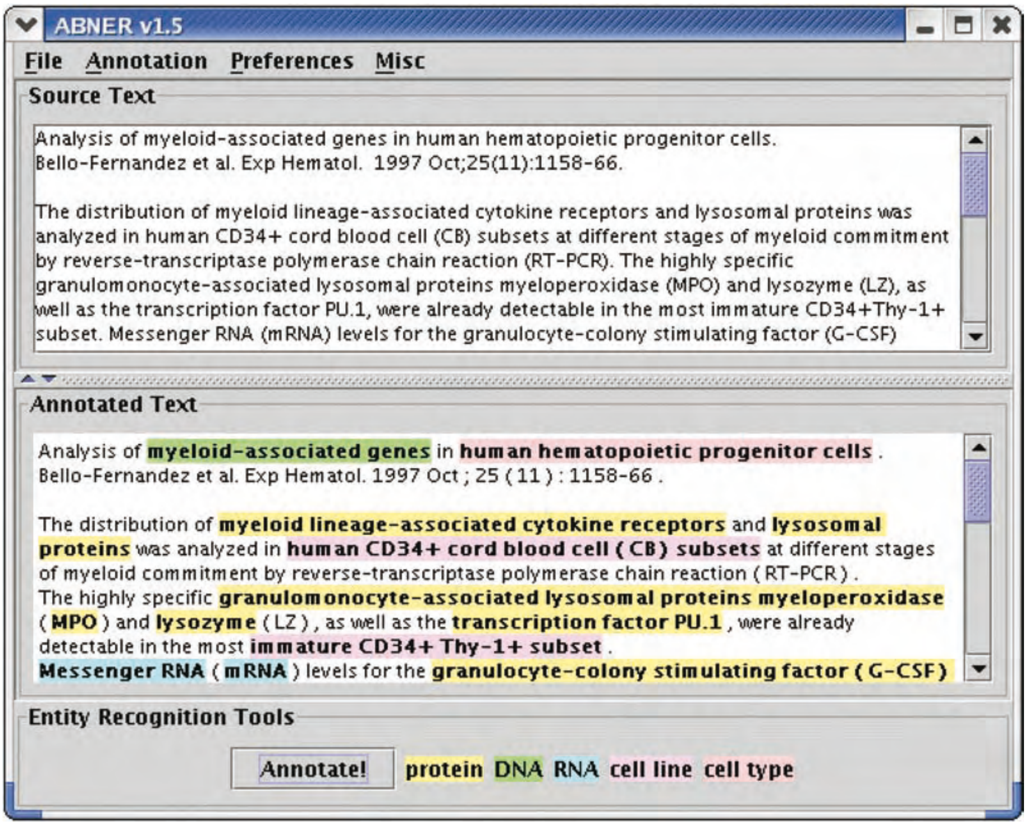
When addressing the NER of proteins, two basic perspectives can be distinguished. The bioinformatics perspective (gene dictionary based) focuses on the exploration of typographical variants of gene names and symbols extracted from biological databases and the use of approximate string matching [57]; whereas the computational linguistics perspective (NLP based) uses linguistic aspects such as POS information [29]. Most of the currently available tools are hybrid systems combining characteristics of both approaches. They integrate methods such as statistical analysis, machine learning techniques, rule-based strategies, morphological features, context and lexical exploration. A sample case of the first perspective is the ProMiner system [34] – a rule-based strategy which also integrates a disambiguation procedure to associate a detected gene to its database entry. To associate genes to database entries, the contextual words in which these gene names occur as well as information about the organism source of the gene symbol is generally used. The disambiguation between mouse genes and human genes is in practice especially difficult, as many homologous genes have the same symbols in both organisms; additionally, often within a given text passages both organisms are mentioned. In the case of machine learning strategies the PowerbioNE system is one of the most effective systems to detect biological entities [107]. It uses morphological, grammatical and syntactic features which are integrated into an hidden Markov model (HMM) entity recognizer. Although a number of NER systems have been constructed for the biology domain, only few of them are available and used in practice. Some of them are available as online taggers such as GAPSCORE [17], a SVM-based system which scores each word of an input text based on statistical models and permits a cutoff setting different degrees of stringency to be defined. Some NER systems can be integrated into local text mining systems. The ABNER open-source tool [86] uses machine learning techniques, i.e. conditional random fields (CRFs), to tag biological entities. It identifies protein DNA, RNA, cell lines and cell types (Figure 2). This system provides an easy-to-use graphical interface and incorporates routines to train new modules on other text collections. Another system which has been used to identify bio-entities is the AbGene system [92] – a program which uses POS information, manually generated rules, and suffix and context information to identify potential gene names. In addition, it applies naive Bayes learning to analyze the whole document context for the likelihood of whether it contains gene names. The drawback of these two systems is that they lack a linking procedure for connecting identified proteins to existing database entries. A useful tool which also carries out the database-linking step and can be run locally is called NLProt [67]. It combines SVMs with dictionary and rule-based filtering to identify protein names in biomedical articles, but lacks identification of other entities such as cell types. A sample output of the NLProt system would be:

```
<?xml version="1.0" encoding="ISO-8859-1"?>
<abstract id="">
<protname score="1.023" method="SVM" dbid="ICE3_HUMAN" idreliab="100%"
org="homo sapiens">Caspase-3</protname> was partially activated by <protname
score="1.105" method="SVM" dbid="ING_HUMAN" idreliab="100%" org="homo
sapiens">IFN-gamma</protname>.
</abstract>
```

NLProt also provides a reliability score for the identification and linking of the recognized proteins.

Other useful biological entities are chemical names. useful biological entities are chemical names. The identification of chemical concepts in text was studied by Wilbur and coworkers [99]. They tested various strategies and implemented a statistical method that could reach 97% classification accuracy.

Users often like to search for related articles by means of a query protein sequence rather than protein symbols. MedBlast is a literature-mining tool which allows both search strategies for retrieval of relevant articles, i.e. searching with a query sequence or using gene symbols [93]. It integrates a BLAST search of GenBank and then retrieves the relevant articles for genes with a significant sequence similarity directly from PubMed. It thus integrates both sequence searches with protein name identification.



Analysis of myeloid-associated genes in human hematopoietic progenitor cells.
Bello-Fernandez et al. Exp Hematol. 1997 Oct;25(11):1158-66.

The distribution of myeloid lineage-associated cytokine receptors and lysosomal proteins was analyzed in human CD34+ cord blood cell (CB) subsets at different stages of myeloid commitment by reverse-transcriptase polymerase chain reaction (RT-PCR). The highly specific granulomonocyte-associated lysosomal proteins myeloperoxidase (MPO) and lysozyme (LZ), as well as the transcription factor PU.1, were already detectable in the most immature CD34+Thy-1+ subset. Messenger RNA (mRNA) levels for the granulocyte-colony stimulating factor (G-CSF)

7.2 Associating Proteins with Biological Features from Databases and Ontologies

Database curators extract functional protein annotations manually through a time-consuming and labor-intensive process of scientific literature analysis. Due to the vast amount of literature currently available and the increasing number of genes studied, humans are only able to review a small fraction of the existing publications. Thus, the manual annotation process lags behind the information that accumulates in biomedical articles. Text mining and IE methods have been developed. to avoid this bottleneck and to assist in the identification of functional descriptions of proteins and in automatic annotation extraction.

Procedures extracting functional descriptions of proteins rest upon characteristics of IE and IR methods, and exploit all the different features of natural language, especially grammatical, syntactic and semantic features.

There are two basic types of text mining strategies designed for functional annotation extraction, although many tools combine aspects of both:

- Identification of annotation-relevant sentences: methods which automatically classify text passages or sentences according to whether they contain functional descriptions of proteins.

- Identification of protein-term associations: extraction of relations between proteins and predefined terms, such as concepts from biological ontologies (e.g. GO) or functional keywords from biological databases (e.g. Swiss-Prot keywords).

In the first approach, the context information provided by text passages or sentences in which the proteins are mentioned aids in the appraisal and interpretation of the descriptions. In addition, as descriptions are not limited by a predefined set of functional terms, they account for the variety of language expressions involved in functional descriptions. The main drawback of these strategies is their limitation when inferring function from electronic annotation (i.e. based on sequence similarity) as they do not provide associations between proteins and controlled vocabulary concepts (e.g. GO terms) as well as the implicit difficulty while dealing with certain uninformative words. This means that the extraction of annotation-relevant sentences requires human interpretation.

The system developed by Andrade and coworkers [3] extracts functional information from PubMed sentences by means of statistical analysis of the word frequencies of sentences related to each protein family compared to the background frequencies of those words for the whole set of protein families. It thus detects biologically significant words useful to describe functional aspects of protein families. An inherent difficulty of this approach is the existence of words which are statistically associated to a protein group, but are not useful for describing functional aspects.

Beyond the level of single words, the identification of consecutive word patterns, which are often used in functional descriptions of proteins in abstracts, has been studied [55]. In the presence of protein names, these patterns indicate that a functional description is provided, e.g. "*gene is essential for*". Such approaches are useful in combination with NER systems to classify whether sentences correspond to functional descriptions. The main limitation of such techniques is related to the construction and evaluation of extensive lists of word patterns, which is a time-consuming process and requires domain expert knowledge.

A more sophisticated approach was used by the BioIE system – a rule-based method for identification of informative sentences [25]. For a given query term (e.g. gene names) it returns a list of sentences which match a set of manually defined templates and rules for the extraction of informative sentences. The identified templates are highlighted within those sentences and information of the word distributions is also provided. This system (available as an online server), focuses on the extraction of sentences with information related to predefined categories, i.e. structure, function, diseases and therapeutic compounds, localization and familial relationships. BioIE has been integrated into a web-based annotation tool called METIS. METIS performs for a given query sequence a BLAST search against the Swiss-Prot database. Then, for the retrieved entries, a structured report is generated and informative sentences are extracted from PubMed using BioIE as well as a SVM-based sentence classifier.

The use of a curated set of concepts and functional terms with established value for protein annotation is one of the main advantages of the second strategy. These concepts can be used to transfer function by electronic annotation and, in the case of terms derived from ontologies, even allow inference of other functional terms taking into account the ontology structure. However, the use of a limited set of concepts is a restrictive approach, as the concepts only correspond to a fraction of the possible ways of expressing function in text due to the semantic variability of natural language. Moreover, concepts derived from ontologies or thesauri often do not resemble natural language expressions (which implies lower recall).

The implemented systems that extract protein–concept associations show different degrees of complexity, ranging from simple cooccurrence of gene- and concept-indexed sentences to complex pattern matching and machine learning techniques. In addition, the unit chosen as context for the associations may vary – some use single sentences, others use passages or whole abstracts.

The simplest approach is concerned with cooccurrence extraction, i.e. mining those text fragments in which gene products and functional terms cooccur [47]. The Gene Information System (GIS) selects sentences containing functional information by indexing abstracts with genes and functional terms contained in a domain-specific lexicon (lexicon analysis). The iHOP [40] applications offer the possibility of extracting sentences with genes and functional terms such as GO or UMLS terms (Figure 3).

Most of the term-association extraction tools derive their functional concept lexicon from GO [5] or UMLS [11], or use Swiss-Prot keywords. GO concepts are principally constructed for annotating gene products unambiguously and consistently, regardless of their use for NLP tasks. Therefore, only a fraction of these terms can be mapped directly to biomedical abstracts [65]. Krallinger and coworkers [54] analyzed the compositional structure of GO terms to construct a rule-based system which generates natural language variants for certain GO terms. They also considered the individual word tokens that build-up these terms to retrieve annotation-relevant text passages.

However, mAkt could act synergistically with Wnt-1 or Frat to **activate** LEF-1.

Beta-catenin: a common **target** for the regulation of cell adhesion by Wnt-1 and Src signaling pathways.

Wnt-1 **regulates** Fgf8 expression in the adjacent metencephalon, most likely via a secondary mesencephalic signal.

Cultured cells transfected with a membrane-tethered form of Wnt-1 **bind** epitope-tagged Frzb-1 in the 10(-10) M range.

In mammalian cells, Axin **inhibits** Wnt-1 stimulation of beta-catenin/lymphoid enhancer factor 1-dependent transcription.

Furthermore, beta-catenin is the **target** of two signal transduction pathways mediated by the proto-oncogenes src and wnt-1.

Ectopic expression of Wnt-1 in 3T3-L1 preadipocytes **stabilizes** beta-catenin, activates TCF-dependent gene transcription, and blocks adipogenesis.

Wrch1 gene is a down-stream **target** gene of Wnt1 in C57MG cells, and encodes a Cdc42-related GTPase with the potential to activate the JNK pathway.

Wnt-1 **induces** morphological transformation of C57MG mammary epithelial cells and accumulation of cytosolic beta-catenin whereas Wnt-5a has no effect.

On the contrary, coexpressed Wnt-1 and Frat **activated** LEF-1 but did not show significant inhibition of GSK-mediated phosphorylation of a peptide substrate.

The specificity of the approach enabled us to identify an Max-1 consensus DNA site within the transcriptional **control** region of the developmental regulatory gene Wnt-1.

FrzA efficiently **inhibited** the Wnt-1 mediated increase in cytoplasmic (beta)-catenin levels as well as the Wnt-1 induction of transcription from a Lef/tcf reporter gene.

Furthermore, a similar phenotype is not observed in Wnt1/RCAS-infected brains, demonstrating that ectopic Wnt1 is insufficient to mediate the **effect** of ectopic Lmx1b in our assay.

Figure 3 iHOP. The iHOP application allows for the automatic extraction of annotation-relevant sentences by identifying links between proteins and functional terms.

GoPubMed is a useful online resource which carries out an ontology-based literature search for a given PubMed query (e.g. using gene names) [26]. It utilizes a GO term extraction method based on morphological features (word stemming) and alignment of words forming GO terms to words which build-up PubMed abstracts. The terms forming the actual query as well as GO terms are highlighted in the retrieved abstracts and for each GO term an accuracy value as well as the definition of the term is provided.

Koike and coworkers followed a more NLP-based approach. They describe the association between genes/proteins/protein families and the functional concepts in the form of an *Actor* (which performs the action) and *Object* (which receives the action) relationship. To extract these relationships, they used shallow parsing and sentence structure analysis techniques. Terms which are semantically related to GO concepts are semiautomatically generated through literature-based term cooccurrence analysis and rules that result in morphological and syntactic variations of GO concepts.

The Medical Knowledge Explorer (MeKE) tool uses a different approach to creating synonyms for GO terms. It applies stemming and flexible matching before indexing the word tokens forming GO terms in the corresponding PubMed sentences. Then it extracts new GO synonyms by calculating the *edit distance* between the candidate synonyms and the actual GO terms. Via alignment of words forming sentences, MeKE also learns sentence motifs (consecutive words) relevant to functional descriptions. Finally, a naive Bayes classifier is used to estimate the overall likelihood of a given sentence corresponding to a gene–product–function description.

A statistical analysis of words appearing in Medline records is the basis of the GO engine [104], which calculates the frequency of association between terms derived from the literature and distinct GO concepts. The GO engine combines this text analysis with sequence similarity information and protein clustering to annotate proteins automatically.

A machine learning approach to the annotation of proteins with GO concepts based on whole abstracts was explored in Ref. [80]. They classified the documents associated with a given query protein according to their association with GO concepts by using a maximum entropy algorithm. The query protein is then annotated by combining the GO classifications from all the documents by means of a weighted voting scheme.

Regular expressions are often used to map biological concepts to the literature. The Textpresso system [68] consists of a text mining tool available online developed to support the process of WormBase database curation. It also operates on full-text articles, and includes classes of biological concepts and relations that include genes, alleles, cells and phenotypes as well as GO concepts. Additionally, classes which relate objects to each other (e.g. associations) are used. To tag these concepts, an extensive list of regular expressions was integrated into Textpresso.

Many of the tools which extract functionally relevant sentences or associations of proteins to functional terms are at an early stage and constitute recent developments, and therefore need further evaluation by the user community.

7.3 Mining Interactions and Relations from Text

Proteins instantiate their biological function by interacting with other biomolecules in the context of biological systems. For instance, enzymes which function as protein kinases catalyze the transfer of phosphate from ATP to the hydroxyl side-chains of the interacting proteins, and are part of important signaling pathways. The assembly of interaction networks of single proteins into a complex pathway is crucial to generalize function for a set of proteins (biological process) and to understanding the mode of operation of whole biological systems.

Large-scale techniques such as the yeast two-hybrid system or protein pull-downs are used to experimentally identify protein interactions. The biomedical literature holds information on both interaction partners and interaction types. II and IR methods are used to automatically identify these interactions from articles. One of the main advantages of text mining techniques with respect to the high-throughput experimental approaches (i.e. yeast two-hybrid or pull-down approaches; see Chapter 31) is their capacity of characterizing the nature of the interactions and their directionality, and not only the pure presence of an interaction. Interestingly, the structure of the interaction networks derived from the literature is similar to the one determined experimentally and both follow a characteristic power-law distribution with a scale-free topology [18, 42].

The extraction of protein interactions has attracted special attention within the biomedical text mining community. It is currently one of the most popular topics, and several online applications devoted to protein interaction extraction are currently available.

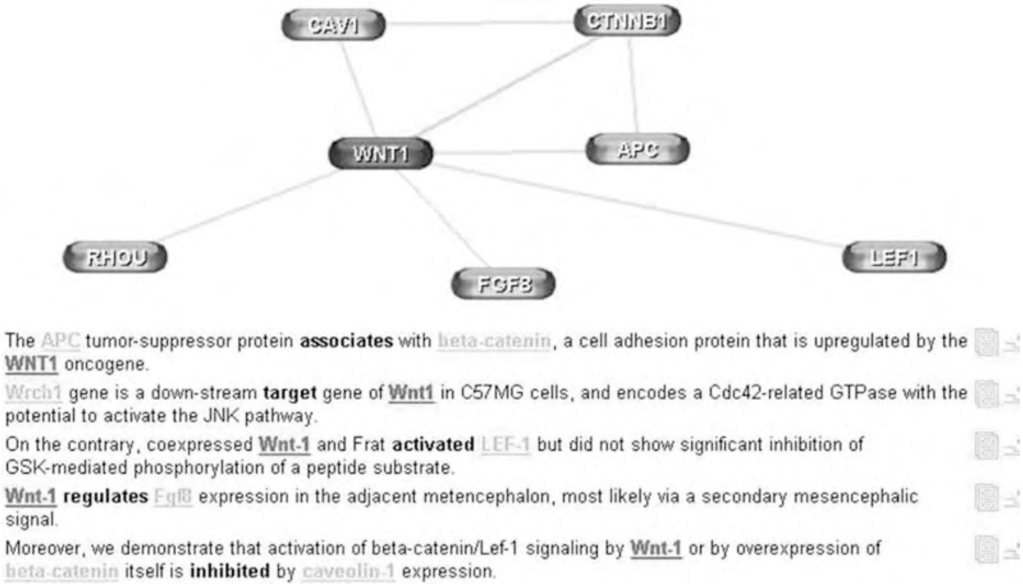
A straightforward strategy for extracting protein interactions is based on simple cooccurrence of previous gene- and protein-indexed articles. These approaches assume that, if two proteins frequently appear together in documents, they display a biological relationship. The PubGene system exploits the cooccurrence idea by indexing PubMed abstracts and titles with human proteins, and then constructing an interaction network based on all the binary interactions retrieved between cooccurring proteins [47].

Co-occurrence analysis alone does not permit the type of relationship between the interacting proteins to be determined. This was addressed by the SUISEKI [10] system, which is based on the use of frames, i.e. patterns which correspond to language expressions used to describe protein interactions within single sentences. Each interaction is scored on the basis of the frequency of repetition of cooccurring proteins within frames as well as on the individual reliability score calculated for each frame type.

The Internet-based Chilibot application [18] includes NLP methods such as POS tagging and shallow parsing, as well as a set of rules to extract relationships between biological entities, i.e. genes, proteins and drugs. This tool defines the directionality of interactions and classifies sentences into five basic types: in addition to abstract cooccurrence, it defines stimulatory, inhibitory and neutral interactions, as well as negative interactions (noninteractions).

The Biomolecular Interaction Database (BIND) contains information about curated molecular interactions. Extracting these interactions manually from the literature is very time consuming. To speed-up the discovery process, a machine learning technology called PreBIND [27], based on SVMs, was developed. This online tool is able to classify whether articles describe biomolecular interactions.

iHOP consists of an application that automatically links proteins detected through their cooccurrence in the literature. It offers an easy-to-use web interface that highlights in text functional terms and interaction patterns of proteins, allowing navigation between concepts by jumping from protein to protein in hyperlinked space. The interaction network for a given protein query is visualized as a graph and allows for navigation through the associ-



The APC tumor-suppressor protein **associates** with beta-catenin, a cell adhesion protein that is upregulated by the **WNT1** oncogene.

On the contrary, coexpressed **Wnt-1** and Frat **activated** LEF-1 but did not show significant inhibition of GSK-mediated phosphorylation of a peptide substrate.

Wnt-1 **regulates** Fgf8 expression in the adjacent metencephalon, most likely via a secondary mesencephalic signal.

Moreover, we demonstrate that activation of beta-catenin/Lef-1 signaling by **Wnt-1** or by overexpression of beta-catenin itself is **inhibited** by caveolin-1 expression.

Figure 4 Interaction graph provided by iHOP.

ated proteins. Interactions supported by experimental evidence are ranked higher in the returned list of interaction sentences (Figure 4).

The Genomics Information Extraction System (GENIES) [84] uses a knowledge base to organize and structure information about molecular pathways derived from the literature, and also considers the extraction of complex nested expressions referring to interactions.

One of the main difficulties encountered in protein interaction extraction strategies has been the lack of large, well-curated training and test data sets consisting of sentences of text passages referring to protein interactions. Although a recent community-wide evaluation addressed this issue [70], many tools are evaluated using information provided by interaction databases such as DIP [103]. These databases contain well-curated protein interactions generally extracted by domain experts from full-text articles [18]. As protein interaction extraction tools in general only have access to abstracts rather than full-text articles, many of the interactions contained in other sections of the articles are missed. Also, the prior protein-tagging step is crucial to identify potential protein interactions [10].

A commonly accepted formalization of interaction types which can be derived from the literature is missing. Therefore different tools define interactions (relations) at different degrees. Some consider interactions at a rather coarse level [44], focusing more on extraction of relationships between proteins than on extraction of physical protein interactions. Those tools are able to also extract relationships based, for instance, on homology, e.g. the mention of to homologous genes from different organism. Other methods are more centered on extraction of very specific interaction types, e.g. inhibitory or stimulatory relations [18] or even phosphorylation [10]. Even if the different existing online approaches provide complementary information to each other, it is still far from possible to connect them in useful workflows. Although the most common interactions studied are those between proteins, some effort has been done for the analysis of the interactions between proteins and drugs.

7.4 Discovering Information Associated with Groups of Proteins

The coordinated expression of a certain gene within a group of genes studied in microarray experiments provides important information about coregulation within biological processes (for a detailed description of microarray technologies, see Chapter 24). Text mining tools have been developed to assist in the interpretation of microarray data. These techniques characterize groups of genes by extracting words with functional meaning that are statistically associated to the corresponding literature [8] and use this information to score the coherence of gene clusters [81]. Moreover, text mining techniques are used to complement the description of the relationships between genes within gene clusters obtained through the similarity of their expression patterns by, for example, pointing out genes that are coexpressed, but do not share a known biological function. These genes can be detected by the associated functional terms extracted from the literature) and can therefore correspond to the discovery of a new biological association. Jenssen and coworkers [47] superimposed gene expression data on a literature-based network, detecting gene relationships which were not previously identified by clustering techniques. Another study showed that, in general, there is a correlation between the similarity of the expression patterns and the significance of functional information derived from the literature [75]. The GEISHA system [8] uses terms extracted from the literature with a given significance value to characterize the functions potentially associated to each cluster of genes. GEISHA additionally uses double-words and sentences to increase the interpretability of the extracted information in biological terms.

The ConceptMarker algorithm has been applied to integrate analysis of gene expression data associated to juvenile arthritis with biomedical literature analysis [59]. It uses the ProMiner protein tagger to the detect genes in abstracts – mapping the genes studied in the microarray experiment with articles mentioning them [34]. To aid in the interpretation of information associated to the experimental gene clusters it identifies a set of literature terms, which describe consistently these clusters using VSM-based term weighting and singular value decomposition (SVD) methods.

A number of systems have been developed that instead of using literature mining directly, exploit associations of genes to GO terms provided in annotations databases like GOA. The corresponding terms are used in ways that are similar to the above methods to characterize functions common to genes with similar expression profiles and to discover new potential associations. An example of this type of systems is FatiGO, that uses statistical tests to identify relevant GO terms for groups of genes based on GOA associations [2].

An advantage of approaches based on IE methods are that the amount of functional information contained in the scientific articles is clearly more complete than incorporated in databases and ontologies, and they can also benefit from a richer expressivity regarding functional characteristics. In contrast, the GO-based approaches are easier to implement and have very simple interpretations since they use a controlled vocabulary.

Even if it is clear that both literature- and GO-based approaches have advantages that can be complementary, a full documented study of their possible combination has not yet been performed.

7.5 Other Applications

Although the majority of IE and IR tools for life science literature are concerned with the identification of biological entities, interactions, functional descriptions and functional terms describing gene clusters, other biological problems have also been considered.

Chromosome aberrations are known to be associated in many cases to human pathologies and cancer conditions. To extract the corresponding breakpoint manually from the literature is a labor-intensive task. The HCAD database contains information on human genomics breakpoints and chromosome aberrations automatically extracted from the literature [40].

For the detection of genomic variations, especially in the context of cancer-specific texts, a tool named VTag based on machine learning methods is available [66], with an f-score of 0.8192.

The regulation of gene function in higher organisms is subjected to tissue-specific control mechanisms. In fact, transcript diversity is especially important for tissue-specific gene expression. NLP methods have been developed to identify alternative transcripts of genes detected in PubMed [87].

Although most gene and protein sequences are stored in biological databases, short sequence patterns with significant functional properties like binding sites or epitopes are frequently mentioned directly in texts. An information extraction method based on Markov models to locate such sequence patterns in large text collections has been implemented. For the identification of peptide epitopes, this system is able to reach a considerable level of precision (precision of 67% with a recall of 85%) [102].

The efficiency of reactions carried out by enzymes can be expressed through kinetic parameters. Although databases such as the Kyoto Encyclopedia of Genes and Genomes (KEGG) contain extensive descriptions about enzymes, existing information about kinetic aspects is still often hidden within articles. A text classification system based on SVMs tackles this problem and assists researchers in the search for information relevant to kinetic aspects of enzymes [33].

Eukaryotic cells compartimentalize certain biological processes. The subcellular location of proteins gives additional clues about certain functional aspects, e.g. transcription factors display their molecular function in the nucleus. Not only bioinformatics methods are able to classify protein sequences according to their subcellular location, but also literature associated to a given protein is useful to infer its subcellular location [69, 90].

Protein sequence similarity searches are the base for automatically annotating protein function or finding suitable templates for protein structure prediction methods. To determine if two proteins are remotely homologs in cases where sequence similarity is in the twilight zone often requires human intervention and manual consultation of annotation database records. The combination of sequence search methods such as PSI-BLAST with standard text similarity method such as the VSM has been used in the SAWTED system to enhance remote homology searches [62, 94].

8 Evaluation of Text Mining Strategies

The importance of community-wide evaluations has been realized by both the bioinformatics and NLP communities. In the case of the bioinformatics field, open evaluations have been carried out for tasks such as protein structure prediction microarray data analysis [48] and gene finding [83]. Evaluations of NLP strategies for IE systems (MUC) and IR end-document classification methods have also been performed for several years [39, 95].

Each of the first IR, IE and text mining tools developed for the biomedical domain used their own evaluation data sets and strategies, which hindered performance comparison and determination of the state art. The construction of suitable textual test and training data requires involvement of domain experts and is labour intensive. Therefore, many systems evaluated performance using small data sets that were not sufficiently representative.

"Gold standard" data sets provided by human experts are used to consistently score performance of different text mining systems. The agreement of these experts is evaluated by means of inter-annotator agreement. The lower this agreement, the more difficult the task. In order to ensure objective evaluation metrics, comparing cross-system performance and producing "gold standard" data sets community-wide evaluations are crucial.

The retrieval of documents with relevant information for a given biological problem is the first step in the processing of text collections. To assess document categorization and retrieval systems in the biomedical domain was the main goal of the TREC Genomics [37] track. In the case of the TREC Genomics track 2004, one of the main challenges was related to retrieval of PubMed abstracts relevant to previously defined topics. These topics consisted basically of information needs formulated by biologists and which should reflect common information demands encountered in this domain. The average precision of the top-scoring systems was around 43% of the retrieved articles containing correct information. The second task of TREC 2004 was organized into subtasks. One of them, the triage subtask, focused on the classification of full-text articles regarding the presence of experimental evidence useful for database curators to extract annotations. The annotation subtask had the goals of identifying, given an article and gene name, which GO categories (i.e. molecular function, biological process and cellular component) were used in the articles to annotate gene products. These two subtasks actually reflect some of the initial steps undertaken by database curators to derive documents relevant for further manual curation.

A similar task was posed at the The KDD challenge cup [106], concerned with the retrieval of papers containing experimental evidence for a given set of *Drosophila* gene products (relevant to extract annotations).

The task of indentifying entities (gene and protein names) was addressed by the BioCreative comunity [105]. A total of 15 teams participated in this experiment (subtask 1A), trying to locate precisely gene names within full-text articles provided by the annotators as valid references for those genes. Top-scoring groups reached an f-score (balanced precision and recall) of 0.8, which is a promising result, but still far below the 0.9 f-score for detection of other names such as company names of locations tagged in newswire texts.

A similar challenge was held at the shared task of the JNLPBA [50]. In this contest the recognition of different biological entities included protein names, DNA, RNA, cell line and cell type. The introduction of additional entities decreased the overall performance when compared to BioCreative task 1A, reaching an f-score of 0.76. The ABNER protein tagger (f-score of 0.703) [86] and a system based on PowerbioNE were among the top scoring strategies [107].

For biological applications the tagging of protein names in text is not sufficient and it is additionally necessary to link them to the corresponding sequence database entries. Subtask 1B of the BioCreative challenge [38] addressed this point, requiring the identification of protein/gene names and their corresponding database links in examples from three model organisms:

yeast, fly and mouse. Among the best-performing systems was the rule-based ProMiner approach [34]. The differences between the results in the three organisms were interesting – whereas yeast genes were rather easy to identify (f-score of 0.92), fly genes (f-score of 0.82) and mouse genes (f-score of 0.79) were more complicated to link to database entries. An explanation for this difference could be that yeast genes are commonly mentioned in articles using short names or well-defined unambiguous symbols, whereas fly and mouse genes are mentioned often using ambiguous or long gene names.

Many applications relating to the recovery of protein interactions from the literature were implemented. The Genic Interaction Extraction Challenge [70] supplied a training and test set to benchmark the state of the art in text-based protein interaction extraction. In this case, the best-performing teams could reach an f-score of 0.518.

In the KDD cup and Genomics TREC contests, articles which contain relevant information for curators are retrieved, but the annotations and annotation-relevant text passages must be identified manually by domain experts. The second task of the BioCreative community addressed a more advanced step in text mining – the automatic identification of functional annotations associated to genes and proteins [7]. In subtask 2A, a protein identifier (Swiss-Prot Id), a GO concept and a full-text article selected by the GOA annotators as representative of the protein–GO association were provided to the participants, and they were asked to highlight significant passages of the text demonstrating the protein–GO relation. In this case, in addition to the difficulty of tagging gene names common to task 1, references to the GO terms had to be identified, and both had to be correlated within the same passage – a difficulty of considerable magnitude given the large semantic variability in which GO terms can be expressed in texts. Top-scoring systems submitting results for all the posed queries reached a precision of 0.28, while participants only submitting results for a small number of high-confidence cases reached a precision of 0.8. Subtask 2B was even more challenging as only protein–full-text article pairs were provided and participants were asked to predict the GO term useful for annotating the proteins together with the text passage containing the evidence supporting the annotation.

9 Resources for Text Mining

A range of resources is available to develop text mining and NLP applications suitable to extract information from biology literature, including text repositories and databases, annotated text corpora for training and testing purposes, gene dictionaries as well as generic and domain specific NLP tools. Table 2 gives a detailed list of resources and resource types.

9.1 Literature Databases

The biomedical literature and especially abstracts from the PubMed database constitute the primary data resource. Interestingly systems developed for processing generic texts are increasingly being adapted to biomedical text processing. A more detailed of description of existing biomedical literature databases is provided in Section 3.

9.2 Annotated Text Corpora

Tagged biomedical text corpora are essential to train text classifiers, machine learning techniques and to extract text patterns. Although there is increasing interest in producing open access corpora for biomedical text mining applications, only a few large data sets are currently available.

The GENIA corpus [49] consists of a collection of biomedical abstracts which have been semantically annotated and which has been used as a benchmark set for biology NER tools [50]. The annotation of biological entries is based on a predefined ontology (GENIA ontology). GENIA Corpus Version 3.0x consists of 2000 abstracts related to human, blood cells, and transcription factors.

The BioCreative challenge resulted in data sets useful for tagging protein and genes in articles to protein database entries. Additionally, it produced a data set of text passages describing protein–GO associations evaluated by GOA database curators as positives and negatives (Blaschke et al.).

Another data set used for protein entity tagging is the Yapex corpus, which has been used to test the NLProt tool [28]. The Genic Interaction Extraction Challenge has provided both a training and test set for protein-protein interaction discovery from text [70].

A list of other text data sets useful for different text mining task is contained in Table 2.

9.3 Generic NLP Tools

A vast amount of existing online tools and software can be found for processing generic literature or newswire texts. It is beyond the scope of this chapter to provide a complete list of different applications and only a small number of systems will be mentioned. In principle, when developing NLP tools for biomedical literature, existing software for generic texts could be adapted.

∗: Software S, Web site/server W, Data set D.

For statistical text analysis, the Bow Toolkit is very useful [64]. It is written in the C programming language, and provides libraries for text retrieval (arrow), classification (rainbow), and clustering (crossbow) tasks.

Generic tools for analyzing all the different features of natural language are available. To explore the grammatical and syntactical characteristics of language, toolkits such as GATE [12], NLTK and CCG integrate many text-processing applications such as POS tagging and parsing [61].

Morphological features (e.g. stripping off suffixes of words) can be analyzed by stemmer algorithms and are a useful step in IR. Among the existing stemming algorithms for English texts are the Porter stemmer [78], which carries out a rather deep analysis, and the Krovetz system, which can be mentioned as an example of "light" stemming [58].

9.4 Dictionaries and Ontologies

Collections of gene and protein names, symbols and synonyms stored in biological databases such as Swiss-Prot are valuable resources, providing the base for name identification and linking of text to database identifiers. Thesauri and ontologies are also essential for building the background knowledge in which to map the information extracted from text. In the biomedical domain, the two larger collections are GO and UMLS. w

GO consists of a controlled vocabulary of concepts which are relevant to biological aspects such as molecular function, biological process and cellular location [5]. GO is part of a repository of ontologies, called Open Biomedical Ontologies (OBO), which contains additional ontologies such as the Human Disease Ontology and the Sequence Ontology. GO contains more than 16 000 concepts, and for some of them synonyms and definitions are also provided. There are over 200 000 annotations of gene products using GO terms, contained in annotation databases such as GOA (see also Chapter 29).

Although GO is currently the most widespread vocabulary resource for annotation purposes, it lacks ways of quantifying similarities between concepts. Also, the relationships between terms are mainly restricted to "is a" and "part of" relations. Finally, for text mining purposes, many terms have a limited use because they do not correspond to language constructs or expressions used in the literature.

The UMLS Metathesaurus [11] contains more than 1 million concepts in biomedicine and health science as well as the relationships between them. As it focuses on medical terms rather than molecular biology vocabulary, it has been shown to be more useful for medical than for biology text mining. Finally, the MeSH thesaurus provides a set of controlled vocabulary terms organized in a hierarchical structure which is used to index PubMed records [71]. It contains more than 22 000 terms ranging from very broad ones such as

"Anatomy" to more specific ones like "Ankle". As in the case of the UMLS, MeSH is tailored towards medical literature rather than biology.

9.5 Biomedical Domain NLP Systems

A considerable number of biomedical NLP applications have already been mentioned throughout this chapter. Some of them are useful for very specific tasks, such as the MedPost [88] tool – a POS tagger adapted to biomedical texts. A range of protein name taggers is available either as a downloadable software or as online servers. The NLProt tagger, a SVM-based tagger, also links the identified proteins to database entries [67], while the ABNER tagger identifies additionally cell lines, RNA and DNA.

Providing graphical representation of information useful for the human interpretation of knowledge is an essential challenge for the text mining field and will ultimately influence its perception in the large community of potential users. iHOP facilitates the understanding of extracted protein relationships by highlighting the identified entities, allowing a graph representation of the interaction network, and facilitating the navigation between different concepts and databases [40]. Other systems that provide comprehensive graphical web interfaces are EBIMed and Chilibot [18] (Table 2).

10 Concluding Remarks

Processing of scientific text is a challenging task due to the complexity of human language. Nonetheless, there is growing interest in text mining and IE technology applied to biomedical literature as a considerable fraction of existing biological information is only available in the literature. This technology will play an important role in the exploration of high-throughput experiments, in the annotation of biological databases and in the analysis of complex biological problems.

The biological database community was perhaps the first with defined expectations towards the development of NLP tools which could assist human experts in accessing relevant functional descriptions or helping in the extraction of relevant annotations. Collaborations of databases including Mouse Genome Informatics (MGI), FlyBase, Swiss-Prot, NCBI and annotation databases like GOA with biomedical text mining groups have resulted in fruitful community-wide evaluations where practical tasks were posed. The GO consortium has even considered text-based computation as one of the strategies for its annotation process. There are already some examples of text mining tools assisting biological databases, as is the case of iHOP, and the interaction database IntAct [36] or PreBIND and the BIND database [27]. Integration of NLP tools will increase efficiency of data acquisition and traceability in the future.

Still, the construction of suitable data sets for the development and assessment of NLP systems in this domain will require further efforts of collaboration with databases and biology domain experts. A particularly crucial aspect for the development of this field would be the availability of domain ontologies and thesauri. The rapid advance of technologies in molecular biology and biomedicine is producing large and complex collections of data, for which we essentially lack the appropriate formalized structures and terminologies. All these developments have a clear incidence in text mining technologies that use structured field knowledge as platform. Finally, the assessments of NLP strategies applied to biology literature have been revealed as a powerful natural way of creating community, focusing on key biological problems and fostering developments. They also provide a comprehensive view of the status of the field.

The first NLP systems applied to molecular biology and biomedicine were initially developed 10 years ago, and centered on identifying protein names and interactions. Meanwhile, they have diversified to larger a set of applications. This diversification was partially promoted by the fact that very specific functional information was missing in many of the existing databases, but was relevant to the needs of different areas of biomedicine and molecular biology. These NLP developments included extraction of information about kinetic parameters, chromosome aberrations or alternative transcripts.

Although PubMed is the central literature repository for biologists, it does not facilitate specific retrieval or extraction of gene-related information. When querying PubMed, it is necessary to browse through large lists of abstracts until information of interest is detected. New systems like iHOP or Chilibot allow more efficient access and visualization of gene-relevant textual data, and constitute alternatives to traditional PubMed searches.

The possibilities for complementing traditional bioinformatics approaches with NLP methods, creating hybrid systems, are still largely unexplored. Initial attempts have been restricted to enhance sequence searches with information extracted from abstracts. The development of new hybrid approaches integrating a larger diversity of data types such as diseases, phenotypic information or experimental conditions remains as a challenge for the years to come.

Acknowledgments

The work of our group was supported by grants of the European Commission (ENFIN LSH6-CT-2005-518254 , Biosapiens LSHC-CT-2003-505265). Thanks to Burr Settles for providing Figure 2, to Robert Hoffmann for providing Figures 3 and 4, to Boris Galitsky for additional information about his QA system, and to Ana Divoli and Thomas Lengauer for useful comments and suggestions.

Integrating Information for Protein Function Prediction

William Stafford Noble and Asa Ben-Hur

1 Introduction

Most of the work on predicting protein function uses a single source of information – the most common being the amino acid sequence of the protein (see Chapter 30). There are, however, a number of sources of data that are predictive of protein function. These include protein–protein interactions (Chapter 31), the genomic context of a gene (Chapter 32), the protein's structure (Chapter 33), information mined from the biological literature (Chapter 34) and data sources indicating coregulation, such as gene expression and transcription factor binding [10]. A classifier that predicts function based upon several sources should provide more accurate predictions than can be achieved using any single source of data. However, the heterogeneous nature of the data sources makes constructing such a unified classifier challenging.

We have divided the various methods for data integration into five categories (Figure 1). First, *vector-space integration* consists of characterizing proteins in various ways by a set of variables, i.e. as vectors. Any standard classification method can then be applied to the resulting vector-space representation. An alternative – *classifier integration* – is to train a classifier on each source of data and then combine the predictions of the various classifiers into a single prediction. *Kernel methods* are a recent advance in the field of machine learning [41]. These methods provide a coherent framework for integrating various sources of data, applicable even when there is no explicit vector-space representation of the data. Several sources of data form a network that is informative of functional relationships. The prime example of such a network is protein–protein interaction data. Proteins that interact often do so because they participate in the same pathway. Therefore, the network of protein–protein interactions in a cell can be informative of protein function (see Chapter 32). The final two approaches model such networks and their relationship to protein function. Graphical models, both directed and nondirected, provide a probabilistic framework for data integration [23]. Modeling is achieved by representing local probabilistic dependencies; the network

(e) Integration of several networks of functional relationships into a single network.

structure of these models makes them a natural choice for capturing networks of functional relationships. The last form of integration we discuss does not aim at explicit prediction of protein function, but instead integrates several networks of functional relationships, such as various forms of interaction, coexpression, coregulation, etc., into a single network that unifies all those relationships.

2 Vector-space Integration

Perhaps the simplest form of data integration is to summarize, for each protein, a variety of relevant types of data in a fixed-length vector and feed the resulting collection of vectors into a classification algorithm. This approach has the advantage of simplicity, but treating each type of data identically does not allow us to incorporate much domain knowledge into the design of the classifier. For example, certain sources of data may benefit from a different measure of similarity than others (see Section 4).

An early example of such an approach is described in Ref. [14]. This work presents a limited form of data integration: many different types of protein features are used, but most of these features are derived from the protein's amino acid sequence. Such features include protein length, molecular weight, charge, amino acid composition (i.e. residue frequencies) and isoelectric point. For a subset of the data for which three-dimensional (3-D) structures are available, the authors also include several features based upon secondary structure features; however, the experiments suggest (somewhat surprisingly) that these features are not very informative. The authors apply three different out-of-the-box machine learning algorithms to their data and compare the resulting performance with that of the BLAST sequence comparison algorithm [1] at predicting whether a sequence is an enzyme as well predicting the first two digits of the protein's Enzyme Commission (EC) number. Among the three machine learning algorithms – the C4.5 decision tree, naive Bayes and *k*-nearest-neighbor algorithms – the best-performing algorithm is *k*-nearest-neighbor, which predicts the class of a query protein by finding the most similar protein in the training set and outputting the corresponding label (see Chapters 24 and 27 for more detailed descriptions of this algorithm). This simple approach works as well as BLAST at discriminating between enzymes and nonenzymes, but less well when the task is more specific. The latter result is not surprising, since many of the enzyme classes are characterized by highly specific sequence features [4].

A closely related set of experiments was described 5 years later in Ref. [24]. Like in the previous work, the authors summarize each protein using a fixed-length vector of features derived from the amino acid sequence. After considering 25 such features, the authors settle on 14, which include straightforward features such as average hydrophobicity and number of negatively charged residues, as well as outputs from nine different previously described prediction methods. These predictions include subcellular location, various types of post-translational modifications, low-complexity regions, transmembrane helices, etc. The resulting 14-element feature vectors are given to a feed-forward neural network, which can subsequently predict EC numbers and "cellular role" Gene Ontology (GO) terms with good accuracy.

A larger version of this type of experiment was described in Ref. [46]. In this work, the authors build classifiers for all EC protein families that include 50 or more members (299 families), as well as 233 Pfam families [45]. Each protein is represented using an extremely rich collection of 453 features. These features include statistics derived from the protein sequence, including amino acid frequencies, predicted secondary structure content, molecular weight, average hydrophobicity, isoelectric point, etc. In addition, the authors extract information about sub-cellular location, tissue specificity, etc., from the Swiss-Prot database [3] and encode this information in nine of the 453 features. The paper demonstrates the utility of probabilistic decision trees on this task. This algorithm is essentially an improved version of the C4.5 decision tree classifier, and does a better job of handling unbalanced data sets (when negative examples far outnumber positive examples) and missing data, and which exhibits more stable learning behavior.

Protein structure is often conserved when no significant sequence conservation can be detected. Instead of making predictions using direct structure comparison, one can represent structural features of the protein, analogously to the methods presented earlier, that represent features of the protein sequence [15]. This paper characterizes a protein using several structural features: the total surface area attributable to each residue type, the fractal dimension of the protein surface (which quantifies how "crinkly" the surface of the protein is), surface area to volume ratio, secondary structure content, and the presence of cofactors and metals. Then a support vector machine (SVM) classifier is used to predict the the first digit of the EC number of enzymes whose structure is known. The prediction task prepared by Dobson and Doig [15] is a very difficult one: in each of the six enzyme classes no two structures belong to the same SCOP superfamily. Therefore, sequence-based methods will provide very poor results. The authors have not compared their approach to a sequence-based approach that uses the same set of sequences, so it is unclear whether these structure-based features provide added value. In general, the advantage of using sequence-based classifiers is that many more protein sequences are available than protein structures.

One of the challenges in vector-space integration is determining the contribution of each feature to the accuracy of the classifier and finding small subsets of features that maintain or improve classifier accuracy. This task is known as *feature selection* and is an active area of research in machine learning. The interested reader can find a wealth of information about the state-of-the-art of the field in Refs. [18,19]. The simplest approach to feature selection is the so-called *filter* method whereby one computes for each feature a statistic that reflects how predictive the feature is. Statistics that achieve this goal include the area under the receiver operating characteristic (ROC) curve, the Pearson correlation coefficient, the Fisher criterion score, etc. [18, 19]. Independently scoring each feature does not take into account the redundancy that often exists in high-dimensional data such as gene expression and also ignores the classifier with which the data will be ultimately classified. These issues are handled by *wrapper* or *embedded* methods (see Refs. [18,19]). Wrapper methods use a classifier to evaluate the merit of subsets of features and, as such, can be combined with any classifier. In embedded methods, on the other hand, the classifier is part of the selection process and uses the properties of the classifier to select relevant features. An example of a simple embedded method is the recursive feature elimination (RFE) method [20], that for a linear classifier iteratively removes features for which the magnitude of the corresponding component of the classifer's weight vector is the smallest.

The drawback of vector-space integration is modeling all features the same way. One way to address this issue is to train different classifiers for each source of data and then to combine the predictions of the different classifiers. We call this integration method *classifier integration*, which is described in the next section. *Kernel methods*, which are presented in Section 4, train a single classifier, but allow more flexibility in combining data sources than the vector-space integration methods, by allowing the user to define a different similarity measure for each data source and thereby incorporating more domain knowledge into the design of the classifier. Moreover, kernel methods are applicable in modeling data sources such as protein sequences where no obvious vector-space representation is available.

3 Classifier Integration

The second approach to building a unified protein classification algorithm trains several classifiers and then combines their predictions. Gene finding is a well-known bioinformatics problem for which combining the predictions of several classification methods can provide more accurate predictions [40]. Conceptually, there are several classes of methods for combining the output of different classifiers:

(i) Integration of different classification methods, each trained on the same data.

(ii) Integration of the same method trained on different subsets of the data or on different subsets of features. This is an active field of research in machine learning called *ensemble methods*, and includes methods such as boosting [16], random forests [9] and various "committee machines" [6].

(iii) Integration of several classifiers, each trained on a different source of data.

In our context we are focusing on the third class of methods. The standard method for integrating the results of several classifiers is by a majority vote. A more sophisticated approach is to use a classifier whose job is to integrate the predictions of the various classifiers [6]. Not much work has been done to apply classifier integration methods to protein function prediction. One example of integrating the predictions of several classifiers is described in Refs. [36, 37] and is compared with kernel-based integration in those papers.

See the next section for details. Classifier integration is most useful in cases in which each classifier is available as a black-box, e.g. as is the case for gene finders.

4 Kernel Methods

Recently, a class of algorithms known as kernel methods have become popular in the machine learning community [41, 43] and this popularity has extended into computational biology [42]. A *kernel* is a function that defines similarities between pairs of data objects and a kernel method is an algorithm whose implementation depends on the data only through the kernel. More specifically, a kernel is a similarity measure that satisfies the condition of being a dot product in some space, i.e. $K(x, y)$ can be expressed as $\langle \Phi(x), \Phi(y) \rangle$, where Φ is some possibly nonlinear mapping. This mapping technique has been known for decades, but has gained popularity recently in the context of a particularly powerful classification algorithm, known as the support vector machine (SVM) [8, 12, 50]. The so-called "kernel trick" – mapping data into a higher-dimensional space by means of a predefined kernel function – often results in a problem with more dimensions than examples. The SVM, it turns out, can cope remarkably well with such cases, effectively reducing the curse of dimensionality. Other kernel methods have subsequently been described for classification, regression, clustering, principal components analysis, etc. [43].

Kernel methods provide a coherent framework for data integration. The kernel function provides a form in which to represent a wide variety of data types, including vectors, matrices, strings, trees and graphs. As a kernel method represents data via the kernel function, any data set of n elements can be summarized as an n-by-n matrix of pairwise kernel values. This kernel matrix is a sufficient representation: once it is computed, the original data can be discarded and the kernel method can still perform its function. Furthermore, kernel matrices from different data sources can be combined in a simple kernel algebra, that includes the operations of addition, multiplication and convolution [22]. The simplest way to combine kernels is by adding them: adding kernels is equivalent to concatenating their feature space representations. When the kernels are linear kernels over an explicit vector-space representation this is the same as the vector-space integration described in Section 2. The feature space for the multiplication of kernels is the product of the feature spaces of the kernels. This approach has been used in the context of predicting protein–protein interactions [5].

It is possible to perform vector-space integration with kernel methods. Since kernel methods are sensitive to the scale of each feature, it is often useful to normalize the features such that they are on a similar scale, e.g. by standardizing each feature. When performing integration at the kernel level, an alternative is to normalize the kernel itself, rather than its feature space representation by using a cosine-like kernel $K'(x, y) = K(x, y)/\sqrt{K(x, x)K(y, y)}$, which is the same as projecting the feature-space representation to the unit sphere.

In two related papers, Pavlidis and coworkers apply a kernel-based data integration technique to the problem of protein function prediction [36, 37]. The authors use kernels to combine microarray expression data with phylogenetic profiles and use the resulting combined kernel to train an SVM classifier to place yeast genes into MIPS functional categories [33]. This kernel-based approach is compared to a vector-space integration scheme, which simply concatenates the two types of data into a single vector, and a classifier integration scheme, which trains two different SVMs and then sums the resulting discriminants. In this case, the primary difference between the vector-space integration scheme and the kernel approach is the use of a third-degree polynomial kernel on each data set prior to integration. The polynomial kernel maps each data set into a higher-dimensional space whose features are all monomials over the original features with degree less than or equal to 3. By performing this mapping on each data set individually, rather than on the concatenated vectors, the method incorporates the prior knowledge that inter-feature dependencies within one data set are more likely to be relevant than dependencies between two different types of data. This prior knowledge is borne out by the results, which show that the kernel-based integration scheme provides better classification performance than either of the other two schemes. Data integration by kernel summation has been applied in several other bioinformatics applications: prediction of protein–protein interactions [5] and prediction of metabolic networks [51]. Prediction of metabolic networks, i.e. associating enzymes with metabolic pathways, can be considered a form of function prediction; prediction of pairwise relationships, or networks, is discussed in detail in Section 5.

Rather than simply adding kernels, one can consider a linear combination of kernels, which can take into account how informative each kernel is. For example, if we know that data set A is more useful (i.e. more relevant or less noisy) than data set B, then we can combine the corresponding kernels as a weighted sum: $K_{\mathrm{AB}} = \lambda K_{\mathrm{A}} + K_{\mathrm{B}}$. The only difficulty, of course, is how best to select the data set weighting factor λ. The value of the weighting factor can be set using cross-validation over several choices for its value. This is feasible when combining two kernels. When using a larger number of kernels this is no longer practical and a different approach for weighting the different kernels is required.

Lanckriet and coworkers present a statistical framework for performing kernel-based data integration with weights assigned to each data set [26, 28]. Rather than requiring that the weights be assigned *a priori*, the authors train an SVM and learn the kernel weights simultaneously, using a technique known as semidefinite programming (SDP) [27, 35, 49]. In Ref. [28], this SDP-SVM approach is compared to a previously described Markov random field method for data integration [13] (described in Section 6). Lanckriet and coworkers use the same classification of yeast genes into 13 broad MIPS functional categories and five types of data as [13]: (i) the domain structure of the protein, according to Pfam [45], (ii) known protein–protein interactions, (iii) genetic interactions and (iv) cocomplexed proteins, as identified by the comprehensive yeast genome database, and (v) cell cycle gene expression profiles. Performance is measured using ROC curves [21]. The SDP-SVM approach provides far better performance across all 13 functional classes. A subsequent article [26] applies the same framework to two more yeast classification problems – recognizing membrane proteins and recognizing ribosomal proteins – and provides more details about the SDP-SVM method.

Borgwardt and coworkers propose a kernel method for predicting protein function using protein structure [7]. They represent the structure of a protein as a graph whose nodes are secondary structural elements and whose edges represent proximity in sequence or in 3-D space. The authors propose a kernel that quantifies the similarity between two proteins using the random walk kernel [17], combined with kernels that quantify the similarity between the secondary structural elements of the protein. The proposed kernel thus combines local properties of the protein with the global 3-D structure. They use this kernel with an SVM classifier, as well as with more sophisticated hyper-kernel machinery, to distinguish between enzymes and nonenzymes, and predict the first EC number of an enzyme on a data set used in Ref. [15]. Their more sophisticated approach provides slightly better results than the SVM vector-space integration approach of Dobson and Doig; it is likely that integrating additional structural features into their kernel will provide further improvement.

5 Learning Functional Relationships

Much of the data relevant to predicting the protein function is in the form of a network or can be converted into a network structure. Protein–protein interaction data is an example of such a network: proteins that interact often participate in the same biological process, have a similar localization pattern and, to a lesser extent, have a similar function [5]. Other sources of data that are not directly in the form of a network can be converted into a network structure. Gene expression data can be represented by a graph whose edges represent comembership in a gene expression cluster or weighted by the correlation between the nodes; sequence data can be similarly converted to a graph by means of sequence similarity scores from algorithms such as Smith–Waterman [44] or PSI-BLAST [2]. Other sources of data for weighting edges include similarity of phylogenetic profiles, gene fusion and cocitation from the literature [29] (see also Chapter 32).

Given several networks of pairwise functional relationships, an important task is to unify those networks into a single network [32]. Marcotte and coworkers demonstrate how to combine pairwise functional relationships from three different sources: correlated evolution using phylogenetic profiles [39], correlated mRNA expression profiles and patterns of domain fusion [31]. The data fusion approach is simple: the authors make a list of all pairs of functionally related proteins in yeast according to each method. This list contains 93 000 pairs of proteins. Functional links that are supported by two out of three of the methods are considered "highly confident" and functional annotations from proteins of known function are then propagated across this high-confidence network. This simple approach yielded functional annotations for more than half of the 2557 yeast proteins that were unannotated at the time.

This simple approach of trusting only predictions that are made by more than one method clearly has drawbacks, especially when some of the contributing methods are more reliable than others or when the methods assign confidence values to their predictions. Lee and coworkers address this issue and propose a framework for unifying the scores associated with different networks [29]. The following function assigns a log-likelihood score to a linkage L between two proteins in the presence of a network E in the context of a particular pathway or annotation:

$$LLS(L|E) = \log \frac{P(L|E)/P(\bar{L}|E)}{P(L)/P(\bar{L})},$$

where $P(L|E)$ are the frequencies of the linkage L observed in the data and $\bar{L}$ are instances where the linkage is not observed.

A similar problem is addressed by the MAGIC system [47]; MAGIC estimates the probability that proteins i and j share a functional relationship. The existence of a functional relationship is modeled using several pairwise relationships between proteins: coexpression, colocalization, physical interaction, genetic interactions and comembership in a complex. The paper proposes a Bayesian network model for estimating the probability of a functional relationship. A Bayesian network is a probabilistic model that represents a probability distribution in a form that makes it amenable to efficient computation by encoding the probabilistic dependencies in the data in the form of a directed

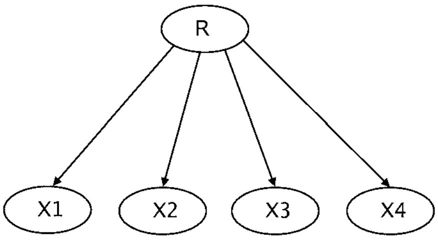

Figure 2 A naive Bayes model: Given that a functional relationship exists between two proteins, the existence of any two relationships between the two proteins (interaction, coexpression, etc.) are independent.

graph (see Refs. [34,38] for textbooks on Bayesian networks). To illustrate the approach we will consider a very simple model. Let R be the random variable that denotes the existence of a functional relationship and let $X_1, \ldots, X_d$ be the pairwise relationships that serve as evidence for the existence of the relationship. We are interested in the probability $P(R|X_1, \ldots, X_d)$. Using Bayes rule, this probability can be expressed as:

$$P(R|X_1, \ldots, X_d) = \frac{P(X_1, \ldots, X_d|R)P(R)}{P(X_1, \ldots, X_d)}.$$

The naive Bayes model is the assumption that each data source X_i is conditionally independent of the other data sources, i.e. $P(X_i|R, X_j) = P(X_i|R)$ for $j \neq i$ [34,38]. This assumption enables us to write:

$$\begin{aligned}
P(X_1, \ldots, X_d|R) &= P(X_1|R)P(X_2, \ldots, X_d|X_1, R) = P(X_1|R)P(X_2, \ldots, X_d|R) \\
&= P(X_1|R)P(X_2|R)P(X_3, \ldots, X_d|X_2, R) \\
&= P(X_1|R)P(X_2|R)P(X_3, \ldots, X_d|R) \\
\ldots &= \prod_{i=1}^{d} P(X_i|R) \, .
\end{aligned}$$

Finally, we have:

$$P(R|X_1, \ldots, X_d) = \frac{\prod_i P(X_i|R)P(R)}{\prod_i P(X_i)}. \tag{1}$$

The classifier resulting from this independence assumption is known as *naive Bayes*. The independence assumption underlying the naive Bayes classifier can be expressed as the directed graph shown in Figure 2. The interpretation of the network structure is that a particular pairwise relationship between two genes, e.g. physical interactions, is a consequence of the existence of a functional relationship between the genes. The Bayesian network suggested by Troyanskaya and coworkers introduces some dependencies between the various sources of data, but the general dependency structure is similar to the one presented here. The conditional probability distributions at the nodes of the network were determined by surveying a panel of experts in yeast molecular biology. Thus, there is no learning involved in the construction of the system. The pairwise relationships used in MAGIC are matrices whose i, j element is the degree to which protein i and j share a particular relationship. For some data sources this is a binary score, e.g. the proteins coded physically interact or their genes belong to the same gene expression cluster. For other data sources, the score is continuous, e.g. when measuring expression correlation.

Learning of metabolic networks is an example of learning of functional relationships. In this problem, one learns a network whose nodes are enzymes and whose edges indicate that the two enzymes catalyze successive reactions in a pathway. Yamanishi and coworkers [51] integrate many sources of data in the context of kernel methods and consider two approaches to this problem. (i) A "direct" approach: a classifier is trained on positive examples – pairs of enzymes that are known to belong to the metabolic network versus pairs of enzymes that are not part of the network. (ii) "Learning the feature space": before training a classifier, a low-dimensional feature space is computed. This space captures the proximity between enzymes that belong to the metabolic network. Yamanishi and coworkers find that learning the feature space significantly improves the results, and, further, that integration of several kernels based on expression data, phylogenetic profiles, localization and chemical compatibility gives better results than any individual kernel.

6 Learning Function from Networks of Pairwise Relationships

When pairwise relationships between proteins are known, the function of unknown proteins can be inferred using the "guilt by association" rule by looking at the annotations of its neighbors in the network. This rule assigns a functional annotation using a majority vote among the annotations of the neighboring nodes. This method of assigning function is clearly an oversimplification of the problem since it ignores the larger context in which a node appears. An alternative approach is to integrate information across the network, rather than relying only upon local information. In this section, we describe several approaches that consider the network as a whole when making predictions. All the methods predict a single function of interest using a network in which each protein is a node. Binary node labels indicate whether the protein has the function of interest and a third label value can be added to represent proteins with unknown function. The nodes are connected with edges whose weights reflect the degree to which the two proteins are related. Multiple networks can be used either by merging the networks or by having several networks sharing the annotation variables.

Deng and coworkers proposed a Markov random field (MRF) model to take into account multiple networks of relationships between genes [13]. Relationships such as protein–protein interaction and coexpression are symmetric: no directionality can be assigned to such relationships. Therefore, Bayesian networks that rely on a directed graph to model the dependencies between variables are not readily applicable. MRFs, which represent probabilistic dependencies using undirected graphical models, are therefore a more appropriate modeling choice. The reader is referred to Ref. [38], for example, for an in-depth discussion of MRFs. Deng and coworkers estimate an MRF model for each function of interest, and each protein is assigned a variable X_i with a state of either 1 or 0, depending on whether or not the protein has that function. The joint probability of X, the vector of variables, is written as: $\exp(-U(x))/Z(\theta)$, where x is a value of X, $Z(\theta)$ is a normalization factor that depends on the parameters of the model and:

$$\begin{aligned} U(x) \quad = \quad & -\alpha \sum_{i=1}^{N} x_i - \beta \sum_{(i,j)\in S} \left[(1-x_i)x_j + x_i(1-x_j)\right] \\ & - \gamma \sum_{(i,j)\in S} x_i x_j - \kappa \sum_{(i,j)\in S} (1-x_i)(1-x_j)\,, \end{aligned} \tag{2}$$

where S is the set of edges of the graph, $\alpha = \log(\frac{\pi}{1-\pi})$ and π is the prior probability for observing the function of interest. The first term in Eq. (2) represents the prior probability of observing the configuration x. The rest of the terms represent interactions between neighbors in the network: the first counting the number of neighbors that do not agree on the assignment of function, the second counting the neighbors that share the function of interest and the third counting neighbors that are negative examples.

The training data is a subset of the proteins whose function is known. Using this data, the probability distribution of the function of the rest of the proteins is estimated by conditioning on the state of the known proteins. The probability of an unknown protein having the function of interest can then be obtained by summing over the possible configurations of the rest of the unknown proteins. The authors propose a Gibbs sampling scheme for estimating these probability distributions.

So far we presented the MRF model that uses a single network. When several networks are available, the probability distribution is a product of terms, each of which is of the form (2), sharing the same values of X. The authors also add a component that takes into account the domain composition of the given proteins (see Ref. [13] for the details). The prior probabilities for a protein to be assigned the function of interest is determined using data on protein complexes, according to the fraction of members of the complex that have that function. When that information is not available, a global prior based on the frequency of the annotation is used. Given a set of possible annotations, one can estimate the probabilities of each annotation. Multiple annotations can then be assigned on the basis of the assigned probabilities. The correlations between different annotations are not taken into account.

The authors apply their method to classify yeast proteins using MIPS annotations combining networks from several sources:

- Physical interactions taken from the MIPS database, including 2448 interactions between 1877 proteins.
- MIPS genetic interactions.
- Comembership in a complex obtained using TAP data, including 232 complexes involving 1088 proteins with known function.
- Cell cycle gene expression data. A network is formed by forming edges between proteins whose expression is above some threshold (0.8 in the paper).

The authors find that combining multiple sources of data improves their performance relative to learning from any single data source.

Karaoz and coworkers propose a general framework for integrating and propagating evidence in functional linkage networks [25]. This approach is a generalization of the "guilt by association" rule which, in essence, repeatedly applies the rule until the network reaches a state that is maximally consistent with the observed data. They begin with a functional linkage network in which the edges are defined by protein–protein interactions and the edge weights are defined by correlating the corresponding mRNA expression profiles. A separate network is defined for each functional annotation (GO term) and each node in the network is assigned a label based upon whether the protein is assigned the current GO term (1), a different GO term in the same GO hierarchy (-1) or no GO term at all (0). The optimization procedure attempts to assign labels (1 or -1) to the zero-labeled nodes so as to maximize an "energy" function. Their energy function is similar to the one used in Ref. [13], but the approach is limited to a single network and, rather than assigning function according to the distribution of a variable, they use a local minimum of the energy function. As described, the method integrates two types of data: one used in the definition of the network topology and the other defines the edge weights. A larger number of sources of data can be integrated by performing a preprocessing step of network integration by one of the methods described in the previous section so that the network or the weighting are computed by more than a single source of data. A similar approach is described in Ref. [11]; to address the situation that a node has no annotated neighbors and "guilt by association" cannot be applied at the node, their model has a state space that indicates whether "guilt by association" is ready to be applied at a node.

Rather than trying to estimate a probabilistic network model, one can take a more direct approach of making predictions on the protein graph. An example of this approach is found in Ref. [48]. This paper follows the standard machine learning paradigm of optimizing a two-part loss (or fitness) function. This function is composed of an error term that measures how well the predicted function follows the training data (existing annotations) and a regularization term that ensures the "smoothness" (regularization, in machine learning terms) of the predicted biological function. In the context of learning on a graph, smoothness means that adjacent nodes have similar predicted function. As in the previous approaches, the authors define a graph whose nodes are proteins labeled as "+1" or "−1", depending on whether the protein is annotated with the function of interest. Let n be the number of proteins, and assume that the function of the first p proteins is known and is given by a vector y with elements equal to ±1. Proteins with unknown function have $y_i = 0$. They define a variable f_i which is the predicted annotation of node i. The value of f is estimated by minimizing the function:

$$\sum_{i=1}^{p}(f_i - y_i)^2 + \mu \sum_{p+1}^{n} f_i^2 + \sum_{i,j} w_{ij}(f_i - f_j)^2 \,,$$

where w_{ij} is the weight on the edge connecting nodes i and j. The first term is the error term; the rest are regularization terms: the second term ensures that the value of f for unlabeled nodes is bounded and the third term ensures that adjacent nodes have a similar annotation. Setting $\mu = 1$, this expression can be written as:

$$\sum_{i=1}^{n}(f_i - y_i)^2 + \sum_{i,j} w_{ij}(f_i - f_j)^2$$

where we take into account that the last $n - p$ entries of y are zero. In order to facilitate extending this formulation to multiple networks this is written as:

$$\min_{f,\gamma} \sum_{i=1}^{n}(f_i - y_i)^2 + c\gamma, \;\; f^{\mathrm{T}} L f \leq \gamma \,,$$

where L is the Laplacian matrix $L = D - W$, where $D = \mathrm{diag}(d_i)$, $d_i = \sum_j w_{ij}$. Multiple networks are incorporated as:

$$\min_{f,\gamma} \sum_{i=1}^{n}(f_i - y_i)^2 + c\gamma, \;\; f^{\mathrm{T}} L_k f \leq \gamma,$$

where L_k is the Laplacian for network k. Sparsity and a dual formulation of the problem yield efficient algorithms that enable solving the problem even for large networks. The authors apply their method to predict MIPS categories in yeast (the same data used in Refs. [13, 28]). They use networks based on Pfam domain composition similarity, coparticipation in a protein complex, MIPS physical interactions, genetic interactions and cell cycle gene expression similarity. They obtain similar performance to that of the SDP-SVM method [28] and better than the MRF method [13].

7 Discussion

The methods described in this chapter illustrate that integrating several sources of data provides improved accuracy in protein function prediction. We described several approaches for data integration. Selecting among these various approaches is difficult, because a large-scale experimental comparison of different integration techniques has not been performed. In the end, researchers tend to select the modeling technique that they are most comfortable with.

A related problem for which data integration yields improved classification accuracy is prediction of protein–protein interactions and the related problem of prediction of comembership in a complex. In this domain, examples of vector-space integration include the works described in Refs. [30, 52]. These papers use a collection of features to predict comembership in a complex using probabilistic decision trees and random forests. In these experiments, features include microarray experiment correlations, transcription factor-binding data, localization, phenotype, gene fusion, gene neighborhood and phylogenetic profiles. An example of kernel-based integration is found in Ref. [5] where sequence-based kernels are used in conjunction with kernels based on features such as GO annotations to predict protein–protein interactions. The use of kernel-based classifiers allows the use of a high-dimensional feature-space that cannot be represented explicitly in practice. As in the other examples presented in this chapter, the combined method performs significantly better than methods that use only a single source of data.

The Molecular Basis of Predicting Druggability

Bissan Al-Lazikani, Anna Gaulton, Gaia Paolini, Jerry Lanfear, John Overington, and Andrew Hopkins

1 Introduction

Medicinal chemists have learnt through the experience of many hundreds of screening campaigns in the pharmaceutical industry that for many targets no small-molecule modulators have yet been discovered, even when screened against a diverse chemical file of hundreds of thousands to millions of compounds. Even when the medicinal chemist is fortunate enough to discover a small-molecule modulator of the biological target of interest, it is common for many 'leads' compounds to be unsuitable for optimization into prototype drugs. Chemical biologists may not require such optimized chemical tools, but both the chemical biologist and the medicinal chemist can learn from each other in their experience of discovering chemical tools and leads. The failure of many screening campaigns to discover drug-like leads or chemical tools against certain targets has lead to two competing hypotheses to explain and overcome this phenomenon. The first hypothesis is that the discovery of a chemical tool against a target is a function of the diversity of chemical space screen against the target, independent of the target – the *diversity argument*. The second hypothesis claims that the ability to discover a small-molecule modulator is an inherent property of the physicochemical topology of a biological target, independent of chemical space – the *druggability argument*. These constraints are more severe if the aim is to discover drugs that can be orally administered. The concept of *druggability* postulates that since the binding sites on biological molecules are complementary in terms of volume, topology and physicochemical properties to their ligands, then only certain binding sites on putative drug targets are compatible with binding compounds with high affinity to compounds with "drug-like" properties [15]. Furthermore, the concept also asserts that molecular recognition on biological targets, such as proteins, has evolved to be exquisitely specific at discrete sites on protein surfaces and creates stringent physicochemical limits that restrict the target set available to modulation by small molecules. The extension of

ISBN: 978-3-527-31278-8

this concept to a whole genome analysis leads to the identification of the *druggable genome* – the genes and their expressed proteome predicted to be amenable to modulation by compounds compatible with drug-like properties [14,25].

2 Chemical Properties of Drugs, Leads and Tools

For *in vitro* or cellular experiments the chemical biologists would require a minimum set of physicochemical characteristics of the compound to ensure that the compound is within a range of solubility and polar/hydrophobic balance of properties that enable the tool to permeate the cell membrane and reach the site of action. For the medicinal chemist, the same principles apply, but the great range of biological barriers that a drug needs to pass through in order to affect the biological system of a whole organism is far greater and thus reduces the molecular property range of chemical space. Lipinski introduced the concept of physicochemical property limits to the drugs, with respect to solubility and permeability of drugs from a seminal analysis of the Derwent World Drug Index which demonstrated orally administered drugs are far more likely to reside in areas of chemical space defined by a limited range of molecular properties. Lipinski's analysis demonstrated that 90% of orally absorbed drugs had molecular weights of less than 500 Da, less than five hydrogen-bond donors (such as the OH and NH group count), fewer than 10 hydrogen-bond acceptors (such as the total, combined nitrogen and oxygen atom count being 10 or less) and lipophilicity less than calculated $\log P \leq 5$ [20]. The multiples of five observed in the molecular properties of drugs led to the coining of the term *Lipinski's "Rule of Five"*. Since the work of Lipinski and coworkers, various expansions of the definition and methods to predict "drug-likeness" have been proposed in the literature [1,9,17,19–22, 27,28,31,34–36]. The common thread emerging from the field is that drug-likeness is defined by a range of molecular properties and descriptors that can discriminate between drugs and nondrugs for such characteristics as oral absorption, aqueous solubility and permeability. This is illustrated by the observation that the distribution of mean molecular properties of approved oral (small-molecule) drugs has changed little in the past 20 years, despite changes in the range of indications and targets [33].

3 Molecular Recognition is the Basis for Druggability

The molecular basis of the *a priori* druggability hypothesis derives from biophysical study of molecular recognition. The binding energy (ΔG) of a ligand to a molecular target (e.g. protein, RNA, DNA, carbohydrate) is defined as:

$$\Delta G = -RT \ln K_i = 1.4 \log K_i \tag{1}$$

where R is the gas constant (1.986 cal mol^{-1} K^{-1}).

The affinity of binding is predominately driven by the van der Waals and entropy components of the binding energy by the burying of hydrophobic surfaces. Thus for a ligand, such as a drug molecule, to bind with an affinity of K_i = 10 nM it requires a binding energy (ΔG) of –11 kcal mol^{-1}. A lower affinity "hit" from a high-throughput screen of K_i = 1 μM affinity equates to 8.4 kcal mol^{-1}. Thus, a 10-fold increase in potency is equivalent to 1.36 kcal mol^{-1} of binding energy. The binding energy potential of a ligand is, in general, proportional to the available surface area and its properties. The hydrophobic effect from the displacement of water and the van der Waals attractions between atoms contributes approximately 0.03 kcal mol^{-1} $\mathrm{Å}^{-2}$. Thus a ligand with a 10 nM dissociation constant would be required to bury 370 $\mathrm{Å}^2$ of hydrophobic surface area, assuming there are no strong ionic interactions between the protein and the ligand. Empirical analysis of nearly 50 000 biologically active drug-like molecules reveals a linear coloration between molecular weight and molecular surface area (Figure 1). The contribution of the hydrophobic surface to binding energy is demonstrated by the phenomenon of the "magic methyl", where experienced medicinal chemists often observe that a single methyl group, judiciously placed, can increase ligand affinity by 10-fold, approximately equivalent to the maximal affinity per nonhydrogen atom [16]. The accessible hydrophobic surface area of a methyl group is approximately 46 $\mathrm{Å}^2$(if one assumes all of the hydrophobic surface area is encapsulated by the protein binding site and thus forms full contact with the target) with a hydrophobic effect of 0.03 kcal mol^{-1} $\mathrm{Å}^{-2}$ equal approximately to 1.36 kcal mol^{-1}, equivalent to the observed 10-fold affinity increase. In addition to the predominantly hydrophobic contribution to the binding of many drugs, ionic interactions, such as those found in zinc proteases (such as ACE inhibitors) contribute to the binding energy. The attraction of complementary polar groups contributes up to up to 0.1 kcal mol^{-1} $\mathrm{Å}^{-2}$, with ionic salt bridge approximately 3 times greater, enabling low-molecular-weight compounds to bind strongly. Unlike hydrophobic interactions, complementary polar interactions are dependent on the correct geometry. Thus, encapsulated cavities are capable of binding low-molecular-weight compounds with high affinities since they maximize the ratio of the surface area to the volume.

Thus, the physicochemical characteristics of the binding site define the physical and chemical properties of the ligand. Therefore, a target needs a pocket, whether the pocket is predefined or formed on binding by allosteric mechanisms. In general, thermodynamics and selection pressure play a part in reducing the accidental existence of such favorable pockets for ligand

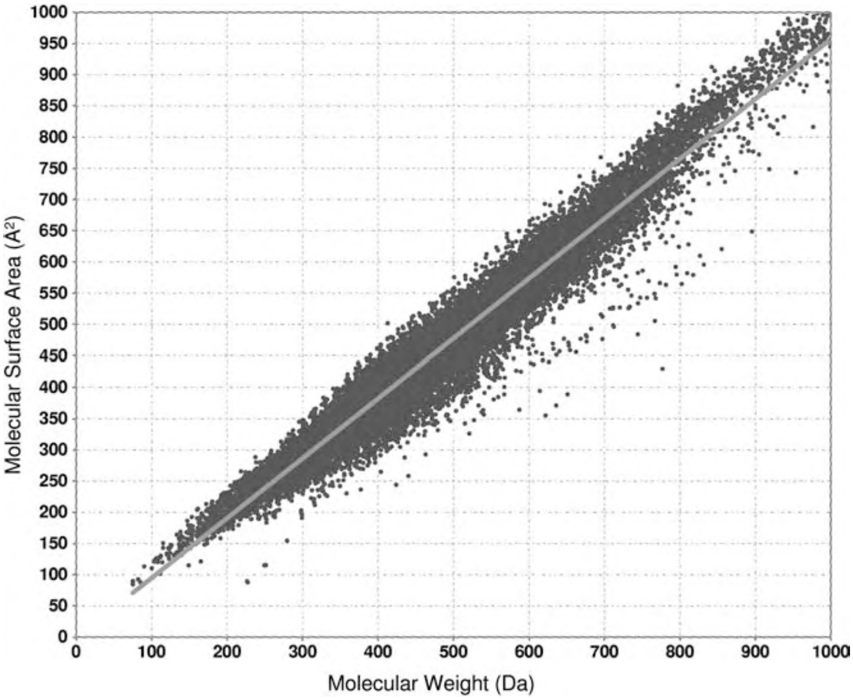

Figure 1 Relationship between molecular weight and molecular surface area. Analysis of 49 456 biologically active, drug-like compounds with $IC_{50} \leq 100$ nM. Molecular weight was calculated from the chemical structures represented as desalted, canonical SMILES strings. The calculated molecular surface area of N, O, P and S atoms was estimated using the fast Ertl method [10] using a two-dimensional approximation. All other atom types (excluding H atoms) were estimated using an overlapping spheres method. All calculations were performed using Scitegic's Pipeline Pilot (San Diego, CA.).

interactions. The thermodynamic argument contests that it costs energy to maintain an exposed hydrophobic pocket in an aqueous environment. Selection pressure may also increase the specificity of molecular recognition for ligand pockets to avoid inappropriate signaling or inactivation from the milieu of metabolite and small molecules in which cells are bathed.

A quantitative approach is already well established for assessing the drug-like properties of a small molecule, could such a quantitative approach for assessing the properties of proteins as drugs? The "Rule of Five" is a set of properties to suggest which compounds are likely to show poor absorption or permeation, since such compounds are unlikely to show good oral bioavailability [20]. Physicochemical constraints such as this limit the type of proteins we see as drug targets; simply put, drug targets need to be able to bind compounds with complementary properties. As a receptor binding site must be complementary to a drug, it is reasonable to assume that equivalent rules could be developed to describe physicochemical properties of binding sites with the potential to bind "Rule of Five" compliant molecules with a potent binding constant (e.g. $K_i < 100$ nM). A number of properties complementary to the "Rule of Five" can be calculated, e.g. the surface area and volume of the pocket, hydrophobic and hydrophilic character, and the curvature and shape of the pocket. Following the assumption that properties of the drug are complementary to those of the binding site, analysis of the calculated physicochemical properties of the putative drug binding pocket on the target protein can provide an important guide to the medicinal chemist in predicting the likelihood of discovering a drug against the particular target site. Based on the known physicochemical properties of passively absorbed oral drugs, one would predict "druggable" binding sites to be predominately apolar cavities of 400–1000 Å^{3}'where over 65% of the pocket is buried or encapsulated, with an accessible hydrophobic surface area of at least 350 Å^{2}.

Druggability predictions have been empirically explored using heteronuclear nuclear magnetic resonance (NMR) to identify and characterize the binding surfaces on protein by screening around 10 000 low-molecular-molecules (average molecular weight 220, average cLog$P$ 1.5) [13]. Screening results from 23 proteins reveal 90% of the ligands binds to sites know to be a small molecule ligand binding sites. In the relative small sample of proteins studied, Hajduk and coworkers note a high correlation between experimental NMR hit rates and the ability to find a high affinity ligands. Only in three out of the 23 proteins were distinct uncompetitive new binding sites were discovered. The authors' postulated that these new sites could possibly play an unknown physiological role in the proteins functions.

4 Estimating the Size of the Druggable Genome

Whilst our current knowledge may be limited in predicting *a priori* where uncompetitive allosteric binding sites may appear from a protein sequence, we may be able to identify at the sequence and structural level which targets are more likely to be potentially amenable to modulation by drug-like small molecules from extrapolation of our current knowledge.

Using knowledge of proteins to which current drugs and leads bind, we can infer the subset of the human genes and protein that have a high probability of being potentially druggable, i.e. capable of binding drug-like small molecules with high affinity. Outlined below are a number of methodologies and approaches that have been used to infer the druggable portion of targets encoded by the human genome. In this chapter we have extended the work of Hopkins and Groom, and attempted to estimate the size of the druggable human genome using three distinct methodologies:

- Homology-based analysis from comprehensive survey of drugs and leads
- Feature-based probabilistic druggability analysis
- Structure-based amenability analysis

4.1 Initial Estimates

In order to begin to gauge the number of possible drug targets in the human genome, one should begin with a survey of the knowledge of the current modes of action of existing drugs. In a review of the pharmacological literature, Drews [7, 8] identified 483 targets for known drugs. From this figure Drews later estimated the number of ligand binding domains as a measure of the number of potential points at which small molecule therapeutic agents could be close to 10 000; however, the methodology of how these numbers were derived is not disclosed [6].

4.2 Hopkins and Groom's Method

The first systematic survey of the druggable genome, following the publication of the draft human genome [18, 32], was by Hopkins and Groom [14]. Hopkins and Groom attempted to identify the genes which produced potentially druggable proteins by their membership of druggable gene families. The explicit assumption of a gene family-based analysis is that the conserved architecture of the druggable protein domain is likely to be conserved amongst related members of that domain's gene family. Hopkins and Groom approached the problem in two stages. (i) A database of drug target sequences from a comprehensive survey the literature and investigation drug databases was complied. (ii) The constructed drug target sequence database as used to identify related members of a putative druggable gene family from the protein domain annotation of the translated human protein sequences. Hopkins and Groom's analysis of the literature, the Investigational Drugs Database and the PharmaProjects databaseidentifies 399 nonredundant molecular targets shown to bind "Rule of Five" compliant compounds, with binding affinities below 10 μM. Whilst there is some degree of overlap with Drews' work [7, 8], a significant amount of redundancy was observed in the initial study. In addition a number of new proteins targeted by experimental drugs were captured. Likewise, some targets for biological agents, for which modulation by "Rule of Five" compliant compounds has not yet been shown, were eliminated from the survey. Nearly half of the targets fall into just six major gene families: G-protein-coupled receptors (GPCRs), serine/threonine and tyrosine protein kinases superfamily, zinc metallopeptidases, serine proteases, nuclear hormone receptors, and phosphodiesterases (PDEs). Of the 399 targets of marketed and experimental drugs identified, 376 sequences could be assigned to 130 drug-binding domains, as captured by their InterPro domain annotation. Of these, 125 are domains with homologs and orthologs present in the human proteome. The sequence and functional similarities within a gene family assume a general conservation of binding site architecture between family members. The explicit assumption being that if one member of a gene family is modulated by a drug molecule, other members of the family could also be able to bind a compound with similar physicochemical properties. Following the above logic, 3051 genes were identified as belonging to the 125 druggable InterPro domains and thus predicted to encoded proteins that have some precedence for inferring their ability to bind a drug-like molecules.

Hopkins and Groom's database identifies only 120 biological targets as the modes of action for marketed, "Rule of Five" compliant drugs – significantly less than the previous estimate that launched drugs acted on 483 targets. Interestingly, the vast majority of the drugs and leads identified in this survey, about 90%, are competitive with an endogenous ligands at a structurally defined binding site. This figure is similar to the rates of discovering new binding sites by Hajduk and coworkers [13] (Hopkins, personal communication).

4.3 Orth and Coworkers Update 2004

Orth and coworkers [24] based an estimate on the druggable gene families on the InterPro domain assignments in the annotated gene-encoding loci of the 2004 release of the Consensus CoDing Sequence (CCDS) database. The authors estimate the 3080 nonredundant gene-encoded loci in the human genome predicted to be belonging to the druggable genome with over 2950 druggable gene sequences in public databases.

4.4 Russ and Lampel's Update 2005

Russ and Lampel [30] conducted an estimate on the druggable genome based on the preliminary final assembly (Ensemble Release 35) of the human genome where 99% of the sequence has high quality cover. The authors found Pfam protein domain annotation predicted fewer false positives than the InterPro classification used by Hopkins and Groom [14], estimating 3100 druggable genes from the previously defined set of druggable protein domains, approximately 2900 of which were predicted by both approaches. Of the 3100 predicted genes, 2600 are covered by the consensus CCDS annotation of the major genome databases. Extrapolation from the manual VEGA genome annotation databases (about 40% of total genome) leads the authors to a conservative estimate of around 2500 druggable genes. The authors consider these assessments from the high confident gene prediction databases to be a considered lower conservative estimate of the size of the druggable genome.

5 Homology-based Analysis of Drug Targets

In order to expand the homology analysis methodology for identifying which targets expressed from the human genome are likely to be druggable, it is necessary to expand our survey to identifying all known biological targets of drugs and lead compounds. Inpharmatica commissioned the construction of two databases, DrugStore and StARLITe, to accurately ascertain the number of biological targets modulated by drugs and preclinical medicinal chemistry compounds, respectively.

Inpharmatica's DrugStore is a relational database relating all Food and Drug Administration approved drugs to their molecular targets and approved indication. From this analysis we have identified 26 000 drugs products which reduces to 1783 unique new molecular entities (NMEs), of which 1415 are small molecule chemical entities, 180 are biological therapeutics (18 of which are antibodies), and the remainder are vitamins and supplements. As drug discovery has been more target-centric over the past two decades in its research *modus operandi*, a key point of debate has been how many modes of action acted upon by approved drugs? The first attempt to ascertain this number was by Drews, who estimated known drugs acted on 483 targets – the source of the often quoted "500 targets" figures. Hopkins and Groom's analysis challenged this figure and suggested, irrespective of poly-pharmacology off-target effects, "Rule of Five" compliant (orally administered) approved drugs acted primarily on only 120 modes of action. A subsequent analysis by Burgess and Golden proposed all approved NMEs consisting of new chemical entities (NCEs) and new biological entities (NBEs) targeted 272 proteins [3, 5, 11, 12]. Here, we propose from analysis of the DrugStore database all NMEs primarily act on 301 drugs targets of which 238 are human proteins and only 170 are human proteins targeted by small-molecule drugs (Table 1 and Figure 2). Biological drugs target 59 modes of action with current marketed antibody therapeutics acting on 15 human targets. Only nine targets are currently found to be modulated by both small-molecule and biological drugs. The remaining targets are predominately anti-infective drug targets.

The drug target universe expands considerably if we expand our analysis to include biological targets for which medicinal chemists have developed small-molecule leads. Unlike the bioinformatics community which has developed a wealth of public databases to assemble and disseminate protein and genomic sequences, medicinal chemistry structure–activity relationship (SAR) data is not publicly available in a systematic database and is spread between com-

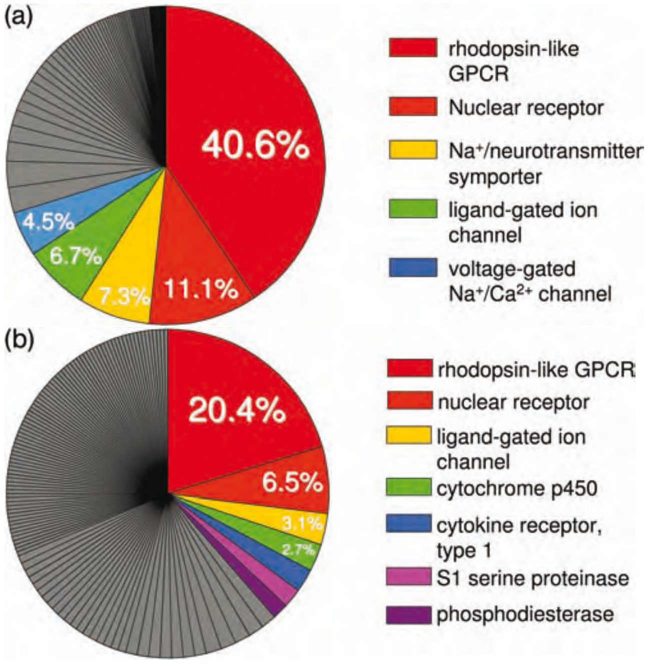

Figure 2 Molecular targets of current Food and Drug Administration approved drugs (a) by numbers of drug substances and (b) by number of drug target in gene family. Targets of approved biologicals	all (anti-infectives and human)	59

pany in house data warehouse, of peer-reviewed journal articles and patents, often in formats not easily accessible to machine processing. In order to survey the universe of drug targets with known leads, Inpharmatica have created the StARLITe database of bioactive compounds by extracting structures, assays, targets and SAR from the key medicinal chemistry journals (i.e. *Journal of Medicinal Chemistry* 1980–2004, *Bioorganic and Medicinal Chemistry Letters* 1990–2004) covering 350 000 compounds and 1 275 000 assay points. The comprehensive survey of medicinal chemistry identifies 1155 targets known to have at least one drug or lead compound bind with an affinity below 10 μM, 707 of which are human molecular targets (Table 2 and Figure 3). Applying

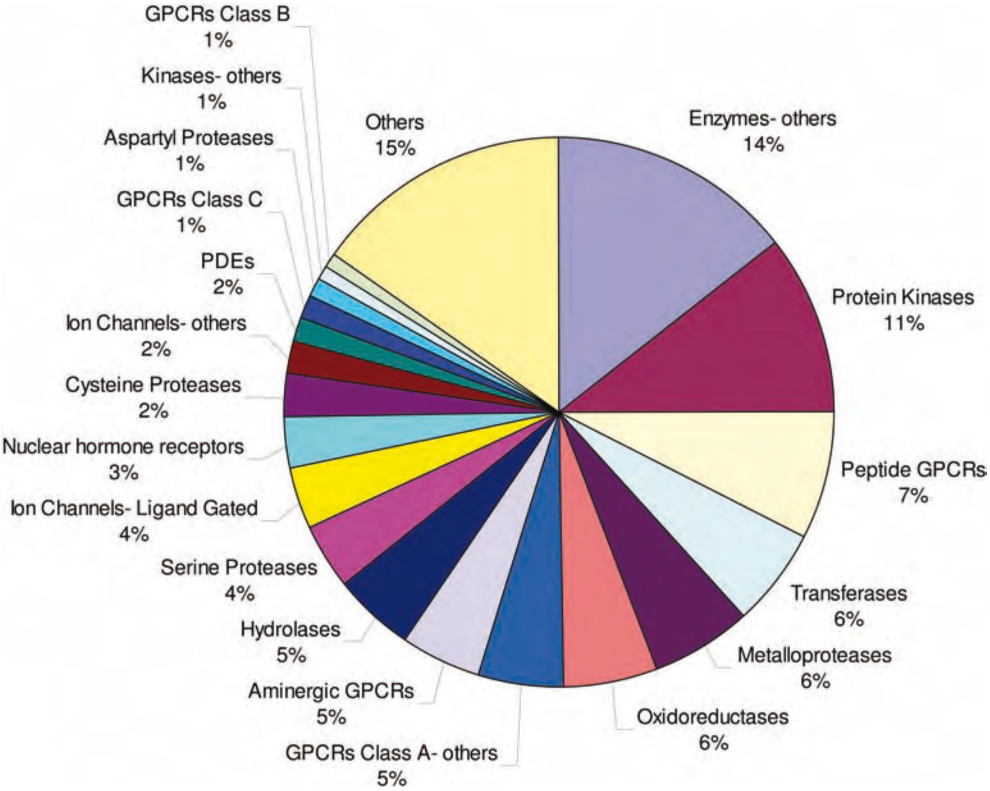

Figure 3 Gene family distribution of nonredundant human proteins with small-molecule chemical leads with binding affinities below 10 μM. Data derived from an analysis of Inpharmatica's StARLITe database.

Lipinski's criteria to the compounds in the dataset (as represented as desalted, canonical SMILES strings) reveals 587 human proteins with at least one or more compounds which complies with the "Rule of Five" with a binding affinity more potent than 10 μM, which could be unambiguously identified and assigned to a protein sequence (Figure 4). The extremely through analysis of the literature, represented in the StARLITe database, more than doubles in size the number of identified proteins with existing lead matter.

Using this larger database of drug targets which show some precedent of modulation by small-molecule leads or drugs we attempted to estimate the size of the potential druggable genome based on a homology to known drug targets. The underlying assumption in this analysis is that if one gene family member has shown the propensity to selectivity bind small-molecule modulates other members of the gene family may significant contain physicochemical and architectural properties that they are also like to bind drug-like small molecules. Proteins that have a similar sequence are generally likely to

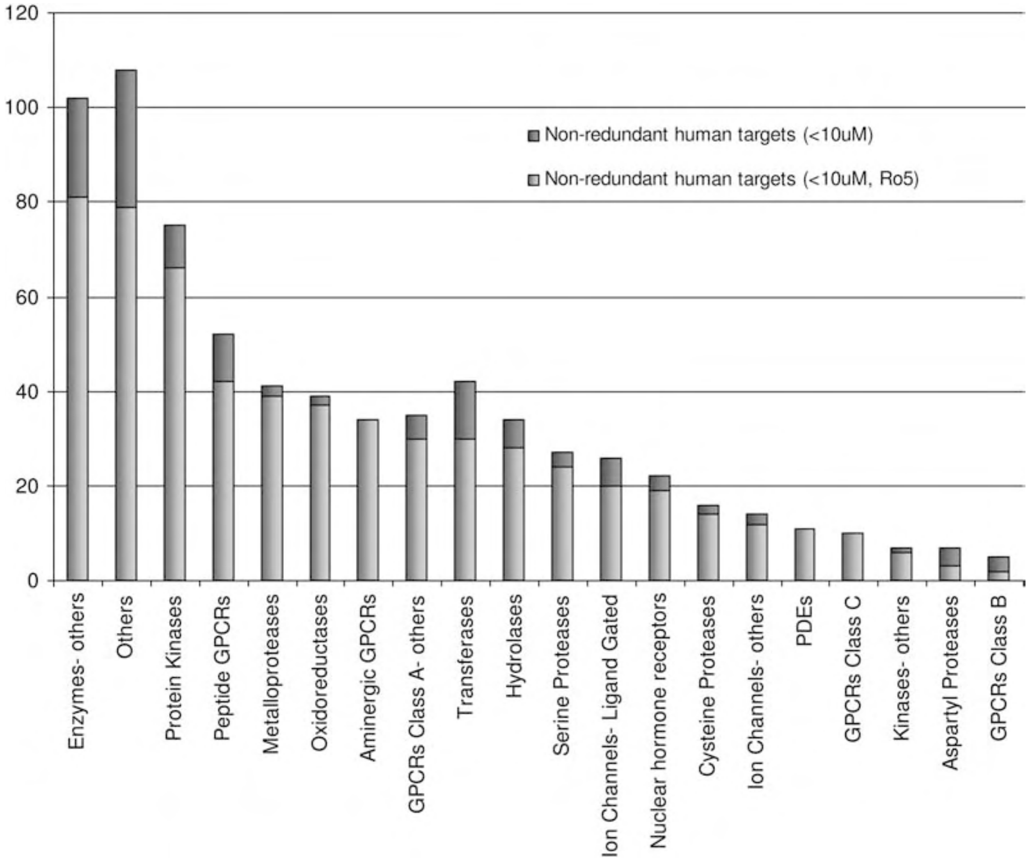

Figure 4 Proportion of targets with leads observed with at least one "Rule of Five" (Ro5) compliant compound within each gene family.

share very similar three-dimensional and perform similar or related functions. If a protein therefore has a high degree of sequence similarity to the target of a drug (or other proteins that is known to be druggable), we predict that proteins is likely to be druggable too, if we believe the binding site architecture to be conserved. Where proteins are less closely related in sequence, it is more difficult to infer druggability. Relatively small differences in the binding site of a protein could have a large impact on its ability to bind small molecules. The authors recognize that this is a simplistic assumption and is likely to overestimate the number of potential members of the predicted druggable subset of the human genome. For example, many individual members of the gene family may bind distinct ligands. The molecular recognition properties of their respective binding sites could be significantly divergent. Using the BLAST sequence alignment algorithm to search each of the sequences against the human genome, we identified 945 distinct genes that show homology to

the molecular targets of approved drugs at a cutoff of 30% sequence identity and E-value less than or equal to 10^{-5}. Expanding the BLAST analysis to include human proteins from the known drug-like leads from the StARLITe database identified a 2921 protein sequences within the same sequence identify cutoffs.

In addition to using a sequence homology approach, we also approached the problem of identifying the druggable subset of the human proteome using a feature-based Bayesian method.

6 Feature-based Druggability Prediction

Drug targets, be they targets of small-molecular-weight drugs or protein therapeutics, may share common sequence-based features that are not necessarily detectable by overall sequence similarity. An alternative approach to using sequence-based similarity methods is to examine the presence of sequence-based features that are enriched in drug targets compared to that of the rest of the genome. A large set of over 100 protein properties and features were calculated for each sequence in the DrugStore database such as the number of transmembrane helices, signal peptides, isoelectric point, length distribution, percentage of helical structure, antigenicity, net charge at pH 7.4, domain complexity, subcellular localization, etc. Features that were enriched in existing drug targets retained and used to construct probabilistic Bayesian models for both small-molecule druggability prediction and protein therapeutic druggability prediction. The implementation of this Bayesian probabilistic scoring allows for ranking any portfolio of targets based on their predicted druggability. The major advantage of this approach is the independence of any prior knowledge about the examined protein, or homology to precedent target families. The Bayesian models also hold the advantage of being tunable to reflect specific gene families, or drug profiles. The probabilistic models were then used to rank all sequences from human genome according to both small-molecule and protein druggability as predicted by the presence of druggable features in the protein sequence. The small-molecule model predicts 2325 gene products to be druggable with high confidence (i.e. achieving scores comparable with those of existing targets).

7 Structure-based Druggability Analysis of Protein Data Base (PDB) Structures

Following the hypothesis that druggable binding sites can be predicted *a priori* we have developed an algorithm to analyze the PDB for druggable binding sites. Actual and putative ligand-binding sites were, respectively, identified either by virtue of the presence of a ligand in the crystal structure or by analysis of the surface of the protein structure. A range of physicochemical properties of the identified binding sites and cavities were calculated from the protein structures including volume, depth, curvature, accessibility, hydrophobic surface area and polar surface area. The algorithm was trained set against a test set of 400 protein complexes binding small molecule, "Rule of Five" compliant ligands. From this analysis a decision tree was derived to predict the druggability of a binding site or cavity from calculated physicochemical properties. The decision tree predicts whether a cavity is druggable within the statistical confidence of the tree. This method has a demonstrated a 91% success rate when predicting druggability on the protein drug targets (of oral drugs as defined in Inpharmatica's Drugstore database of approved drugs). The method requires either an experimentally derived structure or a high-quality homology model. Ideally, due to the inherent flexibility of many protein-ligand binding sites a sample of multiple conformations is preferred. The method is scalable to be employed on the entire PDB (December 2004 release). By removing short peptides, 27 409 files were suitable for analysis, which was further classified into 76 322 structural domains using SCOP [23] and DISCObase of which 28% (21 522) of the structural domains were found to have at least one site predicated, to some degree, to be druggable. Due to the high redundancy in the PDB and the high number of ligand–protein complexes reduced to a nonredundant set of human targets 427 proteins were predicted to contains a druggable binding site, with 281 of these proteins having no prior known compounds or drugs developed against those targets. Structure-based druggability algorithms could be automatically applied to continuously assess the stream of novel structures determined by the structural genomics initiatives.

Combining a nonredundant set of genes from all methods outlined above:

- current targets of approved drugs
- current targets of chemical leads or chemical tools
- sequence homology to current drug targets
- sequence homology to current chemical lead targets
- feature-based sequence probability prediction
- structured-based prediction
- sequence homology to structure-based prediction

we identify a total of 3505 unique genes that are predicted with first- and second-order evidence and high confidence to encode small-molecule druggable proteins of which only 170 are the primary human targets for marketed drugs (Table 3). The results of this combined analysis concur with the previous estimated by Hopkins and Groom [14] which approximately 14% of the human genome could be inferred to be potentially druggable.

Table 3 Predictions of the size of the human druggable genome

Druggability prediction method	No. molecular targets
Targets of approved NCEs	170
Sequence homology to NCE drug targets	945
Targets of chemical leads with activities (binding affinities) below 10 μM	707
Targets of "Rule of Five" chemical leads with activities (binding affinities ≤10 μM)	587
Sequence homology to targets with chemical leads	2921
Feature-based druggability sequence probability prediction	2325
Structured-based prediction	427
Sequence homology to proteins predicted druggable by structure-based method (high confidence)	3541
Sequence homology to proteins predicted druggable by structure-based method (low confidence)	6619
Predicted druggable genome (high confidence)	**3505**

Unique druggable targets from combining drug targets, targets with leads, homology to drug/lead targets and structure-based prediction.

8 How Many Drug Targets are Accessible to Protein Therapeutics?

If our explorations of the proportion of the protein targets expressed by the human genome accessible to modulation by high-affinity, drug-like small molecules is limited, how much larger is the universe for drug targets if we expand our investigations to include targets of protein therapeutic such as antibodies and recombinant biologicals? At the time of writing, approved antibody therapeutics were known to act on 15 human targets, whilst in total all biological drugs in the pharmacopoeia currently work via 59 modes of action. Due to the inherently lower toxicity observed for fully humanized antibodies and the rising rate of biological approvals, it has been argued that antibodies may soon overtake NCE approvals [2]. Interestingly, it has also been observed by studying rates of attrition that antibodies acting against novel modes of action often shown a higher chance of success in phase II clinical studies than small-molecule drugs acting on precedent mechanisms [26, 29, 37]. Thus, we attempted to estimate how many targets are accessible to biological drugs as the targets of antibody therapies. Other criteria, such as antigenicity, are also important in developing inhibitory antibodies. However, these have not been considered in this analysis, as they are not common to both antibody and other protein drugs.

In order to estimate the number of genes expressing products that could be accessible to antibody therapeutics we assume that proteins are required to be located in the extracellular matrix. We assume that extracellular location is the common characteristic of secreted and transmembrane of proteins. Where the extracellular location is known, this is often included in Swiss-Prot and Gene Ontology (GO) [4] database annotation for the protein. Secreted proteins can be predicted by the presence of a signal peptide, whilst transmembrane domains can be identified by sequence property prediction. Analysis reveals 1384 genes predicted to encode secreted proteins with high confidence (i.e. predicted by multiple different methods). If the confidence level is lowered (i.e. signal peptide predicted by single method), 6560 genes are predicted to potentially be secreted. Our transmembrane analysis reveals that 973 genes are predicted, by multiple methods, to have transmembrane domains and be located inside the plasma membrane. This number increases by 1407 genes which are predicted to be plasma membrane proteins only by a single method. Combining these results together we identify the total number of extracellular proteins, with high confidence, to be expressed by 2287 genes. The study was extended to identify proteins that contain feature similar to the current set of biological drug targets using the Bayesian probabilistic featured-based algorithm discussed above. Trained on the existing set of biological drug targets 1637 gene products were predicted to be druggable *via* biological therapeutics with high confidence (i.e. achieving scores comparable with those of existing protein targets). Therefore, the total number of genes predicted to encode protein therapeutic druggable proteins is 3258 genes equivalent to 13% of the gene in the human genome (Table 4).

Table 4 Predictions of the number of genes in the human genome accessible to protein therapeutics (recombinant soluble proteins and antibodies)

Druggability prediction method	No. of molecular targets

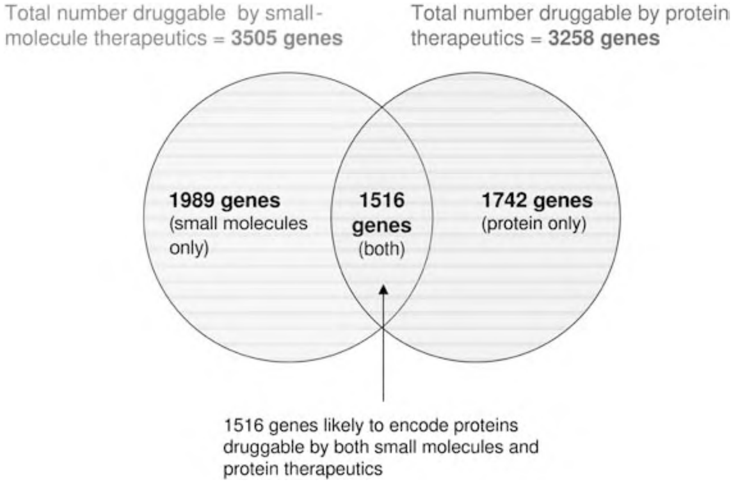
9 Conclusions

From a comprehensive survey of the medicinal chemistry literature, and by combining a variety of methodologies, sequence homology, structure- and feature-based, we have identified approximately 3500 genes in the human genome that are predicted to be accessible to modulation by high affinity



Total number druggable by small-molecule therapeutics = 3505 genes
Total number druggable by protein therapeutics = 3258 genes
1989 genes (small molecules only)
1516 genes (both)
1742 genes (protein only)
1516 genes likely to encode proteins druggable by both small molecules and protein therapeutics

Figure 6 Overlap of antibody and small-molecule druggable universes.

drug-like small molecules: approximately 14% of the human genome. Of the approximate 3500 human druggable genes, small-molecule chemical tools or leads (with binding affinities equal or more potent that 10 μM) have already been identified that act on 707 of these and 170 are the primary targets for approved, small-molecule drugs. Whilst there may be many more proteins expressed by the human genome that may be discovered to be modulated by small-molecule tools or drugs, the proteins identified as belong to the subset known as the "druggable genome" represent those targets we can readily predict have a higher confidence of discovering a small-molecule chemical tool than the remaining genes in the genome. Since it was first proposed that the various physicochemical constraints on drug-like chemicals would reduce the available targets space it has been suggested that the accessible drug target space may expand considerable with the application of biological drugs such as fully humanized antibodies. To date, approved protein therapies act via about 59 human targets, 18 of these are targeted by marketed antibodies. With the commercialization of recombinant protein production the number of biological drugs receiving approval and being studied in the clinic is steadily rising. Several commentators predict that the rise of antibody therapies may challenge the premier position of small-molecule chemical entities as the dominant technology of medicinal chemistry [2]. Our analysis of the proposition of the genome potentially accessible to modulation by protein therapeutics, such as antibodies is around 13%, with 3258 genes predicted to encode proteins potential druggable via protein therapeutic proteins. Interestingly, 70% of all the drug targets are also predicted to be accessible to modulation by antibody therapy. Indeed, if we expand the analysis to compare the overlap between the antibody-accessible druggable genome and the “small-molecule druggable” genome, 1516 genes are predicted to encode proteins druggable by both small molecules and protein therapeutics – approximately 45% of our current estimate of the small-molecule druggable genome (Figures 5 and 6).

Acknowledgments

We would like Colin Groom (UCB Celltech, Cambridge, UK) for his long-standing contribution to this work. We also sincerely thank Edith Chan (Inpharmatica, London), Robin Spencer (Pfizer, Groton), Lee Beeley (Pharmamatters, Ramsgate) and Jonathan Mason (Pfizer, Sandwich) for their helpful discussions in this development of this work.

Part 9
Comparative Genomics and Evolution of Genomes

37
Comparative Genomics

Martin S. Taylor and Richard R. Copley

1 Introduction

Comparative genomics is an approach that uses the signal of past selection as a highly sensitive assay for function in genome sequences. Unlike experimental approaches, it does not require a prior hypothesis of that function. The realization that comparative sequence analysis is crucial to understanding the functions encoded in the human and other genomes is driving a major comparative sequencing effort. The fruits of this labor are a rapidly expanding number of whole-genome sequences and new computational methods to analyze these data in efficient and meaningful ways.

In this chapter, we introduce the concepts and techniques of comparative genomics; in doing so we build on the foundations laid in earlier chapters, particularly Chapter 3 on sequence alignment and Chapter 4 on phylogenetics. In general terms, the approaches we describe can be applied to any collection of organisms, but our emphasis here is primarily on questions of relevance to human genomes. We begin, in Section 2, by presenting an overview of genome structure and content, providing a context for the subsequent discussions. We then introduce the concepts of natural selection, homology and phylogenetic distance that underlie comparative genome analyses in Section 3. In Section 4, we consider the types of questions that can be addressed and the strategies that can be employed to address them. We also consider the availability and accuracy of genomic sequence data. In Section 5, we introduce the three main technical challenges of comparative genomic sequence analysis – genomic sequence alignment, the visualization of sequence relationships and detecting the signal of selection. We review the methods employed to meet

Bioinformatics – From Genomes to Therapies Vol. 3. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

these challenges and discuss the most popular, and the most promising new tools. In Section 6, we illustrate the utility of comparative genomic studies with recent applications that have given new insights into human biology. Finally, in Section 7, we highlight some resources that are likely to have a profound impact on future comparative genomic studies and identify future research challenges.

2 The Genomic Landscape

The human genome is approximately 3 200 000 000 (3.2 Gb) nucleotides long [50]. At first sight, a monotonous repetition of A, T, C and G representing the four nucleotides of DNA, it is in fact a diverse and still in many ways mysterious landscape. Of the total 3.2 Gb, 2.85 Gb have been sequenced to high accuracy [50]; the remainder are largely attributable to heterochromatic regions (centromeres and telomeres) that are highly repetitive and refractory to current sequencing technology.

Proteins are often thought of as the principal functional product of a genome. Consequently, protein-coding sequences are the first place screened for disease-associated mutations and functionally significant polymorphisms. The human genome encodes approximately 22 000 protein-coding genes (http://www.ensembl.org), although the total diversity of proteins produced is likely to be several times this thanks to alternate transcription initiation and processing [19, 67]. However, it appears that this protein-coding sequence accounts for less than 1.5% of the human genome sequence [59]. The situation is similar in rodents [40, 114], other mammals [63] and, to varying degrees, other vertebrates [4, 46]. These estimates of coding sequence content appear to be robust, they are based on the integration of comparative data [90] and transcript evidence [89], and they are also consistent with extrapolation from the detailed investigation of targeted regions [75]. This finding does of course raise the question "What is the function of the remainder of the genome?" and even questions whether the majority of a vertebrate genome is subject to any selective constraint.

A protein is translated from an mRNA which contains a contiguous protein-coding "open reading frame", flanked by stretches of noncoding sequence. In eukaryotes, the genomic DNA that provides the template for mRNA synthesis is often found as a series of collinear but discrete segments (*exons*), interrupted by *introns*. Although transcribed, the introns are spliced from the mRNA prior to protein synthesis. This is a marked difference from the situation in prokaryotic organisms (Chapter 41), where the mRNA template is typically uninterrupted. Particularly in higher eukaryotes such as mammals, the length of introns often far exceeds that of exons. In addition to the sequences that are transcribed into RNA, a gene will have an associated core-promoter region immediately upstream of the transcribed region. The core-promoter region acts to drive transcription and consequently expression of the gene. However, it is common, especially in higher eukaryotes that there are other sequences, potentially distantly located [61], that are also crucial to the appropriate regulation of gene expression.

Pseudogenes are the remnants of functional genes that have apparently lost the ability to perform any useful function. Often, this means that they look obviously like protein-coding genes, but that they have accumulated changes such as in-frame stop codons that would prevent them producing a functional protein. Pseudogenes can arise through duplication where one copy of a gene retains and continues to perform the original function, whereas the other is redundant so free to accumulate changes that disrupt its function without detriment to the fitness of the organism. Alternately, the function of the gene may no longer be required – the human *GLY1* pseudogene possibly provides such an example, the ancestral gene acting in threonine catabolism, but for which the only human copy contains multiple in-frame stop codons [31], again the selective constraint is removed. In both of these cases the gene becomes a nonprocessed pseudogene.

A major component of the human and many other higher eukaryotic genomes is sequence derived from *interspersed repetitive elements (IRE)* such as endogenous retroviruses, retrotransposons and DNA transposons. At least 45% of the human genome is identifiably derived from IREs [59], although this almost certainly underestimates their true contribution as older, more divergent repeat-derived sequences are unlikely to be identified. These elements are often considered "junk" DNA and rarely have organism-level biological functions been attributed to them, although a small number of exceptions are known [52, 58]. It is interesting to note that some vertebrate lineages, most notably that of the pufferfish, are almost devoid of such IRE-derived sequence and have a genome approximately 8-fold smaller than the human despite encoding a similar number, or possibly slightly more, protein-coding genes [4].

Processed pseudogenes are a consequence of a genome rich in repetitive elements, specifically those that replicate and transpose through the reverse transcription of RNA into DNA. Occasionally, rather than reverse transcriptase, the enzyme responsible for reverse transcription, driving the replication of an IRE, it will reverse transcribe the mRNA of a gene. The result is a processed pseudogene – the copy of an mRNA integrated into the genome. These are distinct from the pseudogenes discussed above as they bare the hallmarks of transcript processing, such as the removal of introns and $3'$ polyadenylation [119]. Processed pseudogenes are often incomplete at the $5'$ end – a consequence of reverse transcriptase reading the $3'$ end of the mRNA first. Some genes such as those encoding the ribosomal proteins are particularly susceptible to generating new processed pseudogenes [119], probably reflecting in part the level germline transcript of the gene.

In probably every measure that has been made of the human genome sequence, it has been found to be far from homogeneous. We have already seen the distinction between heterochromatic regions that appear to perform roles in the packaging and segregation of chromosomes. Throughout the rest of the genome (the euchromatic regions), there is considerable variation in gene density (the number of genes per unit sequence), IRE content, nucleotide and dinucleotide frequency, and the observed rates of genetic recombination, nucleotide substitution, insertions and deletions. Many of these attributes have been found to covary across the genome [40, 45, 101], but currently the bases of their interrelationships are not well understood. Of particular relevance to comparative genomic studies is the fluctuation of substitution, insertion and deletion rates across the genome [117], which suggest there may be regional variation in the rate at which mutations occur. At least in rodents, the scale of this variation is of the order of 1 Mb, so that the substitution rates for two neutrally evolving regions of sequence are highly correlated if they lie within this distance of each other, but the correlation decreases rapidly with increasing genomic distance [38].

The rate of sequence mutation is not only dependent on the large-scale region of a genome, but also on the sequence and composition of neighboring nucleotides [45, 108]. For example, tandemly repeated sequences and mononucleotide tracts are prone to insertion and deletion mutation [108]. The epigenetic methylation of cytosine nucleotides when they are located directly upstream of a guanine (CpG) is a common occurrence in mammalian genomes and, to a lesser extent, in other metazoa [8]. This nucleotide modification has had a major influence in shaping mammalian genomes. Thanks to a quirk of biochemistry, a methylated C can mutate to T at a much higher frequency than all other nucleotide substitutions can occur. As a result, CpG dinucleotides are grossly under-represented across the majority of the human genome, relative to chance expectation given the frequency of C and G nucleotides (approximately 20% of the expected frequency [59, 104]) and CpG mutation rates tend to be substantially higher than those of other dinucleotides. However, within specific islands of sequence (commonly known as CpG islands), CpGs are not methylated, at least in the germline [9], so are not under-represented. CpG islands are often associated with the $5'$ end and promoters of some genes [9], so represent sequences that are often of particular interest in comparative genomic studies.

Segmental duplications are a genomic feature that can often cause problems for sequence assembly such that they are frequently overlooked. These are large (typically 5 kb is taken as a minimum threshold in their definition) tracts of sequence that occur multiple times in a genome, often as tandem repeats. These duplicated regions can contain whole genes or even multiple genes. Recent segmental duplications will share a high degree of nucleotide identity and are likely to be polymorphic in the population, and the mechanism of segmental duplication provides a rapid means of divergence between species [60, 80].

3 Concepts

The replication of DNA is imperfect – new mutations are continually arising with each generation. In the absence of natural selection, the eventual fate of a new mutation will be determined by genetic drift, i.e. chance fluctuations in frequency that result from sampling a finite population. For most mutations this will result in their loss from the population, but some will drift to fixation. As this is a random process, any observed sequence changes can be considered an unbiased sample of all mutations that occurred. However, natural selection disrupts this unbiased sampling of mutations.

Through the cumulative action of past evolution, most functional DNA is expected to have attained a sequence that is near-optimal for its environment. Consequently, mutational changes are likely be detrimental, i.e. to result in a departure from the optima and removed by purifying selection. As a result, functionally important sequences are expected to accumulate fewer mutational changes than neutrally evolving DNA, so functional regions of two sequences diverged from a common ancestor are expected to be more similar than nonfunctional regions. Local regions of sequence similarity resulting from selective constraint are often referred to as a phylogenetic footprint [105].

At the opposite end of the selective spectrum is diversifying (positive) selection. Following environmental change, an existing sequence may no longer be optimal and new mutations could provide a selective advantage, in which case they are likely to increase in frequency in the population, as it responds to the change in selective pressure. Diversifying selection can lead to changes accumulating at a faster rate than in neutrally evolving sequence. There are instances such as sexual selection and host– pathogen arms races where there is sustained selective pressure for diversification [81], but in the majority of cases a period of diversification will be both preceded and succeeded by longer periods of purifying selection. As such, diversifying selection can be difficult to unambiguously identify and the majority of comparative studies outside protein-coding sequences currently focus on the identification of purifying selection. For an in-depth discussion of genetic drift, selection and the influence of population size, see Ref. [65].

Both purifying and diversifying selection result in a departure from the neutral rate of sequence evolution; this departure is diagnostic and can be considered the signature of selection. Natural selection can only act on genetic variation that manifests as phenotypic differences between individual organisms of a population. It is a stringent filter – even a 0.001% reduction in fitness will result in a polymorphism being efficiently removed from most mammalian populations [83, 86]. Therefore, the signature of selection defines a sequence as significantly contributing to the biology of the organism. As we have discussed (Section 2), vertebrate and many other higher eukaryotic genomes are dominated by sequences that appear to have no biological function. This means that although the human genome is approximately 3.2 Gb in size [59, 112], most of the biological functions, and, consequently, disease-associated polymorphisms and biological insight are concentrated into as little as 0.16 Gb of sequence [40, 64] (Section 6.1). Comparative genomics provides a means of identifying that rich vein of functional sequence and, unlike laboratory-based approaches, it does so without requiring prior assumptions of what that function may be.

The rate of sequence evolution is measured from an alignment (Chapter 3) between sequences that have diverged from a common ancestor, i.e. they are homologous. If the point of divergence for two homologous sequences was a speciation event, then they are referred to as orthologs. Otherwise, they are paralogs of one another. The distinction between *orthology* and *paralogy* is important for two reasons. (i) Orthologs are more likely than paralogs to have conserved the same function since divergence because the processes giving rise to paralogs such as intra-genome duplication and horizontal gene transfer provide an opportunity for functional diversification through the relaxation of selective constraint [43]. (ii) When comparing multiple orthologs loci between the same range of organisms, a common phylogenetic relationship and divergence times can be assumed for all of the loci, enabling direct comparison between loci. No such assumptions can be made for comparisons involving paralogous loci. For these reasons the majority of studies are based on alignments of orthologous sequences.

Phylogenetic scope, a term introduced by Cooper and coworkers [23], defines the range of organisms being considered in an analysis, denoted by their most recent common ancestor. For example, a study involving sequences from zebrafish, chicken, frog, mouse and human would be vertebrate in scope, whereas one looking at human, chimp and macaque is primate in scope. The phylogenetic scope of a study must be matched to the biological questions being asked. In general, more closely related species are more likely to have similar biology than distantly related species. The *Sonic hedgehog* gene discussed later (Section 6.3) provides a good example of the potential pitfalls of an inappropriate phylogenetic scope.

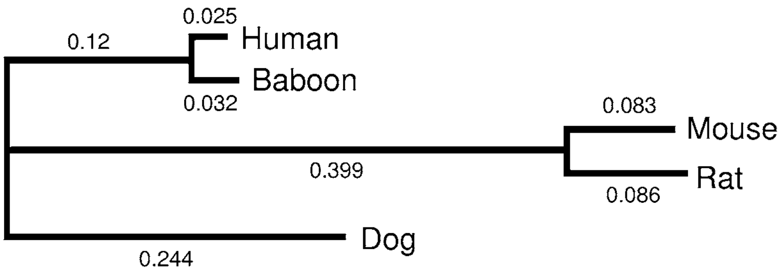

Figure 1 Phylogenetic tree showing branch lengths. An unrooted tree with branch lengths derived from nucleotide substitution rates of anonymous aligned sequence in the greater cystic fibrosis transmembrane conductance regulator gene (**CFTR**) region. Individual branch lengths are shown on each branch segment.

The number of expected differences between sequences has important implications for the utility of a particular sequence in a comparative analysis and how the analysis should be performed. It is useful then to have some standard measure of the expected degree of sequence divergence. For orthologous sequences, a widely used measure has been divergence time in millions of years, estimated through the integration of fossil records and molecular data. The greater the divergence time, the greater the number of changes that are likely to have accumulated. However, these date estimates vary wildly with the methods used and assumptions made, e.g. the divergence between rodent and primate lineages has been estimated as occurring between 75 and 121 million years ago [40,41,114].

A more useful measure for comparative genomics analysis is that of branch length, sometimes simply referred to as distance. The concept of branch length is introduced in the chapter on phylogenetic reconstruction (Chapter 4) where it denotes the number of mutational changes per unit of sequence, e.g. substitutions per nucleotide, deletions per amino acid or inversions per kilobase. The most useful and widely used measure when considering comparative genomics is that of substitutions per nucleotide, as it is readily calculated (Chapter 4) and is reasonably robust to alignment methodology. As a measure it also relates directly to the amount of information present in aligned sequences and also how accurate an alignment between those sequences is likely to be (see below). For the phylogenetic tree shown in Figure 1, the total branch length between human and mouse is $D = 0.63$ substitutions per site in neutrally evolving sequence, calculated by summing branch lengths between the human and mouse terminal nodes (0.025 + 0.12 + 0.399 + 0.083). It should be noted that branch length is often not the same as the sum of sequence differences, as the methods used to calculate substitution rates typically take into account the likelihood of multiple changes at the same site.

In theory, the power of a study to discriminate non-neutral from neutral evolution is proportional to the total divergence (branch length) of the analysis, in the case of Figure 1, this would be the sum of each value shown on the tree (total 0.989). Under the simplest scenario of identifying selective constraint, one is evaluating the likelihood that a segment of nucleotides has remained unchanged by chance, given an expected neutral rate of evolution D. For small values of D, we can use the Poisson distribution (e^{-D}) to approximate the probability that a neutrally evolving site will be unchanged [23,30]. For a human:mouse alignment with $D = 0.63$, there is a 53% likelihood that a neutral site will be unchanged by chance.

In practice, a pairwise alignment between orthologous sequences cannot discriminate selective constraint from neutral evolution for a single nucleotide position. Rather, a region of consecutive nucleotides is evaluated collectively. The size of region necessary to identify selective constraint scales inversely with the value of D for the analysis [30]. A simple way to increase the sensitivity of an analysis, to detect shorter or less conserved sequences, is to compare more distantly related sequences. Unfortunately, there are two important caveats to this strategy. (i) The more diverged sequences are, the less accurate the alignments are between them [88], so constrained sequences may be missed at the alignment stage rather than in the analysis of the alignment. (ii) The issue of phylogenetic scope – diverged species are less likely to share biological functions or be subject to similar constraints.

An alternative approach for increasing total D of an analysis is to include more sequences through multiple alignment. Based on the branch-length values in Figure 1, a comparison of human and mouse has $D = 0.63$, but adding rat as a third species increases total D to 0.72. When calculating total D for an analysis, each unique section of branch is counted only once, so rat only adds $D = 0.086$ to the total analysis, considerably more power could be added by using dog instead of, or in addition to, rat as it would contribute $D = 0.244$ of unique branch length. A further advantage to increasing comparisons from pairwise to multiple sequences is that it allows the direction of mutational changes to be resolved, such as the discrimination of insertion from deletion and the ability to assign changes to a specific lineage [40].

Alignment of closely related pairs of sequences such as human–chimp or human–macaque orthologous regions ($D = 0.009$ and 0.052, respectively [70]) are of little use for phylogenetic footprinting studies (Figure 2). However, extending the approach described above to the alignment of many such similar sequences can in theory provide sufficient total D to usefully detect selective constraint [23,30]. As the sequences are closely related, their alignment should be highly accurate, covering most nucleotides [88], and the phylogenetic scope is narrow, so little functional divergence is expected. This paradigm, know as *phylogenetic shadowing* [11], represents an ideal combination of attributes for comparative genomic studies. Using phylogenetic shadowing, Boffelli and coworkers [11] were able to demonstrate the identification of constrained sequences specific to primates and showed that as few as four to eight well-chosen genomes could capture much of the information present in deeper alignments of up to 17 primate sequences. The principal limitation is the need for multiple closely related, orthologous sequences (Section 3).

4 Practicalities

4.1 Available Genomic Sequences

At the turn of the millennium, comparative genomic projects in vertebrates involved the laboratory-based identification of homologous regions and their sequencing [26], prior to any comparative analysis. This situation has changed markedly, with an extremely high-quality reference human genome sequence in hand [50], and high-quality draft sequences from mouse and rat [40, 114]. The target for all three of these genomes is "finished" sequence, highly accurate and completely contiguous. Finished sequence is the "gold standard" and the ideal for comparative analysis. Unfortunately, the production of finished vertebrate sequence currently demands considerable human time and skill, and is correspondingly expensive. In contrast, a well-designed whole-genome shotgun sequencing and assembly project [115] can be largely automated at every stage. As a result of these economics, the majority of eukaryotic whole-genome sequencing projects now being undertaken have adopted a purely whole-genome shotgun strategy (Chapter 2), producing "draft" assemblies with no finishing step planned for the foreseeable future.

Draft assemblies have been produced from multiple other vertebrates including chicken (*Gallus gallus* [46]), dog (*Canis familiaris* [63]), zebrafish (*Danio rerio*), frog (*Xenopus tropicalis*), macaque (*Macaca mulatta*), chimpanzee (*Pan troglodytes* [22]) tiger-pufferfish (*Takifugu rubripes* [4]), domestic cattle (*Bos taurus*), rabbit (*Oryctolagus cuniculus*), armadillo (*Dasypus novemcinctus*), African elephant (*Loxodonta africana*), opossum (*Monodelphis domestica*), medaka (*Oryzias latipes*) and freshwater pufferfish (*Tetraodon nigroviridis* [51]). This list is expanding at an accelerating rate, driven largely by the realization that sequence comparisons between multiple vertebrate genomes is crucial to understanding the structural and functional components encoded in the human genome [21].

Whole-genome assemblies, rather than individual clone sequences, now provide the primary resource of genomic sequence for most comparative analyses in the vertebrate scope, and there is a similar situation for biologists focusing on prokaryotes, viruses, fungi, plants, nematodes and insects, with at least draft status sequence available for over 1000 genomes. However, the quality and completeness of sequences should be considered when undertaking an analysis. For finished sequence, the accuracy is expected to be high with less than one nucleotide error per 100 000 nucleotides and fewer than one insertion/deletion error per 200 000 nucleotides, the vast majority of which are located in tandemly repetitive sequence [50], and there should be no gaps in sequence coverage. The quality of draft sequences depends to a large degree on the depth of coverage. With 8-fold coverage (every base sequenced on average 8 times), a whole-genome shotgun sequencing project can produce a high-quality sequence with good long-range ordering of sequences [77]. As coverage is reduced, the rate of all types of error increase; in particular, there is a rapid reduction in sequence contiguity [116].

Even in high-quality and "finished" genomic sequences, there is still a chance of mis-assembly, especially in regions rich in repetitive elements. However, a more common issue is that of segmental duplication (Section 2) where very recently duplicated regions, that may encompass several genes, cannot be reliably discriminated during normal assembly procedures resulting in the collapse of multiple duplications into a single sequence [98]. Efforts are currently being made to identify and resolve these problematic regions [96]; however, it has become apparent that the copy number of high-identity (above 97%) segmental duplications is often polymorphic in the human population, diverges rapidly between species [20] and may be associated with disease susceptibility [32]. A further consideration is that the small number of differences between segmental duplicates will appear as polymorphisms in almost all assays, having potentially disruptive effects on genetic studies. For these reasons it is often prudent to check for indications of segmental duplication such as the "WSSD" and "Segmental Dups" tracks from the University of California at Santa Cruz (UCSC) Genome Browser (http://genome.ucsc.edu) prior to investigating a new region.

Considerations of sequence quality and coverage are set to become more important as the emphasis of genome sequencing continues its shift from high-accuracy sequencing to sampling more genomes, but with lower individual coverage. As discussed above (Section 3), an optimal strategy for the identification of constrained sites is to analyze sequence from many closely related genomes to achieve a large total branch length. The cost of sequencing one genome to 8 times is almost the same as eight genomes once, and there is then a trade-off between high quality sequence and maximizing the number and diversity of sequenced genomes. Margulies and coworkers [70] have explored this trade-off with both real and simulated data, demonstrating that as little as 2 times shotgun, although insufficient to produce a good-quality assembly, can be useful in the identification of constrained sequences by directly aligning reads to more completely sequenced genomes.

The National Human Genome Research Institute (NHGRI; http://www.genome.gov) has adopted this strategy of many genomes at low coverage and is currently coordinating the low-coverage sequencing of 16 additional mammalian genomes, selected to maximize total branch length for comparative analysis. The full list of organisms, target sequence coverage and progress in sequencing can be monitored online (http://www.genome.gov/10002154). Based on the equations of Eddy [30] and simulations of Margulies and coworkers [70], these genome sequences should provide resolution of selective constraint down to a segment length of eight nucleotides – approaching the same scale as individual transcription factor-binding sites. If successful, this strategy is likely to be applied to an even greater number of mammalian and other genomes (a fruit fly-based project is also currently under way; http://rana.lbl.gov/drosophila/multipleflies.html) the most exciting of which from the perspective of human biology is the proposal to sequence multiple primate genomes (http://www.genome.gov/12511814).

4.2 Defining and Obtaining Genomic Sequences

When undertaking a comparative genomic study, it is necessary to delineate a locus or loci of interest and to obtain corresponding homologous, often orthologous, sequences. Typically, an approximate locus will be defined by either arbitrary distances from an identified feature of interest, the confidence intervals of a preceding genetic study or the extent of a sequenced genomic fragment. It can be useful to extend a region of analysis slightly beyond the minimal extent so that the region is bounded by features that are well conserved between species, e.g. protein-coding exons, that serve as anchors for the analysis. A pair of well-conserved anchors provides confidence that the full extent of a locus has been isolated from each species under analysis.

Pre-assembled genomes are the most accessible source of defined genomic segments, as the problems of stitching together overlapping sequence fragments have already been tackled and the assemblies will have been subject to some degree of validation and quality control. Complete assemblies can be obtained from a number of disparate sites depending on the organism and assembly method. However, the UCSC Genome Browser, Ensembl (http://ensembl.org) and the National Center for Biotechnology Information (NCBI) (http://www.ncbi.nlm.nih.gov) all provide portals to the most current, and archived, public assemblies. These sites also provide means of searching the assemblies, such as BLAST [2], BLAT [56] and SSAHA [82], as well as precomputed annotation for the genome assemblies that can be readily incorporated into comparative genomic analyses.

There are several routes to identifying homologous loci in target genome sequences. An obvious approach is based on sequence similarity searches, but caution must be taken to distinguish orthologous from paralogous loci. Processed pseudogenes, in particular, are common [99], these are the reverse-transcribed copy of an mRNA that has integrated into the genome, but which does not code for a functional protein. As processed pseudogenes lack introns, they can score better than an orthologous locus in a similarity search. Genome-wide, reciprocal best matches [106] can be used to increase confidence that two loci are orthologous. Ensembl also provides precomputed assignments of gene orthology, currently based on reciprocal best matches for several genomes in the "geneview" pages and from the EnsMart data repository. Conservation of the order and orientation of genes in and neighboring the locus can also provide additional support of the orthology of two loci.

Probably the simplest currently available route to identifying orthologous loci is with the Net alignments at UCSC. These genome-to-genome pairwise alignments show genome-wide best matches and local rearrangements within them. They provide a direct means of jumping between an orthologous location in two genomes and can be used directly to delineate an orthologous locus in a target genome. For example, with the genome browser showing a complete locus of interest in a human assembly, clicking on the human to dog Net will provide an option to open the dog genome browser in a corresponding window from which the canine sequence and associated annotation can be obtained. An extension of this method is to use the genomic alignments to transfer annotation from one perhaps well-annotated genome to another that may have been recently assembled. The LiftOver tool at the UCSC Genome Browser (http://genome.ucsc.edu/cgi-bin/hgLiftOver) provides this facility for a limited set of genome pairs. This can provide a rapid way to get a baseline annotation which can then be filtered and refined. The Net alignments are generally good quality, but problems do arise, particularly where segmental duplications and assembly gaps are involved.

If there is uncertainty in the assignment of paralogy or orthology between multiple sequences, it can often be resolved through rigorous phylogenetic analysis (Chapter 4) of either whole genomic alignments or more discrete regions such as protein-coding sequences within them. This is often a problem with comparisons involving teleosts such as pufferfish and zebrafish, which may have been subject to a past whole-genome duplication [47] with the subsequent loss of many genes.

5 Technology

There are three general challenges that are common to most comparative genome analysis: (i) the production of an alignment, (ii) visualization of the alignment and (iii) detection of departures from neutral sequence evolution in the alignment. As alignments form the foundation of the comparative analysis, we will spend some time discussing the different options available and the consequences for interpreting results. There are also several options available for the visualization of large-scale genomic alignments. We have already discussed the principles and general approaches taken for the detection of departures from neutrality (Section 4); in Section 5.3, we present the tools that are currently available to apply these methods.

5.1 Alignments

The starting point for the majority of comparative genomic analyses is an alignment between homologous sequences. Precomputed alignments are available between several whole genomes as well as tools (Table 1) for producing such alignments. To a large extent, the genomic alignment tools and precomputed alignments can be treated as "black boxes". It is not necessary to understand in fine detail the process of producing the alignment to address a biological question with it. However, knowing in general terms how an alignment was generated, and the parameters used, can be crucial to its meaningful interpretation, especially when considering the apparent absence of conservation. Here, we present an overview of the genomic alignment problem, highlighting the limitations of available methods as well as recent advances in the field.

There are two general approaches to sequence alignment – local alignment and global alignment. Both of these strategies are introduced and discussed in detail in Chapter 3. When performing a *local alignment*, one is asking to be shown every similarity, scoring above a predefined threshold, between two sequences. The aligned subsequences (alignment segments) need not be in the same order or orientation in the parent sequences and one-to-many matches are permitted. In contrast, in a *global alignment* the entire length of one sequence is aligned with the entire length of the other through the insertion of gaps in both sequences. There is a maximum one-to-one correspondence between nucleotides, and their order is constrained such that duplications, inversions and other rearrangements cannot be detected. Rather than competing and redundant, these approaches should be considered complementary as they provide different insights into the relationship between two or more sequences.

Table 1 Summary of widely used and recommended genomic alignment tools

Program	Alignment method	Alignment tool	Ref.	Comment
AVID	global	pairwise	12	http://genome.lbl.gov/vista
BlastZ	local	pairwise	94, 95	the most widely used local genomic alignment tool; http://pipmaker.bx.psu.edu/pipmaker
Blat	local	pairwise	56	efficient use of memory and rapid execution make this a good choice for defining approximate regions to align with more sensitive methods
CHAOS	local	pairwise	15	by itself it lacks the heuristic refinements of BlastZ, but is used by DIALIGN and Lagan to identify initial alignment matches
DIALIGN	global	multiple	76	only practical for alignment of large (more than 10 000 nucleotides) sequences when used in conjunction with CHAOS [18]; http://dialign.gobics.de/anchor
GLASS	global	pairwise	6	one of the first available tools, now superseded by AVID
Lagan	global	pairwise	16	http://genome.lbl.gov/vista
MAVID	global	multiple	13	http://genome.lbl.gov/vista
mLagan	global	multiple	16	http://genome.lbl.gov/vista
MultiZ	global	multiple	10	based on BlastZ local alignments, but with a tiling path of aligning segments chosen (chaining, see main text) and integrated into multiple sequence alignments; this is the method used to produce high-resolution alignments for the UCSC Genome Browser (http://genome.ucsc.edu)
sLagan	global	pairwise	17	also known as Shuffle-Lagan – produces "glocal" alignments which have relaxed some constraints of global alignment so inversions, translocations and duplications can be detected; http://genome.lbl.gov/vista
TBA	global	multiple	10	a prototype standalone tool to produce threaded blockset multiple sequence alignment, similar to the output of MultiZ
WABA	global	pairwise	57	readily handles large gaps and can predict the protein coding/noncoding status of a sequence region based in part on the periodicity of divergent sequences

Note that several visualization tools, such as MultiPipMaker, emulate multiple alignment by stacking the percentage identity plots of multiple pairwise alignments without actually producing a character-based multiple alignment.

5.1.1 Local Genomic Alignments

All of the local alignment methods commonly applied to genomic sequences (Table 1) employ an index-based search strategy based on the same principle as that employed in the original BLAST algorithm [2]. Briefly, this approach produces an index of all *k*-length words (*k*-mers) in one of the input sequences and searches the other sequence for identical words. When a match is found, it is extended in both directions to define a maximally scoring segment of alignment. If that score is above the predefined threshold the alignment is reported.

There are three methods applied to genomic local alignment tools that elaborate this basic procedure to increase the sensitivity and specificity. (i) Requiring two matching words to be separated by a maximum distance from each other. This is a common approach used by BLASTN and most of the local alignment methods in Table 1. The principal exception is CHAOS, which identifies multiple matching words but does not perform alignment extension. Instead, the matching words are clustered (*chained*) if they lie in the same orientation and within a threshold distance of each other. It is this chain of words that is scored by CHAOS rather than BLAST-like extended initial matches. (ii) Using degenerate *k*-mers, which can tolerate a mismatch in any position of the *k*-mer, is a strategy that adds considerably to the computational load in the initial search step but provides more flexibility in defining word matches. This method is used by CHAOS in conjunction with the novel chain-of-words approach. (iii) Matching *k*-mers of nonconsecutive positions, an idea introduced to the field by Ma and coworkers [66]. For example a $k = 8$ word could be represented as 11111111 where each "1" denotes the position of an identity required for a match – a nonconsecutive $k = 8$ could be represented as 11011011011. This is distinct from the degenerate *k*-mer approach as a degenerate *k*-mer can tolerate a mismatch in any position, whereas the position of possible mismatches is constrained in the nonconsecutive *k*-mer case. Such patterns of matches can relate more directly to the underlying biology. The previous example could be useful to identify matches between coding sequence given the periodicity of codon conservation, due to the degeneracy of the genetic code. The nonconsecutive *k*-mer also has a slight statistical advantage over the consecutive *k*-mer, as the failure to match overlapping nonconsecutive *k*-mers is less strongly correlated between *k*-mers than the failure to match those which are overlapping and consecutive [5].

Beyond the limits of sensitivity defined by the initial index search, there are many parameters that can be modified in the available tools to optimize them for a specific purpose or phylogenetic scope. For such insight we direct the reader to the primary literature and associated web servers (Table 1). However, the program BlastZ is one of the most versatile and widely used in this class of program for comparative genomic studies and is the basis for a number of publicly available resources, as such we consider its use in more detail here.

Developed principally by Scott Schwartz and Webb Miller [94, 95], BlastZ is based on the Gapped-BLAST algorithm [2]. An alignment is seeded by a short perfect or defined imperfect match, extended by dynamic programming, initially without gaps and if score thresholds are achieved, then with gaps. Sequence between anchoring alignments is again searched and alignments extended, but using a lower stringency than in the initial search, the stringency being determined by the separation distance between anchors. BlastZ employs heuristics to take sequence complexity into account, requiring low-complexity sequence to align better than high-complexity sequence and to dynamically mask any regions with an unexpectedly large number of matches. As BlastZ is a local alignment tool, matches may overlap, they can be distributed between both strands and are unconstrained in their linear order. However, BlastZ has the option of constraining matches to be colinear between input sequences (chaining) or to select only a best match to each region of a reference sequence (single coverage). Both of these options involve discarding data, but can be useful in interpreting results and subsequent analysis.

5.1.2 Global Genomic Alignments

The prototypical global alignment method is that of Needleman and Wunsch [78]. However, this procedure does not scale well to the large alignments commonly required in comparative genomics. The approach employed by most of the genomic global alignment tools is to define a series of *anchors* – high-confidence matches between a pair of sequences that are constrained to be in the same order and orientation in both sequences. This is effectively the chaining method optionally employed by BlastZ, as discussed above. The portion of each sequence between adjacent anchors is then aligned with lower stringency, defining a new set of anchors and the process is reiterated until all sequence is aligned. The strategy effectively breaks the large alignment down into a series of progressively smaller alignments, with two important consequences. (i) The total search space is quickly reduced and continues to be refined with each iteration, allowing the alignments to be produced quickly and using little memory relative to the length of input sequences. (ii) The chain-of-anchors approach is tolerant of large gaps, which are common in genomic sequence alignments, but poorly dealt with by gap penalties employed by the purely dynamic programming methods such as Needleman–Wunsch (Chapter 3).

Table 1 summarizes the global sequence alignment tools that are often applied to genomic sequences. Of these, AVID [12] and Lagan [16] are the most widely used. AVID identifies maximal matches (identical runs of nucleotides) and from these selects a chain of nonoverlapping alignment anchors using dynamic programming, iterating the process as described above until all bases are aligned or there are no significant matches in the remaining subsequences. The full Needleman–Wunsch algorithm is applied if the remaining sequences are short (less than 4 kb), otherwise a fully gapped alignment of these regions is returned.

A particularly useful feature of AVID is its ability to perform template-directed fragment assembly. Provided with a contiguous and a fragmented sequence, AVID will use high-confidence local matches to order and orient the fragmented sequence relative to the contiguous one, producing a "merged draft" which is then used for pairwise alignment. Such a utility can be invaluable in the analysis of early-draft genomic sequences.

Lagan [16] proceeds in a very similar iterative manner to that described for AVID, making use of the application CHAOS to produce local alignments from which the anchors are defined. In a further development, Brudno and coworkers [17] have generalized this approach by relaxing the criteria for colinearity in the order of alignment anchors, instead requiring them to be sequentially ordered along only one of the input sequences, the designated reference sequence. This relaxation allows for the detection of genomic rearrangements such as inversions, translocations and duplications relative to the reference sequence. This method is implemented as Shuffle-Lagan (Table 1). In recognition of similarities to both local and global methods, the authors have termed these "glocal" alignments. The approach is innovative and has potential to be developed further, but there are two key drawbacks to the current implementation: (i) as the two input sequences are treated differently, the resulting alignment depends on the order sequences are presented, and (ii) our current lack of understanding of the frequency of genomic rearrangements to appropriately parameterize such alignments.

5.1.3 **Multiple Sequence Alignments**

The local and global sequence alignment methods we have discussed so far are only able to produce pairwise alignments. We have seen in Section 3, however, that the combined analysis of multiple sequences provides much greater insight, statistical power and resolution to comparative genomic studies. Unfortunately, the difficulties of producing pairwise genomic sequence alignments are exacerbated in the challenge of producing multiple alignments.

To perform a progressive multiple alignment in this manner, the phylogenetic relationship between sequences being aligned needs to be established. This can either be calculated from initial all-versus-all pairwise alignments of the sequences or for some programs can be provided in the form of a previously established phylogenetic tree. If the multiple sequence alignment is between orthologous sequences, their relationship is often known in advance, e.g. (((human,chimp),(mouse,rat))dog). Provision of the tree in advance removes uncertainty in the order a program aligns the sequences, providing consistency between the alignment of multiple loci and expediting the alignment process, as well as ensuring the correct phylogeny is used. After producing the initial multiple sequence alignment, the location of gaps can be optimized, making use of the greater information content of multiple sequences. There are multiple alignment versions of AVID and Lagan, denoted by the "M" prefix to the name (MAVID and mLagan) – both of which use the general method outlined above to produce the global multiple sequence alignments.

Although MAVID and mLagan produce true multiple sequence alignments, many visualization tools (Section 5.2) display conservation profiles relative to a chosen reference sequence. A similar approach is frequently used to integrate conservation measures between multiple pairwise alignments [94] and to define multiply conserved sequences (MCS) (Section 5.3). The reference sequence approach is an obvious choice if the objective is the annotation or investigation of a particular sequence. However, it is increasingly the case that comparative genomic studies intend to measure how a locus has evolved in multiple lineages and how selective forces have changed during that evolution, rather than just detecting regions of the reference sequence that are selectively constrained. For these analyses the reference sequence approach has two major drawbacks. First, any regions conserved between a subset of aligned sequences, but not the reference, will not be detected. This problem can be overcome by generating several multiple sequence alignments – one with each of the sequences under study as the reference. This solution is time consuming, raises the additional problem of integrating results between alignments and exposes the second major drawback to the reference sequence approach, i.e. the potential for inconsistencies when using alternate sequences as the reference.

A solution to the problems presented by reference sequence based alignment and analysis has been proposed in the form of a "threaded blockset" [10]. Under this proposition, a multiple sequence alignment is represented as a series of alignment blocks, termed the *blockset*. Within an individual block, each row corresponds exactly to an input sequence (or its reverse complement) if gap characters are ignored, i.e. no sequence within a block has been rearranged. Additionally, an individual block need not involve every aligned sequence. From this blockset, multiple sequence alignments can be produced using any one of the aligned sequences as the reference sequence, simply by ordering and orienting the blocks according to the selected reference sequence, a process referred to as threading the blockset. This approach ensures consistency of alignment when alternate reference sequences are used and no portions of the alignment are discarded. The threaded blockset aligner (TBA [10]) has been developed as a prototype tool to generate blocksets.

Many eukaryotic genomes are rich in repetitive sequences; these can confuse alignment programs if not treated appropriately. The identification of repetitive sequences is considered in detail in Chapter 7. The simplest treatment of interspersed repeats and low-complexity regions is to mask the sequence prior to alignment, readily achieved with tools such as RepeatMasker (A. Smit and P. Green, http://www.repeatmasker.org/) or available precomputed from the UCSC Genome Browser for a wide range of whole-genome assemblies. However, interspersed repeats can be interesting in their own right and are a useful measure of background mutation rate (Section 5.3). A more satisfactory treatment of repeats is to ignore them in the initial stages of alignment and then align through them if flanking nonrepeat sequence has been aligned. This is often termed "soft-masking", and is implemented in several alignment tools including LAGAN, Blat and AVID.

5.1.4 Assessing the Quality of Genomic Alignment Tools

Which alignment tool is the most accurate? This is an obvious question to ask when deciding which tool is the most appropriate to use. Unfortunately, this appears to be impossible to definitively answer. For protein-coding sequences, solved three-dimensional protein structures provide a "gold standard" against which alignment methods can be scored [14]. No such equivalent exists for noncoding DNA. A possible solution is the *in silico* simulation of sequence divergence [103], which can provide a population of sequences related to a common ancestor by a precisely known sequence of mutational events, so the true alignment is known.

There is a chance that an evaluation of alignment success based on simulated data is measuring the similarity of evolutionary models rather than the sensitivity and specificity of the alignment methods themselves. Despite this limitation, Pollard and coworkers [88] have performed such an analysis and produced some useful rules of thumb for genomic sequence alignment. All methods rapidly lost sensitivity with increasing divergence, with more than 50% of nucleotides not accurately aligned by all methods with $D = 1.0$ (divergence, substitutions per site) in the most realistic simulations. Local aligners were successful at identifying constrained sites, but performed poorly on neutral sequence with $D > 1.0$. As would be expected from their mode of action, global aligners had the highest overall sensitivity to accurately align orthologous sites in both neutral and selectively constrained sequence. Lagan [16] performed particularly well under almost all of the simulation scenarios. The simulations in this study did not include inversions and duplications which would have only been detected by the local alignment methods.

5.1.5 Using Whole-genome Alignments

As we have seen, there is a good diversity of tools available to produce pairwise and multiple genomic sequence alignments. Although these tools are optimized for genomic sequence alignment, the alignment of whole eukaryotic genomes to each other is still a daunting and specialist task requiring considerable computational resources. Fortunately, several research groups that specialize in such large-scale genomic alignments have made their alignments publicly available (Table 2). The utility of these alignments is not limited to whole-genome analyses and they represent an excellent resource for investigations focused on defined loci.

Table 2 Precomputed whole eukaryotic genome alignment resources

Resource	URL	Reference
MultiZ at UCSC	http://genome.ucsc.edu/	10
Berkeley Genome Pipeline	http://pipeline.lbl.gov/	25
GALA	http://gala.cse.psu.edu/	33, 39

These publicly available alignments have several significant advantages over proprietary alignments produced *ad hoc* to address specific questions. (i) As they are a public resource, they are used by many members of the research community to address a multitude of questions and, therefore, any systematic problems in their construction are likely to be highlighted, whereas in-house alignments are unlikely to be as rigorously vetted. (ii) Results based on the same alignments can be directly compared between research groups, e.g. in the integration of findings in large collaborative projects [40, 114]. (iii) It is faster and simpler than producing your own alignments, especially in the cases where existing annotation has already been mapped to the alignments (http://pipeline.lbl.gov) or can be readily mapped using easily accessible tools (http://pipmaker.bx.psu.edu/piphelper).

However, there are of course limitations to the utility of precomputed alignments. The user is restricted by the predefined phylogenetic scope of the alignments, e.g. at the time of writing, the human-based MultiZ alignments available from UCSC included alignments with chimp, mouse, rat, dog, chicken, pufferfish and zebrafish, but assemblies for the genomes of opossum, rhesus macaque, cow and frog are also publicly available, and could add considerably to the information content of the multiple sequence alignment. It is also the case that for some analyses very specific sets of alignment parameters or constraints are required [55], which are unlikely to be met by off-the-shelf whole-genome alignments.

5.2 Visualizing Genomic Alignments

The visual representation of alignment based data is an important aspect of comparative genomics, especially when the focus of the analysis is a locus of specific interest (see also Chapter 43). One of the most intuitive and logical representations of a pairwise sequence alignment is a dot plot (Chapter 3). Such a representation can summarize all regions of local similarity between two sequences, highlighting inversions, translocations, duplications and deletions. Plotting a sequence against itself is often an excellent first step in the comparative characterization of a locus as it can highlight regions that are tandem repetitive, low complexity and clearly show segmental duplications – all of which are potentially confusing to interpret when visualized with the other methods discussed below. For sequences of up to a few hundred kilobases, the Dotter software [102] is able to produce a complete dot plot and incorporate arbitrary annotation. For sequences above this size, the computation of a complete dot plot is impractical, but tools such as PipMaker [95] can produce dot plot-style summaries of local alignments (Figure 2) which can be interpreted in essentially the same way.

The downside to dot plots is that they take up considerable space and are impractical when it comes to summarizing the similarity between multiple sequences. For these reasons, percentage identity plots (PIPs) were introduced [44] in which the x-axis represents the coordinates of a reference sequence and the y-axis shows percent identity (Figure 2). A horizontal bar within the plot then identifies a gap-free segment of local alignment, the horizontal position and extent of the bar defining the aligning section of the reference sequence. The position of the bar in the y-axis shows the percentage nucleotide identity for the ungapped local alignment. This is a versatile way of displaying pairwise sequence similarity as it can be applied to both local and global alignments, and through stacking of multiple such plots can be adapted to show the conservation of a reference sequence aligned with any number of sequences.

Another intuitive and commonly used representation of nucleotide identity in sequence alignments is to plot a histogram of conservation (Figure 2). As with PIPs, identity is plotted against the coordinates of a chosen reference sequence. Rather than calculating the identity from an ungapped segment of alignment, however, it is calculated from a predefined range of nucleotides in the reference sequence. These can be discrete consecutive bins of, say, 10 alignment columns or, more commonly, calculated as a sliding window, e.g. VISTA [73] uses a window of 100 columns with sliding increments of 1, by default.

5.3 Detecting Selection

Any significant departure form the neutral rate of sequence evolution can indicate the action of selection. The neutral rate is typically calculated from regions of alignment corresponding to one of four types of sequence: 4-fold degenerate (4D) sites, ancient repeats, anonymous sequence or pseudogenes. We consider the advantages and drawbacks of each of these below.

In the standard genetic code, there are eight instances where substituting the third codon position for any other nucleotide will not change the encoded amino acid (CTn = Leu, GTn = Val, TCn = Ser, CCn = Pro, ACn = Thr, GCn = Ala, CGn = Arg, GGn = Gly) – these are 4D sites. 4D sites are readily identified from annotated or well-predicted coding sequences and because they are embedded in generally well-conserved coding sequence they can often be aligned between even highly divergent sequences with a high degree of confidence. For these reasons, 4D sites represent an excellent type of sequence from which to calculate the branch length D. In general such sites are readily identified as less conserved than other coding positions and non-4D third codon positions [79]. However, that is not to say that they are devoid of function or functional constraint – such sites may be involved in the regulation of splicing, translational efficiency, mRNA localization or stability. 4D sites are generally considered to be good for the calibration of nucleotide substitution rates, but they are of no use in measuring the neutral rate of insertion, deletion or rearrangements.

←

Figure 2 Visualization of genomic sequence alignments. The WNT2 locus was aligned between human and orthologous loci from nine other vertebrates for which at least a draft whole-genome shotgun sequence is available. Orthologous regions and extents were defined using the UCSC Nets. In each case, coordinates and annotation are shown for the human sequence and nucleotide identity from pairwise alignment. (A.) Summary view from MultiPipMaker [94] based on BlastZ alignments. The extent of the WNT2 transcript is shown above the alignment, protein-coding exons indicated in purple and untranslated region (UTR) in yellow. Regions of local alignment are shown in green or red if a combined length and identity threshold is achieved. The region highlighted is shown in detail in (B) and (C). (B.) Detailed view of MultiPipMaker output – a percentage identity plot. Exons are denoted by black boxes above the plot and projected as purple-shaded regions across it. Other features above the plot correspond to annotated repetitive elements (triangles and predicted CpG islands (grey and white boxes). (C.) VISTA plot [73] summarizing mLagan [16] global alignments of the sequences. Higher curves show greater conservation; regions meeting a threshold level of conservation are shaded – purple for sequence annotated as protein coding, blue for UTR and red for anonymous sequence. Exons 2 and 3 are readily aligned in all cases, whereas the relatively short and poorly conserved exon 1 is not always aligned (panel C, frog and pufferfish). An additional complication when using draft sequences is the presence of assembly gaps – the apparent failure to detect exon 1 in chicken in this case coincides with a gap in the chicken assembly.

IREs are widespread through most vertebrate genomes and are thought to be free from selective constraint (Section 2). Unlike 4D sites, IREs are free to accumulate insertion, deletion and rearrangement as well as substitution changes [85]. Using the tool RepeatMasker (http://repeatmasker.org) combined with an appropriate repeat database (Repbase; http://girinst.org) IREs can be grouped into families and subfamilies based on sequence similarity. Each copy of an IRE subfamily is thought to have been almost identical at the time of insertion as they were all produced from one or a very small number of "parent" elements in a brief period of activity before mutation robbed the parent element of its ability to transpose [59]. Therefore, an IRE that inserted into a genomic location in the common ancestor of a set of sequences being compared is expected to accumulate mutational changes independently in each of the diverging lineages and those changes are likely to be invisible to selection.

This assumption of identity between IRE subfamily members at the time of insertion provides them with additional advantages over other categories of candidate neutral sequence. For example, using the IRE subfamily consensus sequence as an out-group, mutational changes can be assigned both a direction and a lineage from just pairwise comparisons rather than requiring a minimum three aligned sequences.

For mammalian and other genomes rich in interspersed repeats, IREs appear to be the ideal solution to measuring the neutral rate of mutation. However IREs are typically defined on the basis of their sequence similarity to previously defined repeats and to other sequences in the genome. This means that highly diverged members of a repeat family may not be detected, resulting in an under estimation of the mutation rate. The distribution of IREs is nonrandom across a genome [45], some favoring A/T-rich insertion sites, others showing preferential retention based on nucleotide composition. The nonrandom distribution may result a systematic bias in mutation rate estimation. The abundance of these elements in the genome may also lead to nonorthologous recombination between elements [53], resulting in a high frequency of gene conversion within the elements [91].

Another possibility is anonymous sequence. In genomes dominated by nonfunctional sequence such as those of mammals (Section 2), the background mutation rate can be approximated by simply taking the average rate across the whole alignment. This estimate can be improved by specifically excluding annotated functional sites such as protein-coding exons and core promoters. The remaining unannotated (anonymous) regions of alignment will be enriched for selectively neutral sites. An interesting variation is to use sequences that align between closely related species but do not align with a more distant out-group, because the sequence has been inserted in one lineage or lost from the other [24]. Again, it can be argued that the sequence is less likely to contain important functional elements and is thus enriched for selectively neutral sites.

Pseudogenes (Section 2) are particularly interesting for estimation of the neutral rate because their starting point is a functional gene, with all the associated sequence biases, periodicity, and, in the case of nonprocessed pseudogenes, introns, splice junctions and regulatory sites. These are often the features we are most interested in identifying or investigating in comparative studies. If a gene pseudogenized before the common ancestor of compared sequences, we can see the effect of mutation and genetic drift free from the action of selection superimposed upon it. This is the ideal scenario. Unfortunately nonprocessed pseudogenes are too rare – only 37 having been found in a systematic screen of the human genome [59] – to be of general use in calculating background mutation rates. Processed pseudogenes have been useful for the investigation of protein-coding sequences [84], but again their uneven distribution limits their use in estimating local mutation rates and some sequences identified as pseudogenes may still have functional roles [87].

For a comparative study that aims to identify highly constrained sequences that are evolving many times slower than the neutral rate, it can be adequate to estimate the neutral rate on a genome-wide basis. Such studies include the identification of protein-coding sequence with distant pairs of sequences, e.g. human versus pufferfish [26, 107], and the ultra-conserved elements [7] discussed later (Section 6.2). For more sensitive studies it is necessary to calculate the neutral rate in localized regions, as the rate of mutation has been found to vary spatially across genomes [45, 117] (Section 2).

Regional estimates of the neutral rate can be calculated in a sliding window manner or by calculating it for an arbitrarily defined region of interest. The principal problem with this approach is that sites subject to selection cannot be assumed to be randomly distributed across the genome. For instance, anonymous sequence around the *PAX6* gene [74] is highly enriched in functionally important conserved sites (Section 6.3). An estimate of the neutral rate based on anonymous sequence around this gene would give an artificially low estimate for the neutral mutation rate in the region. The larger the window used to estimate the regional neutral rate, the less likely it is to be dominated by non-neutral sites, but a larger window reduces the resolution for detecting regional variation in mutation rate. The optimum window size for neutral rate estimation will be a balance of these two opposing needs. If recent findings [38] for the rodent lineage can be generalized to other vertebrates, then typically a window of 10 kb is likely to show a consistent neutral rate across its length and even windows up to 1 Mb may have little variation in neutral rate across them, but substantially larger than this and neutral rate fluctuations may be compromised by neutral rate variation. Testing for concordance between different measures of the neutral rate such as those derived from 4D, ancient repeat and anonymous sequence allows the influence of cryptic non-neutral sites to be evaluated and provide a justification for the selected window size.

Having established a neutral rate estimate for the sequences of interest, the challenge is to identify and delimit regions of sequence that significantly deviate from it. At its simplest this can be a relative rate test, dividing the rate of evolution in the test sequence by the neutral rate. Values of one indicate neutrality, significantly less than one, constraint and more than one indicates diversifying selection. There are many variations on this basic principle, including the commonly used K_a/K_s ratio test, where K_a denotes the rate of substitutions that lead to amino acid changes and K_s the rate of substitutions in protein-coding sequence that do not lead to a change in the encoded amino acid. K_a/K_s equal to 1.0 indicates neutral evolution (no selection), below 1.0 indicates purifying selection and above 1.0 positive (diversifying selection) to detect selection in the protein-coding sequence [48]. The differences between approaches predominantly relate to how to score constraint between multiply aligned sequences and how to define the boundaries of a constrained sequence.

Several studies have defined the extent of constrained regions on the basis of ungapped segments of alignment [28, 29] – a strategy that lends itself well to analyses based on local rather than global alignments. Often, these studies will use precalibrated thresholds for significant constraint rather than calculating relative rates directly, e.g. 70% identity over 100 ungapped nucleotides are commonly used parameters for human to rodent alignments [28].

Sliding windows have been widely used to arbitrarily define the extent of sequences which are then evaluated for constraint [73, 114]. The approach can accommodate alignment gaps, generally treating them as nucleotide mismatches [73], but their sensitivity is crucially dependent on the size of the evaluation window and by how much the window is moved along the alignment for each evaluation. Analyses based on sliding windows have also been applied to phylogenetic shadowing [11]. In this case, rather than scoring conservation or substitution rate directly, the substitution rates for each alignment column were compared to the rates of sequences known to be evolving neutrally or subject to selection. The final score being a likelihood ratio of neutral versus constrained evolution for each alignment column. A web server for phylogenetic shadowing analysis is available (http://bonaire.lbl.gov/shadower).

An intuitive way of integrating measures of constraint across multiple aligned sequences is to define MCS – the common core of sequence that aligns in all (or most) sequences from a defined scope can then define the boundaries of the MCS [69, 110]. For instance it is easy to see that exons 2 and 3 of *WNT2* can be considered MCS within vertebrates (Figure 2). The MCS definition is versatile, accommodating local or global alignments and can tolerate missing sequence from incompletely sequenced genomes.

Two highly versatile tools, RankVISTA [71] and phastCons [100], have recently been developed that quantify constraint and operate free of window size constraints and identity thresholds. These tools are also noteworthy because they quantitatively measure constraint rather than the crude binary discrimination into constrained or unconstrained that is common to many of the methods discussed above. RankVISTA integrates pairwise relative rate scores across a multiple alignment using a phylogenetic weighting scheme. The neutral rate estimates are derived from anonymous regions in the submitted alignment and the final score is an easily interpretable probability of observing such conservation in a 10-kb fragment of neutrally evolving sequence. The extent of constrained sequences is determined with dynamic programming (Chapter 3). This tool is available from the standard VISTA web server (http://genome.lbl.gov/vista). The tool phastCons [100] is one of the first practical implementations of a phylogenetic hidden Markov model (phylo-HMM [36]) to score conservation across genomic alignments, in effect scoring how well the observed pattern of substitution matches its internal model of a constrained site. The approach is also noteworthy because it takes into account the tendency for conservation levels to be similar at adjacent sites and it is an extensible model that could incorporate additional parameters. Precomputed phastCons results are available through the UCSC genome browser for multi-species whole-genome alignments.

All of the methods described above focus on nucleotide substitution rates. Insertions and deletions also have the potential to help detect constrained regions; however, estimation of their rate is more sensitive to alignment parameters than is the case of substitution rate calculations [54], and good stochastic models of insertion and deletion in noncoding DNA are not currently available. Alignment gaps are typically treated as either missing data (phastCons) or nucleotide substitutions (RankVISTA) when assessing selective constraint. Neither of these are particularly satisfactory solutions and in the case of phastCons lead to artificially high scores over regions of gapped alignment. A better treatment of alignment gaps is likely to be an important avenue for future work in the development of these methods.

6 Applications

There have been a huge number of published studies that are either centered on comparative genomic analysis or utilize comparative genomics to address specific questions within a wider study. In the next few subsections we highlight a small number of examples that have given new insight into the general biology of vertebrate genomes and provide good examples of the application of methods described in this chapter.

6.1 How Much of the Human Genome is Constrained?

The protein-centric view of genome function (Section 2) has been challenged by recent whole-genome comparative analyses. With publication of both the draft human [59] and mouse [114] genomes it became possible to estimate the total proportion of the human genome that is subject to selective constraint, and so estimate the proportion of the genome that has conserved function, but which is not protein coding. A conservation score was calculated for nonoverlapping 50 nucleotide windows of human:mouse whole-genome pairwise alignments. Two sets of scores were derived, one for the complete alignment and a second derived only from aligned ancient repeats. As ancient repeats are thought to be unconstrained by selection (Section 5.3), the distribution of conservation scores should reflect the pattern expected under neutral evolution. The distribution of scores from the whole-genome alignments substantially overlaps those derived just from ancient repeats, although a significant shoulder specifically towards higher scores is evident [114]. Subtracting the ancient repeat distribution from that of the whole genome suggests that approximately 5% of 50 nucleotide windows are more highly constrained than expected under neutral evolution. Similar analyses based on human to rat comparisons have supported this conclusion [40]. These studies are not without their limitations. In particular, isolated regions of constraint that are substantially shorter than the 50-nucleotide window size used will have gone undetected, suggesting that the estimate of 5% may be a lower bound for the true value. Using a novel method based on insertion and deletion rates rather than substitutions also finds that generally similar fractions of 2.6–3.5% of the human genome show evidence of selective constraint [64]. These studies have led to the important conclusion that much of the functionally constrained sequence in the human genome does not code for proteins.

If coding sequences are not the singularly dominant functional component of the genome, the question arises “What are the functions of noncoding sequence?”. Several types of noncoding elements are known, such as *cis*-regulators of transcription and splicing (see Chapter 6), RNA structures that influence transcript localization and stability, as well as transcripts whose functional product is RNA rather than protein (see Ref. [72] for review). It is also likely that there are classes of functional elements that we have yet to discover. This potential naivety is well illustrated by the relatively recent realization that a major class of noncoding functional elements (microRNAs) had been almost entirety overlooked [3].

It is one of the great strengths of comparative genomics that no prior assumption of the function is required to identify a sequence as functionally important. With the increasing depth of available genomes (Section 5) and the methods described above, we are rapidly approaching the stage where we can confidently identify short regions and possibly even single nucleotides as constrained. A remaining and significant challenge is to characterize the function of those sites. Again, comparative genomics can help. We have already seen that there is a characteristic profile of conservation for protein-coding sequence (Section 5.1) and similar profiles may exist for other categories of functionally important sequence. Dermitzakis and coworkers [27] found that conserved nongenic sequences (CNGs) accumulated sequence changes in a manner that can be statistically distinguished from both protein-coding sequences and noncoding RNA genes. These patterns of sequence change most resembled clusters of protein binding sites.

6.2 Ultra-conserved Regions

The sequences studied by Dermitzakis and coworkers [27] were selected, from chromosome 21, on the basis of a simple threshold identity in human to mouse alignment, and also on the ability to polymerase chain reaction amplify homologous sequences from 14 mammalian species. Consequently, these sequences should represent the subset of CNGs that have both the highest nucleotide identity and are the most constrained through mammalian evolution. Ironically, a whole-genome analysis of noncoding conservation has since shown that human chromosome 21 is the only autosome devoid of so-called ultra-conserved elements [7]. These elements are also defined on the basis of simple length and identity thresholds, but in this case 200 nucleotides of ungapped alignment between human, mouse and rat with 100% nucleotide identity in all three species. In total, 481 of these incredibly well conserved sequences were found.

Although defined initially on the basis of conservation between humans and rodents, 97% of the ultra-conserved elements could be identified in the chicken genome with, on average, more than 95% nucleotide identity and more than 66% of them could be aligned with a pufferfish genome (*T. rubripes*). In contrast, only 5% could be identified in any of the nonvertebrates *Ciona intestinalis* (sea squirt), *Drosophila melanogaster* (fruit fly) or *Caenorhabditis elegans* (nematode worm) and all of these were ultra-conserved elements that overlap protein-coding exons from known genes. It appears then, that although these ultra-conserved elements have been highly constrained for 300–450 million years of vertebrate evolution [7], they are largely confined to the vertebrates. A similar study making use of recently available whole-genome sequence from multiple insects, has also identified ultra-conserved regions between fruit flies and the mosquito *Anopheles gambiae* [42]. However, the majority of ultra-conserved elements identified in files were substantially shorter than the 200 nucleotide threshold used for the human study despite similar evolutionary distances for some of the analyses in both studies.

It has been noted in both mammals and flies that ultra-conserved elements are often located in the introns of, or intergenic regions around, developmentally important genes [7, 42, 118]. These developmental regulators are often DNA-binding transcription factors or RNA-binding proteins [7] that are likely to be involved in the regulation of RNA processing and transport. These observations have invoked the notion of developmental master regulators – regions that integrate multiple signals coordinating the expression of genes which in turn regulate many more genes through transcription and RNA processing. Direct experimental support for this idea has been provided by Woolfe and coworkers [118] in a zebrafish experimental system. Of 25 noncoding sequence elements that are highly conserved between human and pufferfish, 23 showed significant transcriptional enhancer activity in one or more tissues during zebrafish development [118].

The idea that ultra-conserved elements act as developmental regulators fits well with the observation that they are highly conserved within phylogenetic clades that share similar developmental programs, but apparently not conserved between more diverse groups. Could the ultra-conserved elements that are common to both humans and pufferfish be the master regulators that define the basic vertebrate body plan: skeletal structure, musculature, internal organs and the developmental programs to orchestrate their construction? This is an attractive idea, but much more work is required to establish if this is even close to accurate. In particular, some genes are known to be key regulators of developmental programs, and the orthologous genes in both humans and flies are apparently performing the same task in the same tissue. *PAX6*, for example, is crucial in the development of eyes in both human and fruit flies [111]. The human *PAX6* locus is one of the richest in ultra-conserved elements [7] and six out of seven tested elements show enhancer activity, four of which directed expression preferentially in the developing eye [118]. Despite the conserved role of *PAX6* in eye development between humans and flies, and the demonstrated role of mammalian ultra-conserved elements in directing that expression, there is no identifiable sequence similarity between the ultra-conserved elements and the fruit fly *PAX6* locus.

6.3 Specific Locus Studies

In this section we focus on a small number of disease related studies that have been substantially advanced through the application of comparative genomics. We make several references to Online Mendelian Inheritance in

Man (OMIM) – a key human curated resource that brings together published information relating human genetic diseases and disease genes. Full OMIM records can be obtained with their identifier number from the Entrez system (http://www.ncbi.nlm.nih.gov/entrez).

Hirschsprung disease is a congenital disorder characterized by intestinal abnormalities (OMIM:142623). The genetics of this disease have been well studied, but the pattern of inheritance is complex. Mutations have been found in eight loci which contribute to disease susceptibility (OMIM:142623 for review), but these account for only 30% of cases [34]. Genetic evidence indicated that one of those eight loci, the *RET* gene, harbored additional, previously undetected mutations or variants that account for much of the remaining susceptibility [37]. All apparent protein-coding sequence of *RET* had already been screened for mutations, so the challenge was to identify additional functionally important noncoding sites within the locus or identify previously missed protein-coding sequence.

Emison and coworkers [34] identified more than 30 regions of conserved noncoding sequence in 350 kb of genomic sequence centered on the *RET* gene. The analysis used the multiple conserved sequences paradigm (Section 5.3) based on alignment of 12 orthologous loci from vertebrates. Only five of the conserved noncoding regions were within the region maximally implicated by genetic evidence. The comparative analysis also indicated that a human single nucleotide polymorphism (SNP) is located within one of the conserved regions and, not withstanding the polymorphism, the nucleotide has been highly conserved through vertebrate evolution. An obvious candidate for the functional variant, Emison and coworkers [34] were able to show that this conserved element has enhancer activity and that the level of that activity is influenced by the SNP genotype. The comparative alignment allowed the ancestral and derived alleles to be discriminated – the lower enhancer activity and disease susceptibility being associated with the more recently derived allele. The noncoding SNP genotype was shown to account for much of the previously unaccounted for genetic susceptibility contributed by the *RET* locus.

The Hirschprung disease *RET* locus is a good recent example of the utility of comparative genomics and its synergy with genetic studies. It also stands out for several of other reasons. The functional variant identified is common in the population, exceeding 50% in some parts of East Asia, despite being disease-associated. The effect of the genotype is influenced by sex, demonstrating a form of epistasis, and the variant is regulatory rather than protein coding. All of these features are likely to be frequently encountered when searching for the genetic risk factors in common diseases [68] such as cancer, heart disease, diabetes and stroke.

The *RPGR* gene has a similar story to the *RET* locus. *RPGR* is known to be a major locus for X-linked retinitis pigmentosa (OMIM:312610) – a form of retinal degeneration. Several known disease associated coding sequence mutations had been found, but it was apparent from genetic studies that many more cases of retinitis pigmentosa should be attributable to the locus than could be explained by the mutations in the coding sequence [109, 113]. Comparative genomics revealed a previously unknown, alternately spliced protein-coding exon that was specifically expressed in the retina and harbored the missing mutations [113]. In this case all of the disease-associated mutations disrupted the encoded protein. It is likely that such missing mutations are common for even well-studied genes and that they are simply under-reported in the literature, because it is seldom practical to screen large genomic intervals for mutations, nor is it easy to demonstrate their causal role. Our next example demonstrates over how wide an interval *cis*-regulatory sites can act, but also how, even when the region is large and complex, comparative genomics can allow functional sites to be identified an subsequently characterized.

The mouse *Sasquatch* (*Ssq*) mutation was generated serendipitously when trying to insert a transgene into the genome. The transgene integration led to ectopic expression of the developmental signaling molecule Sonic Hedgehog (SHH) and resulted in preaxial polydactyly (extra digits) [97]. Intriguingly, genetic evidence demonstrated that the effect was specifically in *cis* [97], but as the integration site was over 1 Mb from *Shh* and located within the intron of an adjacent gene, identifying the functional regulatory element remained a challenge.

Multiple sequence alignment between orthologous regions from mouse, human, chicken and pufferfish identified a 0.8-kb stretch of sequence close to the transgene insertion site that had been highly conserved throughout vertebrate evolution [61]. It has now been shown that the 0.8-kb element, known as the ZRS, is a limb bud-specific enhancer of *Ssh* expression [61, 92] and that even the fish sequence can drive expression in the mouse limb bud. These studies into the *Shh* locus have shown that *cis*-regulatory elements can be located large distances, at least 1 Mb, along linear DNA from the genes they act to regulate. Not only can these elements be far from their targets, they may also be closer to other genes on which they apparently have no regulatory role – the ZRS is located in the fifth intron of the *Lmbr1* gene whose expression is unaffected by mutations in the ZRS.

Like the ultra-conserved sequences described above, the striking conservation of the ZRS through vertebrate development indicate that even single nucleotide substitutions in the region are likely to be detrimental and strongly selected against. Accordingly, point mutations in the ZRS have been found in four human families and two mouse lines, in each case they lead to preaxial polydactyly (see Ref. [62] for review). In contrast to these point mutations, complete deletion of the ZRS in the mouse abolishes *Shh* expression in the limb bud and results in severely truncated limbs [92] – a similar phenotype to human acheiropodia which is also linked to the *Shh* locus [49]. Several vertebrate lineages such as snakes have substantially reduced or entirely lost limbs, although they were present in their ancestors. Sagai and coworkers [93] have shown that for at least two of these cases, i.e. snakes and limbless newts, this has coincided with the loss of the ZRS, where as it remains conserved in lizards and legged newts. Whether loss of the ZRS was a primary event in the morphological transition of either of these separate lineages or if it represents secondary losses remains unclear; however, it does illustrate two points rather well. (i) The importance of selecting an appropriate phylogenetic scope for a comparative genomic study (Section 3) – an analysis utilizing legless newts and snakes rather than pufferfish and chickens would not have revealed the ZRS in the first place. (ii) It demonstrates the apparently modular nature of conserved noncoding sequence blocks in evolution – the ZRS can be lost apparently without disrupting the many other functions (OMIM:600725) of *Shh* during vertebrate development.

7 Challenges and Future Directions

There has been great progress in understanding the biology and functions encoded by the human genome since the first draft of a reference sequence was produced in 2001 [59], and much of this insight has been derived through comparison both within and between genomes. However, as with many scientific endeavors, more questions arise with each increment in understanding. For example, we have now realized that much of the functionally constrained sequence in the human genome does not encode proteins and our current understanding of these elements is poor. They are the "dark matter" of the genome. A major and current challenge is to identify each of these elements and to start dissecting their function. In particular, it is likely that they will harbor polymorphisms that impact human health, contributing to common disease susceptibility. The integration of comparative genomics with genetic variation data [1] to identify functional polymorphisms is likely to be a rapidly expanding field with the combined assets of multiple mammalian genome sequences and high-density confirmed polymorphism data available.

Sequence comparison alone may be able to identify all constrained sites, but it is unlikely to be able to establish their associated functions. Rather, it is the synergy of comparative studies with laboratory experiment that provides greatest insight. This approach is embodied by the Encyclopedia of DNA elements (ENCODE) project, an international initiative with the aim of identifying all functional elements in the human genome [35], in effect to shed light on the dark matter of the genome. This is an ambitious and relatively long-term goal. As a first step, a pilot project has been undertaken to investigate 30 Mb of the human genome (approximately 1%, randomly selected) in great detail, applying a broad spectrum of experimental and computational methods to identify functionally important sites (http://genome.gov/10005107). These rigorously annotated regions will be important training and testing grounds for the development of methods in comparative genomics. The UCSC genome browser (http://genome.ucsc.edu/ENCODE/) provides a key portal to access the ENCODE pilot project data.

8 Conclusion

In the middle of 2000, credible estimates of the total number of human protein-coding genes plummeted from 80 000–100 000 to 30 000 or so [90]. These lower counts were essentially confirmed by the early analyses of the human genome [59] and, if anything, the real numbers are likely to be smaller still [50]. Although it is difficult, and perhaps even of little value, to interpret these results within the commonly perceived frameworks of organismal complexity, the fact remains that they have created a new impetus for looking beyond protein-coding genes towards other classes of functional elements, such as noncoding RNAs and, in particular, the *cis*-acting elements regulating gene expression. At the same time, it is sobering to reflect on how unanticipated these downward revisions of gene count were and, accordingly, to reserve judgment on exactly how many more functional elements of major relevance we may expect to find. The methods and early results presented in this review are merely the first steps on a long path towards a broader understanding of the totality of information encoded in the genome.

Association Studies of Complex Diseases

Momiao Xiong and Li Jin

1 Introduction

Most complex diseases, including obesity, diabetes, cardiovascular disease, hypertension, asthma, psychiatric illness, cancer and inflammatory disease, are common diseases and hence pose great public health concerns [19]. Health states of individuals are a complex, multidimensional phenomenon. Clinical manifestations arise from integrated actions of multiple genetic and environmental factors, through dynamic, epigenetic and regulatory mechanisms [90, 91]. For example, outcome, severity and progression of ankylosing spondylitis (AS) are influenced by genetic factors, environmental (i.e. nongenetic) factors, psychosocial constructs, treatments, biologic constructs (intermediate phenotypes) such as disease activity, possibly biomarkers themselves, and their interactions. It is assumed that AS is the effect of inflammation leading to ankylosis. The susceptibility genes, environments and their interactions will initiate inflammatory arthritis and enthesitis. The subsequent immune response over time slowly leads to varying degrees of bony ankylosis and, later, to spinal fusion. In some patients, the occurrence of spinal arthritis may be accompanied by peripheral arthritis and other nonspinal manifestations. Subsequently, the severity and persistence of axial and/or joint inflammation will affect the rate and extent of ankylosis. The occurrence of ankylosis, in turn, will lead to the long-term health outcomes – spinal fusion, functional disability and work disability. In general, inflammation results in functional disability independent of ankylosis, while ankylosis is the primary cause of spinal fusion.

Therefore, clinical phenotype can be thought of as a synthesis of genes, gene–gene interactions and gene–environment interactions [14, 40, 78, 81]. A general disease model can be represented by Figure 1.

The general disease model assumes that multiple modules of phenotypes, a set of genes and a set of environments, contribute to the outcome of the disease. A module of phenotypes consists of a number of phenotypes which are influenced by the genes and environments. The genes and environments

can be classified into four categories: (i) the genes and environments directly influencing a phenotype, (ii) the genes and environments influencing several phenotypes in a module of phenotypes, (iii) the genes and environments simultaneously influencing several modules of phenotypes, and (iv) the genes and environments directly influencing the outcome of the disease. Therefore, the genes and environments will have direct and indirect effects on the disease. The genes and environments which affect the disease through influencing the phenotypes in the modules will only have indirect effects on the disease. Therefore, the proposed disease model is based hierarchically organized networks of phenotypes, genes and environments.

In the proposed disease model, intermediate phenotypes play an important role. In the context of complex traits, it is often insufficient to consider individuals who merely show a particular clinical symptom as being “affected” [100]. The clinical symptoms might be accompanied by several intermediate phenotypes, each of which is caused by a set of genes, environments and their interactions. Definition of the phenotype is a key issue in dissecting the genetic structure of complex diseases [81]. A narrowly defined disease phenotype beforehand will result in the collection of samples that are genetically more homogeneous and, thus, can offer advantages over broad definitions. Smaller samples with a precise phenotype are more valuable and powerful than a large number of poorly characterized samples [14]. The intermediate phenotypes are simpler in the sense that the number of genetic and environmental factors influencing each intermediate phenotype is presumably smaller than the number of factors affecting the clinical outcome. Therefore, if we can localize the genes for each of the intermediate phenotypes separately, we can characterize most of the genetic susceptibility genes for the complex disease [14, 100].

In recent decades, linkage analyses have been the primary method for genetic studies of diseases. Linkage analysis tests for the cosegregation of a genetic marker and a disease phenotype using family data. A significant linkage result implies that a marker and a susceptibility gene are genetically linked. Linkage analysis has been highly successful for many rare single-gene disorders [53].

However, the fact that many diseases are caused by multiple mutations and genes that individually contribute only modestly to disease risk limits the power of linkage studies. Furthermore, linkage analysis requires multiplex families with multiple affected relatives, which are not available on many occasions. An alternative method to linkage analysis for genetic studies of diseases is association studies that examine the co-occurrence of a marker and disease at the population level [74, 80, 82, 92]. Association analysis has higher power than linkage studies to detect small effects. Common complex diseases involve many genes, most of which have small effects. This fact, together with the imminent completion of the HapMap Project providing a comprehensive catalogue of millions of single nucleotide polymorphisms (SNPs) and haplotypes across diverse populations [3, 105], and rapid development of high-throughput genotyping technologies [9], has increased the importance of association studies in genetic epidemiology [21]. The existence of disease–marker association implies that either the marker allele itself is a functional variant contributing to disease risk or the marker is close enough to the disease locus.

Genetic association studies offer a potentially powerful approach for mapping causal genes with modest effects, but they also raise great challenges in three at least aspects. (i) Since a genome-wide association study involves a large number of SNPs and statistical tests, it is practically impossible to ensure a genome-wide significance level of 0.05 using traditional statistic methods. (ii) Most phenotypic variations are generated by integrated actions of multiple genetic and environmental factors through complex (primarily nonadditive and nonlinear) interactions between genes, and between gene and environments. Detecting interactions among genes or SNP markers is a daunting task. (iii) Most existing analytic methods analyze each genetic marker (or haplotype) and phenotype individually, and do not consider network structures among multiple phenotypes and multiple markers. In short, statistical and computational methods for genetic studies have not kept pace with data collection in the laboratory. Therefore, new techniques need to be

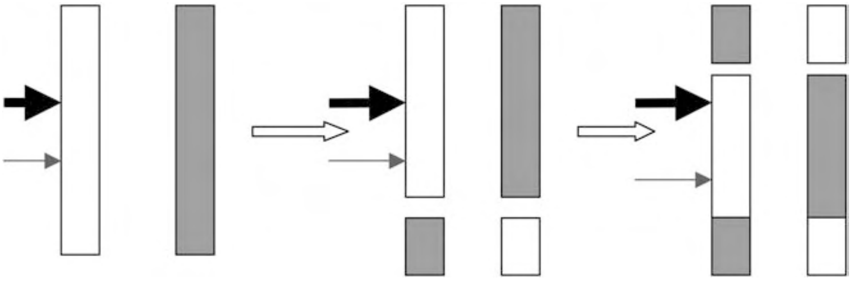

Figure 2 Illustration of generation of LD.

proposed to address these challenging tasks. In this chapter we will focus on how to develop statistical methods which have enough power to ensure a genome-wide significance level.

2 Linkage Disequilibrium (LD), Haplotype and Association Studies

DNA variations are responsible for phenotypic variations. Direct association studies or indirect association studies (nonrandom association with neighboring markers, called LD) can be used to reveal the relationship between DNA variations and phenotypic variations.

2.1 Concepts of LD

LD refers to the nonrandom association of alleles at different marker loci. It is also called *allelic association* or *gametic disequilibrium*. LD is of fundamental importance in genetic studies of complex diseases [50, 82].

LD is due to evolutionary forces in the history of populations such as mutations, recombination and random genetic drift. Suppose that a new mutation arises on individual chromosomes and is flanked by the specific alleles that happen to be present on that chromosome. Over years of transmission of the mutation, through multiple meioses to successive generations, recombination separates the mutation from the original alleles at loci that are unlinked to the mutations. At very closely linked loci, the likelihood of recombination with the disease mutation is low and the original alleles will remain in linkage with the mutation for many generations. By examining the haplotypes at many loci within a large region that does not exhibit recombination, it is sometimes possible to identify a smaller region that appears to be in "LD" with the mutation because the same alleles are present in different families with the diseases. LD provides an indication of which part of the chromosome to study first. See Figure 2.

2.2 Measures of LD

Due to the important implications of LD in association studies of complex diseases, several quantities have been proposed to measure the level of LD between loci, which quantifies the dependence of alleles at two loci. Here, we review several widely used measures of LD.

2.2.1 LD Coefficient D

Consider two marker loci, with two alleles D_1 and d_1 at the first locus and two alleles D_2 and d_2 at the second locus. Assume the population is mating randomly. The disequilibrium coefficient for alleles D_1 and D_2 at two loci is defined as the difference between the haplotype frequency and the product of allele frequencies: $D_{D_1D_2} = P_{D_1D_2} - P_{D_1}P_{D_2}$, where $P_{D_1D_2}$ denotes the frequency of haplotype D_1D_2, P_{D_1} and P_{D_2}, respectively, denote the frequency of allele D_1 at the first locus and the frequency of allele D_2 at the second locus. The maximum likelihood estimate (MLE) of $D_{D_1D_2}$ is estimated by $\hat{D}_{D_1D_2} = \hat{P}_{D_1D_2} - \hat{P}_{D_1}\hat{P}_{D_2}$, where $\hat{P}_{D_1}$ and $\hat{P}_{D_2}$ are the estimated frequency of allele D_1 and D_2, respectively. $P_{D_1D_2}$ is the estimated frequency of haplotype D_1D_2. In practice, the haplotype frequency is unobservable, but can be estimated using one of the algorithms mentioned in the previous section.

2.2.2 Normalized Measure of LD D'

The linkage disequilibrium coefficient $D_{D_1D_2}$ depends on the frequencies of haplotype and alleles, making comparisons between two populations difficult. For the convenience of comparison, Lewontin [61] normalized the above measure of LD by dividing the coefficient D by its maximum value $D_{\max}$, which is given by:

$$\min[P_{A_i}P_{B_j}, (1-P_{A_i})(1-P_{B_j})] \quad \text{if} \quad D_{D_1D_2} < 0$$

$$\min[P_{A_i}(1-P_{B_j}), (1-P_{A_i})P_{B_j}] \quad \text{if} \quad D_{D_1D_2} > 0 \, .$$

This normalized LD measure D' is therefore defined as:

$$D'_{D_1D_2} = \begin{cases} \dfrac{D_{D_1D_2}}{\max(-P_{D_1}P_{D_2}, P_{d_1}P_{d_2})} & D_{D_1D_2} < 0 \\ \dfrac{D_{D_1D_2}}{\min(P_{D_1}P_{d_2}, P_{d_1}P_{D_2})} & D_{D_1D_2} > 0 \end{cases}$$

The normalized LD measure lies between -1 and $+1$, achieving these values when two loci are in complete LD.

2.2.3 Correlation Coefficient *r*

Pearson's correlation coefficient r^2 between two loci is another commonly used measure of the LD. This coefficient is defined as [49]:

$$r^2 = \frac{D^2_{D_1D_2}}{P_{D_1}P_{d_1}P_{D_2}P_{d_2}} \ .$$

r^2 is often used to eliminate the arbitrary sign introduced. When two loci are in linkage equilibrium, r^2 is reduced to zero. There is a simple inverse relationship between this measure and the sample size required to detect association [55].

2.2.4 Composite Measure of LD

LD measures, D, D' and r, assume that individuals mate at random. Under assumption of random mating, the frequency of the genotype is the product of frequencies of haplotypes, and the previously discussed measures of LD can be calculated by estimations of frequencies of alleles and haplotypes which are obtained by MLE. However, this assumption is not always satisfied. When only genotypic data are available and random mating cannot be assumed, the measures of gametic disequilibrium introduced previously cannot be calculated directly. Weir [112] and Weir and Cockerham [113] introduced the following composite measure of LD which combines gametic and nongametic digenic disequilibrium coefficients, and uses only genotype data:

$$\Delta_{AB} = D_{AB} + D_{A/B} = P_{AB} + P_{A/B} - 2P_AP_B \ .$$

This can be calculated as [114]:

$$\Delta_{AB} = \frac{1}{n}\left(2n_{AABB} + n_{AABb} + n_{AaBB} + \frac{1}{2}n_{AaBb}\right) - 2\hat{P}_A\hat{P}_B \ ,$$

where n is the number of individuals sampled, n_{AABB}, n_{AABb}, n_{AaBB} and n_{AaBb} are the numbers of individuals carrying corresponding genotypes at two loci, and $\hat{P}_A$ and $\hat{P}_B$ are the sample frequencies for allele A and B, respectively. The composite measure of LD has the advantage of allowing its determination with genotypic data [46].

2.2.5 The Relationship between the Measure of LD and Physical Distance

Let t denote the age of the mutation which creates the LD. Let θ be the recombination fraction between the two marker loci and $P_{ij}(t)$ be the frequency of the haplotype A_iB_j, at t generations after the mutation causing LD. The haplotype in the next generation is produced either by transmission without recombination or by transmission with recombination between two loci. Thus, we have on average:

$$P_{ij}(t+1) = (1-\theta)P_{ij}(t) + \theta P_{A_i}P_{B_j} \,.$$

Recall that:

$$D_{ij}(t) = P_{ij}(t) - P_{A_i}P_{B_j} \,.$$

Combining above two equations yields the following recursive formula for the calculation of the expectation of the measure of the LD: $D_{ij}(t+1) = (1-\theta)D_{ij}(t)$ and $D_{ij}(t) = D_0(1-\theta)^t$, where $D_0 = P_{ij}(0) - P_{A_i}P_{B_j}$ is an initial measure of LD.

2.3 SNPs and Haplotype Blocks in the Human Genome

2.3.1 SNPs

A SNP is a mismatch between chromosomes in the base present at a particular site in the DNA sequence. It is estimated that about 10 million SNPs (minor allele frequency above 0.1) are present in the human genome, yielding an average density of one in every 200–300 bp [20,58]. These 10 million common SNPs capture 90% of the variation in the population [79] and are widely distributed across the genome, e.g. in exons, introns, intergenic regions, in promoters or enhancers, etc. SNPs play important functional roles. An exonic SNP may directly affect the relevant protein; an intronic SNP can influence the splicing [57]; SNPs in promoters or enhancers can influence gene expression [30]. SNPs are major variations causing diseases.

2.3.2 Tagging SNPs

Millions of SNPs in the human genome provide enough markers to scan the whole genome and their analysis is a powerful tool for genome-wide association studies. However, genotyping a huge number of SNPs is both labor intensive and very expensive. Fortunately, due to the LD between SNPs in a chromosomal region, it is not necessary to type all of the SNPs [115]. Genotyping only a few carefully chosen SNPs which, referred to as "tag SNPs", will provide most of the genetic information in a region with high LD [15,23,42,54] (Figure 3). It was reported from preliminary estimation that most of the genetic variations in the human population could be represented by genotyping 1–2 million tag SNPs across the genome [15, 20, 42]. Thus, using tag SNPs can reduce the number of markers being genotyped without losing much information.

2.3.3 Haplotype Block Model

As a dense set of SNPs markers becomes increasingly available, LD mapping is emerging as a powerful tool for fine mapping of disease susceptibility genes

and genome-wide association studies. The extent and pattern of LD have been debated for several years. Many evolutionary forces such as mutation, genetic drift, selection, recombination and population bottleneck affect the pattern of LD. It is now widely accepted that the pattern of pairwise LD is erratic. The relationship between the level of pairwise LD and the distance between two individual markers is not monotonic, which complicates LD mapping.

In recent years, there has been growing interest in haplotype and haplotype block LD mapping to alleviate the problem of erratic patterns of pairwise LD. A haplotype is a set of polymorphic alleles that co-occur along the same chromosome. Recent studies showed that haplotypes are not uniformly distributed over the chromosome; rather, they are organized in discrete blocks, in which all pairs of polymorphisms are in strong LD (low recombination), whereas pairs of polymorphisms between blocks show much weaker association (recombination hotspots) [13]. Therefore, a haplotype block shows a largely atomistic pattern and island structure of LD, which greatly simplifies association analyses.

There is strong evidence supporting the existence of haplotype block patterns in the human genome. Daly and coworkers [23] reported block-like patterns in a 500-kb region on chromosome 5 in 129 trios for Crohn's disease. They found that two to four common haplotypes can account for more than 80% of the haplotype variation in their sample. Jeffreys and coworkers [52] studied the haplotype patterns in a region of 216 kb of the major histocompatibility complex (MHC) II complex in the sperm of 50 British males. Their results showed that about 94% of the recombinants in the MHC region were located in the low LD regions, suggesting that the block-like pattern was caused by the recombinant hotspots. Studies by Patil and coworkers [72] revealed similar haplotype block patterns in their samples. Block-like patterns have also been observed on chromosome 22 [24]. More recently, Gabriel and coworkers [38] studied the haplotype patterns across 51 chromosomal regions using population samples from Africa, Europe and Asia. Their findings were consistent with the above observations.

These studies implied that the genome can be portioned into blocks with high LD that are separated by regions with low LD. Within a block, very few common haplotypes or markers can uncover the majority of the DNA variations. These studies also suggested that recombination hotspots and population bottleneck might be possible mechanisms underlying haplotype blocks.

The haplotype block model has important implications for genetic studies. It dramatically alleviates the irregular pattern of LD and holds the promise for mapping complex disease genes. It also provides a simple way of choosing SNPs for large-scale association studies. The main haplotypes in each block could be labeled with a small number of "haplotype-tagging" SNPs (htSNPs) (Figure 3), which would provide an efficient tool for screening each haplotype block region for genetic association studies.

To facilitate genome-wide association studies of complex diseases, the International HapMap Project was initiated in 2003 [20]. Its goal is to determine the common patterns of DNA sequence variation in the human genome, to find SNPs, to construct the general haplotype maps, and to discover the haplotype block structure across the genome and several major populations for all investigators. HapMap is expected to provide a very dense map of SNPs, new tools to dissect genetic structures of complex diseases and to a resource for the development of new treatments. HapMap also holds promise to make the candidate gene-based, linkage-based and genome-wide association studies both practically feasible and cost effective [20].

2.3.4 Definitions of Haplotype Block

Three methods have been proposed to define haplotype blocks. Briefly, the first method defines a block as a region in which "LD decays slowly with distance or not all". Unfortunately, the sampling variation of LD shows considerable fluctuation so that analyses of any trends are made difficult. The second method defines blocks through the optimal partition of a chromosome into a minimum number of blocks and minimum number of representative SNPs. However, there has been no clear biological interpretation of such partitioned haplotype blocks. The third method for defining haplotype block is based on recombination. A haplotype block is defined as a region in which there are no recombination events evidenced in the study sample.

2.3.4.1 Definition of Haplotype Blocks based on Pairwise LD

A simple way to define haplotype blocks is to use pairwise LD [23, 38, 80]. A block is defined whenever all pairwise LD coefficients D' or correlation coefficients r^2 (adjacent and nonadjacent) within a region exceed some predefined threshold, although different thresholds may be used to define the boundary of the blocks in the samples.

Disadvantages of pairwise LD-based blocks include that (i) it is unclear how much the levels of pairwise LD should be chosen to define haplotype blocks which are consistent with the haplotype ancestry, and (ii) the thresholds used to define the block boundaries are subjective and arbitrary. Furthermore, some other factors such as genotyping errors and gene conversion may affect the construction of blocks defined by LD coefficients [107].

2.3.4.2 Definition of Haplotype Blocks based on Haplotype Diversity

The second method for defining haplotype block is based on haplotype diversity and involves the optimal partition of a chromosome into a minimum number of blocks and minimum number of representative SNPs [72, 120]. A block is defined such that the minimum number of tag haplotypes (e.g. two to five) and blocks can account for a maximum proportion of the observations (usually above 80%).

Haplotype-diversity defined blocks share the same concern as those defined by the LD-based method. Thresholds used for determining the number of tag haplotypes which can cover the prespecified proportion of observations are subjective. Also, this method requires known phase data, which are often not accessible or computationally intensive to generate.

2.3.4.3 Definition of Haplotype Blocks based on both Pairwise LD and Haplotype Diversity

Recently, Anderson and Novembre [4] used a minimum-description-length principle to define the best block boundaries. This method simultaneously uses information about pairwise LD as well as the diversity of haplotypes to define haplotype blocks. This method may be better than either of the methods discussed above individually because it uses the joint information on pairwise LD and haplotype diversity, and it is expected to be less severely affected by multiple mutations, gene conversion and genotyping errors. However, this method also requires known phase data, which again mostly depend on statistical inference and are often not accessible in practice.

Haplotype blocks defined by pairwise LD and haplotype diversity are closely related. In general, regions with high pairwise LD usually have low haplotype diversity and regions with high haplotype diversity usually demonstrate low LD. Currently, there is no consensus on which method should be used to define haplotype blocks. Each definition works well for some specific cases. The block structures identified in each study depend strongly on the methods used for defining blocks and on the populations studied. Methods for comparison of haplotype blocks between studies have not been well developed, and it is still unclear which definition of haplotype blocks reflects the underlying biological processes such as recombination and population bottleneck better than others.

2.3.5 **Haplotype Reconstruction**

Although over 10 million SNPs for which the frequency of both alleles exceeds 0.1 exist in the genome [14, 20], analyzing each SNP individually is thought to be less powerful and less informative than simultaneous use of multiple marker information in a region of interest [2, 31, 64, 67]. However, haplotypes are not directly observable. Phase-unknown multilocus genotype data are the primary data sources which we currently have. Although several experimental technologies for molecular haplotyping have been developed [73, 102, 119], these methods are labor intensive, low throughput and costly. Therefore, experimental haplotyping methods are not practically useful for large-scale population studies. Analyzing family data with many relatives is another method to infer haplotypes, but (i) collecting family data is costly and (ii) ambiguity still exists, especially as the number of markers increases. Therefore, computational methods for estimating haplotypes using phase-unknown genotype data offer practical and cost-effective solutions.

2.3.5.1 **Clark's Algorithm**

Clark was the earliest to propose an algorithm based on maximum parsimony to reconstruct haplotypes among unrelated individuals using genotype data [17]. This algorithm first determines the haplotypes from all individuals with no haplotype ambiguity, i.e. the individuals which are complete homozygotes and single-site heterozygotes, assuming Hardy–Weinberg equilibrium (HWE), the basic model of stable frequency distribution among haplotypes in the presence of random mating. Then, the remaining individuals with ambiguous haplotypes are sequentially screened for the possible occurrence of previously recognized haplotypes; the complementary haplotype was then added to the list of resolved haplotypes. Clark's algorithm is straightforward, but does not give unique solutions and does not explicitly assume HWE [69].

2.3.5.2 Expectation Maximization (EM) Algorithm

The EM algorithm infers haplotypes based on maximum likelihood that optimizes the likelihood of occurrence of molecular haplotype frequencies from the observed data, assuming HWE [26,35,76]. The advantages of the EM algorithm include its solid theory, good performance for large samples and relative robustness to departure from HWE. However, since the optimization method is greedy, its performance is sensitive to the initial solution. Inappropriate initial solutions may lead to wrong local maxima, which is serious when there are many distinct haplotypes. Therefore, to ensure finding the global MLE of haplotype frequencies, EM algorithms should be started multiply with several initial solutions. Further, a standard application of the EM algorithm may not be feasible when large number of markers are analyzed simultaneously since the number of haplotypes, and hence the computational time, increase exponentially with the number of markers.

2.3.5.3 Bayesian and Coalescence-based Methods

Stephens and coworkers [95] proposed using a Bayesian approach, either using a simple Dirichlet-prior distribution or a prior distribution which approximates the coalescent, to reconstruct haplotypes from genotype data. The algorithm has been implemented in the program PHASE and its modified versions [62]. This algorithm infers haplotypes based on the following logic – a haplotype that is more similar to the commonly observed haplotype patterns has a higher probability of being present in the population than the less similar haplotypes. The principle for Bayesian haplotype reconstruction methods is to treat the unknown haplotypes as random quantities, and to calculate the *a posteriori* distribution of the unobserved haplotypes given the observed genotype data using prior information and the likelihood. The haplotypes (or haplotype frequencies) can then be estimated from maximizing this *a posteriori* distribution [96]. The prominent feature of this algorithm is the incorporation of coalescence theory into the algorithms and that it outperforms two previously introduce algorithms. The disadvantages include the lack of a measure of overall quality of the inferred haplotypes, slow computation and unclear performance in admixed or rapidly expanding populations when the coalescent model does not hold [69].

Several other coalescence-based and Bayesian algorithms as well as modified EM algorithms have also been developed to facilitate haplotype reconstruction for multiple markers [6, 44, 70].

The algorithms mentioned above have their own advantages and disadvantages. Comparative studies and new methods are still needed for haplotype inference. In addition, methodologies for haplotype reconstruction in large families remain challenging.

2.3.6 Measure of Haplotype Block LD

Suppose that there are k loci within a block. Assume that two alleles A_1 and A_2 at each locus have frequencies P_{A_1} and P_{A_2}, respectively. Consider a k locus haplotype $H_{j_1 j_2 \dots j_k}$ with a sequence of alleles $A_{j_1}, A_{j_2}, \dots, A_{j_k}$, where A_{j_i} at the i-th locus is either A_1 or A_2. Let $P_{H_{j_1 j_2 \cdots j_k}}$ be the population frequency of the haplotype $H_{j_1 j_2 \dots j_k}$. An overall measure of the haplotype LD at the k loci is defined as:

$$\delta_{H_{j_1 j_2 \cdots j_k}} = P_{H_{j_1 j_2 \cdots j_k}} - P_{A_{j_1}} P_{A_{j_2}} \dots P_{A_{j_k}} .$$

This overall measure of the haplotype LD includes the pairwise LD measures and higher-order measures.

Such an overall measure can be applied to measuring LD between a haplotype block and a marker locus. Consider a haplotype $H_{j_1 j_2 \cdots j_k}$ consisting of alleles $A_{j_1} A_{j_2} \dots A_{j_k}$ in the block and an allele M_1 at the marker locus which is outside the block. The haplotype $H_{j_1 j_2 \cdots j_k}$ and the allele M_1form a $(k+1)$ locus haplotype $H_{j_1 j_2 \dots j_k M_1}$. The overall measure of LD for the haplotype $H_{j_1 j_2 \dots j_k M_1}$ can be used to measure LD between the haplotype $H_{j_1 j_2 \cdots j_k}$ and the marker allele M_1, and will be denoted by D_{HM}. Some authors suggested that the haplotype block be treated as alleles and multiallelic analysis for the single marker be applied to the haplotype block analysis [12]. Following this approach, the measure of LD between a haplotype block and the marker locus, denoted by D_{HM}, can be defined as:

$$\begin{aligned} D_{\mathrm{HM}} &= P_{H_{j_1 j_2 \cdots j_k M_1}} - P_{H_{j_1 j_2 \cdots j_k}} P_{M_1} \\ &= P_{H_{j_1 j_2 \cdots j_k M_1}} - (\delta_{H_{j_1 j_2 \cdots j_k}} + P_{A_{j_1}} P_{A_{j_2}} \dots P_{A_{j_k}}) P_{M_1} \\ &= P_{H_{j_1 j_2 \cdots j_k M_1}} - P_{A_{j_1}} P_{A_{j_2}} \dots P_{A_{j_k}} P_{M_1} - P_{M_1} \delta_{H_{j_1 j_2 \cdots j_k}} \\ &= \delta_{\mathrm{HM}} - P_{M_1} \delta_{H_{j_1 j_2 \cdots j_k}} . \end{aligned}$$

This measure of LD between a haplotype and a marker is obtained by removing the haplotype block LD from the LD measure between the haplotype and the marker locus.

3 A General Framework for Population-based Association Studies

3.1 Motivation

Genome-wide association studies are emerging as a promising tool for genetic analysis of complex disease [14, 68, 82, 101]. With the imminent completion of the HapMap Project providing a comprehensive catalogue of common genetic variations in human populations [3], and rapid development of technologies enabling efficient and economical genotyping of a large number of variants [9], genome-wide association studies are becoming practically feasible in the near future [48]. However, one of the major barriers in performing genome-wide association studies is a multiple-testing problem, which may prevent the realization of genome-wide association studies.

Three popular strategies have been used to alleviate multiple-testing problems. One strategy is to focus on controlling false discovery rates, defined as the expected proportion of false positives among the declared significant discovery. A traditional quantity for measuring the overall rate of the multiple tests is the family-wise error rate (FWER), which is the probability of making at least one type I error (a false positive) among all the hypotheses. However, the FWER for ensuring genome-wide significance is too stringent. Recently, another multiple-hypothesis testing error measure, known as the false discovery rate (FDR), has been suggested [7, 22, 33, 83, 97–99]. This is a new notion of global significance for simultaneous testing and is more powerful than FWER. Although FDR is more liberal than FWER, since it allows for controlling the fraction of false discoveries, the p-value of a test still needs to be roughly 5×10^{-6} to ensure FDR ≤ 0.05 if 100 SNPs out of a million SNPs being tested show significance and are left for further investigation [97]. In addition, FDR only deals with how many SNPs should be further investigated, but will not change the order of SNPs ranked by p-values, i.e. FDR cannot detect true linkage or association which the existing statistics may not detect. The second strategy is to construct haplotype blocks by studying LD patterns across the genome and to optimally select a set of robust tag SNPs such that all common variants are either directly genotyped or in strong LD with the genotyped tag SNPs [38, 41, 54, 56, 95, 118, 120, 121]. However, it is unclear whether the haplotype block patterns and tag SNPs are consistent among populations or repeated sampling from within a population. Although the multiple-testing problem can be alleviated by selecting and typing tag SNPs [1, 45], the effect of such a strategy on the significance level is still limited. The third strategy is to adjust p-values. Considering the adjustment for millions of statistical tests, a stringent p-value of 10^{-6} to 10^{-7} has been suggested [37, 68, 104, 109, 111] to ensure a genome-wide significance level of 0.05. Unfortunately, with most existing statistics it is difficult to achieve such stringent p-values. Therefore, developing novel test statistics, which can reach stringent p-values for testing true linkage or association and identify new SNPs showing evidence of linkage or association that are undetected by the traditional statistics, requires immediate consideration.

Before developing a general framework for population-based association studies, we first review the traditional statistics for association studies. The primary assumption for association studies is that a mutation (a disease allele) increases disease susceptibility. Under this assumption, one expects that the disease allele will occur more frequently in the affected individuals (cases) than in the unaffected (controls) [75]. The standard χ^2 test for association studies is to identify the disease locus by comparing the differences in allele/haplotype frequencies between the affected and unaffected individuals. More precisely, the χ^2 statistic is a quadratic form of difference of allele/haplotype frequencies between the affected and unaffected individuals [2,16]. As an alternative to comparing differences in allele/haplotype frequencies, a recently developed class of association tests compares similarities of corresponding genome regions between affected and unaffected individuals [10–12, 25, 106, 119, 121].

A natural way of amplifying differences in frequency is to construct a linear transformation of allele/haplotype frequencies in the currently used statistics for association studies. However, it can be shown that any statistics arising from linear transformation will not change the values of pre-transformation statistics. It is suspected that the relationship between genotype and phenotype is nonlinear for complex diseases [66]. Motivated by this, we propose to use nonlinear transformations of allele/haplotype frequencies in cases (P^A) and in controls (P), i.e. $f(P^A)$and $f(P)$, with the expectation that statistics based on the difference $|f(P^A) - f(P)|$ will only amplify signal, rather than noise and hence they will be more powerful than those based on the difference $|P^A - P|$. For example, the case-control differential may be enhanced with some nonlinear transformations of allele/haplotype frequencies. It can be shown that many similarity -based test statistics are version of the χ^2 test with quadratic transformations of allele or haplotype frequencies. Thus, a general framework for association studies which can unify the allele/haplotype frequency-based association tests and similarity-based association tests can be developed.

3.2 The Traditional χ^2 Test Statistic

Traditional association tests compare the differences in allele or haplotype frequencies between affected and unaffected individuals. Let $n^A = [n_1^A, \ldots, n_m^A]^T$ and $n = [n_1, \ldots, n_m]^T$ be vectors of number of alleles or haplotypes in affected and unaffected individuals, respectively. Let n_A andn_G be the number of sampled affected and unaffected individuals, respectively. Let $P^A = [P_1^A, \ldots, P_m^A]^T$ and $P = [P_1, \ldots, P_m]^T$ be vectors of allele or haplotype frequencies in the affected and unaffected individuals, respectively. Define:

$$\hat{P}_i^A = \frac{n_i^A}{n_A} \quad \text{and} \quad \hat{P}_i = \frac{n_i}{n_G} .$$

Let $\hat{P}^A = [\hat{P}_1^A, \ldots, \hat{P}_m^A]^T$ and $\hat{P} = [\hat{P}_1, \ldots, \hat{P}_m]^T$. By standard statistical theory [60], we know that the vectors n^A and n following multinomial distributions with the following variance-covariance matrix:

$$\prod^{A} = n_A[\mathrm{diag}(P_1^A, \ldots, P_m^A) - P^A(P^A)^{\mathrm{T}}] ,$$

and:

$$\prod = n_G[\mathrm{diag}(P_1, \ldots, P_m) - PP^{\mathrm{T}}] ,$$

respectively. Here, $\mathrm{diag}(P_1^A, \ldots, P_m^A)$ and $\mathrm{diag}(P_1, \ldots, P_m)$ denote diagonal matrices with the diagonal elements $P_1^A, \ldots, P_m^A$ and $P_1, \ldots, P_m$, respectively. Let:

$$\Sigma^A = \mathrm{diag}(P_1^A, \ldots, P_m^A) - P^A(P^A)^{\mathrm{T}} \quad \text{and} \quad \Sigma = \mathrm{diag}(P_1, \ldots, P_m) - PP^{\mathrm{T}} .$$

The allele or haplotype frequencies are asymptotically distributed as the following multivariate normal distribution:

$$N\left(P^A, \frac{1}{n_A}\Sigma^A\right)$$

and:

$$N\left(P, \frac{1}{n_G}\Sigma\right) ,$$

respectively.

One form of the standard χ^2 statistic for case-control association studies is given by:

$$T = (P^A - P)^{\mathrm{T}}\Lambda^-(P^A - P) ,$$

where $\Lambda = \frac{1}{n_A}\Sigma^A + \frac{1}{n_G}\Sigma$ and Λ^- is a generalized inverse of the matrix Λ.

Under the null hypothesis of no association of the marker with the disease, T is asymptotically distributed as a central $\chi^2_{(m-1)}$ distribution.

If we ignore the terms $-P_i^2$ and $-P_iP_j$ $(i, j = 1, \ldots, m)$ in the elements of matrix $_\Sigma$, the variance-covariance matrix Σ is reduced to:

$$\Sigma \approx \begin{bmatrix} P_1 & 0 & \ldots & 0 \\ 0 & P_2 & \ldots & 0 \\ \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & \ldots & P_m \end{bmatrix} = \mathrm{diag}(P_i) .$$

Similarly, we have $\Sigma^A \approx \mathrm{diag}(P_i^A)$ for the affected individuals. Thus, T can be reduced to:

$$T = \sum_{i=1}^{m} \frac{(P_i - P_i^A)^2}{\frac{P_i}{2n_G} + \frac{P_i^A}{2n_A}} .$$

If we assume that the numbers of affected and unaffected individuals are equal, i.e. $n_A = n_G = n$, then the χ^2 test statistic T can be further reduced to:

$$T = 2n \sum_{i=1}^{m} \frac{(P_i - P_i^A)^2}{P_i + P_i^A} ,$$

which is exactly the formula of the standard χ^2 test statistic [16].

3.3 Test Statistics

From Section 3.2 we know that the principle behind the standard χ^2 test in case-control studies is to compare differences in allele/haplotype frequencies between two populations (e.g. cases and controls). We expect that amplifying such differences may improve the power of detecting disease susceptibility genes. One strategy for amplifying the difference is to nonlinearly transform the frequencies. The difference in the values of nonlinear function of allele/haplotype frequencies between cases and controls should be larger than the difference in original allele/haplotype frequencies. This observation motivates us to develop a general framework for population-based association studies which is based on the difference in nonlinear transformation of allele/haplotype frequencies between cases and controls.

Assume that n_A affected individuals and n_G unaffected individuals are sampled. Let $\hat{P}_{H_i}^A$ and $\hat{P}_{H_i}$ be the estimators of frequencies of haplotype H_i in cases and controls. The allele/haplotype frequencies are asymptotically distributed as the multivariate normal distributions $N(P^A, \frac{1}{2n_A}\Sigma^A)$ and $N(P, \frac{1}{2n_G}\Sigma)$, respectively, where $P^A = [P_{H_1}^A, \ldots, P_{H_m}^A]^{\mathrm{T}}$, $P = [P_{H_1}, \ldots, P_{H_m}]^{\mathrm{T}}$, $\Sigma^A = \mathrm{diag}(P_1^A, \ldots, P_m^A) - P^A(P^A)^{\mathrm{T}}$ and $\Sigma = \mathrm{diag}(P_1, \ldots, P_m) - PP^{\mathrm{T}}$.

Let $f(x)$ be a continuously differentiable nonlinear function with a nonzero differential at x. Let $X_j = f(\hat{P}_{H-j}^A)$ for $j = 1, \ldots, m$, $X = [X_1, \ldots, X_m]^{\mathrm{T}}$, $Y_j = f(\hat{P}_{H_j})$ and $Y = [Y_1, \ldots, Y_m]^{\mathrm{T}}$. Then, the random vectors X and Y are asymptotically distributed as multivariate normal distributions $N(f(P^A), \frac{1}{2N_A}B\Sigma^A B^T)$ and $N(f(P), \frac{1}{2n_G}C\Sigma C^{\mathrm{T}})$, respectively [87], where $b_{ii} = \frac{\partial f(P_{H_i}^A)}{\partial P_{H_i}^A}$, $b_{ij} = 0$, $c_{ii} = \frac{\partial f(P_{H_i})}{\partial P_{H_i}}$, $c_{ij} = 0$, $B = (b_{ij})_{m \times m}$ and $C = (c_{ij})_{m \times m}$.

Define the matrix:

$$\Lambda = \frac{1}{2n_A} B\Sigma^A B^T + \frac{1}{2n_G} C\Sigma C^{\mathrm{T}} .$$

Let $\hat{\Lambda}$ be an estimator of the matrix Λ. We propose the following test statistic T_N to test the association of the alleles/haplotypes with the disease [123]:

$$T_N = (X - Y)^{\mathrm{T}} \hat{\Lambda}^{-} (X - Y) ,$$

where $\hat{\Lambda}^{-}$ is the generalized inverse of the matrix $\hat{\Lambda}$. The null hypothesis is that there is no association of alleles/haplotypes with the disease, i.e. $H_0 : P^A = P$. Let $r = \text{rank}(\hat{\Lambda})$. Under the null hypothesis, T_N is asymptotically distributed as a central χ^2 with r degrees of freedom (Theorem A, p. 122 in Ref. [87]; p. 13 in Ref. [43]). The test statistic T_N defines a class of nonlinear tests. Various nonlinear functions with some regularity can be used to construct the test statistic. Table 1 lists some of the nonlinear functions used in this study and their corresponding derivatives.

Table 1 Some of the nonlinear transformations for allele or haplotype frequencies

Function	Derivative
Entropy	
$-x \log x$	$-1 - \log x$
Exponential	
e^x	e^x
Polynomial	
$x^2 + x + 1$	$2x + 1$
Sigmoid	
$\dfrac{1}{1+\mathrm{e}^{-x}}$	$\dfrac{\mathrm{e}^{-x}}{(1+\mathrm{e}^{-x})^2}$
Gaussian	
$\mathrm{e}^{-\frac{(x-c)^2}{2\sigma^2}}$	$\dfrac{c-x}{\sigma^2} \times \mathrm{e}^{-\frac{(x-c)^2}{2\sigma^2}}$
Reciprocal	
$\dfrac{1}{x}$	$-\dfrac{1}{x^2}$

3.4 Null Distribution of the Nonlinear Statistics

In the previous sections, we have shown that when the sample size is large enough to apply large sample theory, the nonlinear test statistics under null hypothesis of no association are asymptotically distributed as central χ^2 distributions. To examine the validity of this statement, we performed a series of simulation studies [123]. The computer program SNaP [71] was used to generate haplotypes of the sample individuals. Two datasets with a single haplotype block each were simulated. The first dataset has two marker loci which generated four haplotypes with frequencies 0.2952, 0.2562, 0.1957 and 0.2529. The second dataset has six marker loci which generated eight haplotypes with frequencies 0.1820, 0.1461, 0.1406, 0.1291, 0.1211, 0.1107, 0.0817 and 0.0887. For each dataset, 20 000 individuals who were equally divided into cases and controls were generated in the general population.

To examine whether the asymptotic results of the nonlinear test statistics still hold for small sample size under the null hypothesis of no association, 100–500 individuals were randomly sampled from each of the cases and controls. In total, 10 000 simulations were repeated for each of the nonlinear test statistics. In each simulation, the nonlinear test statistics were calculated. Figure 4(A and B) plots the histograms of the nonlinear test statistics based on entropy and exponential functions using two-SNP haplotypes. It can be seen that the null distributions of nonlinear statistics are similar to the theoretical central χ^2 distributions even under the scenario of smaller sample size. Type I error rates of the nonlinear test statistics for sample sizes from 100 to 500 individuals using two-SNP and six-SNP haplotypes have been summarized, and show that the estimated type I error rates (at the significance level 0.05) of the nonlinear test statistics were not appreciably different from the nominal level $\alpha = 0.05$.

3.5 Power of the Nonlinear Test Statistics and the Standard χ^2 Test Statistic

The standard χ^2 test statistic is a special case of the general nonlinear test statistics. The nonlinear test statistics can be used as the general framework for association studies. To further study the merit of the nonlinear statistics for association studies we need to evaluate the performance of nonlinear tests and compare the power of several nonlinear test statistics with that of the standard χ^2 test statistic.

To gain further understanding the power of the nonlinear statistics, we first study their noncentrality parameters. The alternative hypothesis is that there is at least one allele or haplotype associated with the disease, i.e. $H_a : P^A \neq P$. Under the alternative hypothesis, the test statistic T_{N} is asymptotically distributed as a noncentral $\chi^2_{(r)}$ distribution with the following noncentrality parameter:

$$\lambda_{\mathrm{N}} = [f(P^4) - f(P)]^{\mathrm{T}} \Lambda^{-1} [f(P^A) - f(P)] \, ,$$

where:

$$\begin{aligned}
r &= \operatorname{rank}(\Lambda), f(P^A) = [f(P^A_{H_1}), \ldots, f(P^A_{H_m})]^{\mathrm{T}}, \\
f(P) &= [f(P_{H_1}), \ldots, f(P_{H_m})]^{\mathrm{T}} \, , \\
\Lambda &= \frac{1}{2n_A} B \Sigma^A B^{\mathrm{T}} + \frac{1}{2n_G} C \Sigma C^T, \quad \Sigma^A = \operatorname{diag}(P^A_{H_1}, \ldots, P^A_{H_m}) - P^A (P^A)^{\mathrm{T}} \, , \\
\Sigma &= \operatorname{diag}(P_{H_1}, \ldots, P_{H_m}) - P P^{\mathrm{T}} \, , \quad P^A = [P^A_{H_1}, \ldots, P^A_{H_m}]^{\mathrm{T}} \, , \\
P &= [P_{H_1}, \ldots, P_{H_m}]^{\mathrm{T}} \, , \\
b_{ii} &= \frac{\partial f(P^A_{H_i})}{\partial P^A_{H_i}}, b_{ij} = 0, i \neq j, c_{ii} = \frac{\partial f(P_{H_i})}{\partial P_{H_i}}, c_{ij} = 0, i \neq j, B = (b_{ij})_{m \times m} \\
& \text{and } \mathrm{C} = (c_{ij})_{m \times m} \, .
\end{aligned}$$

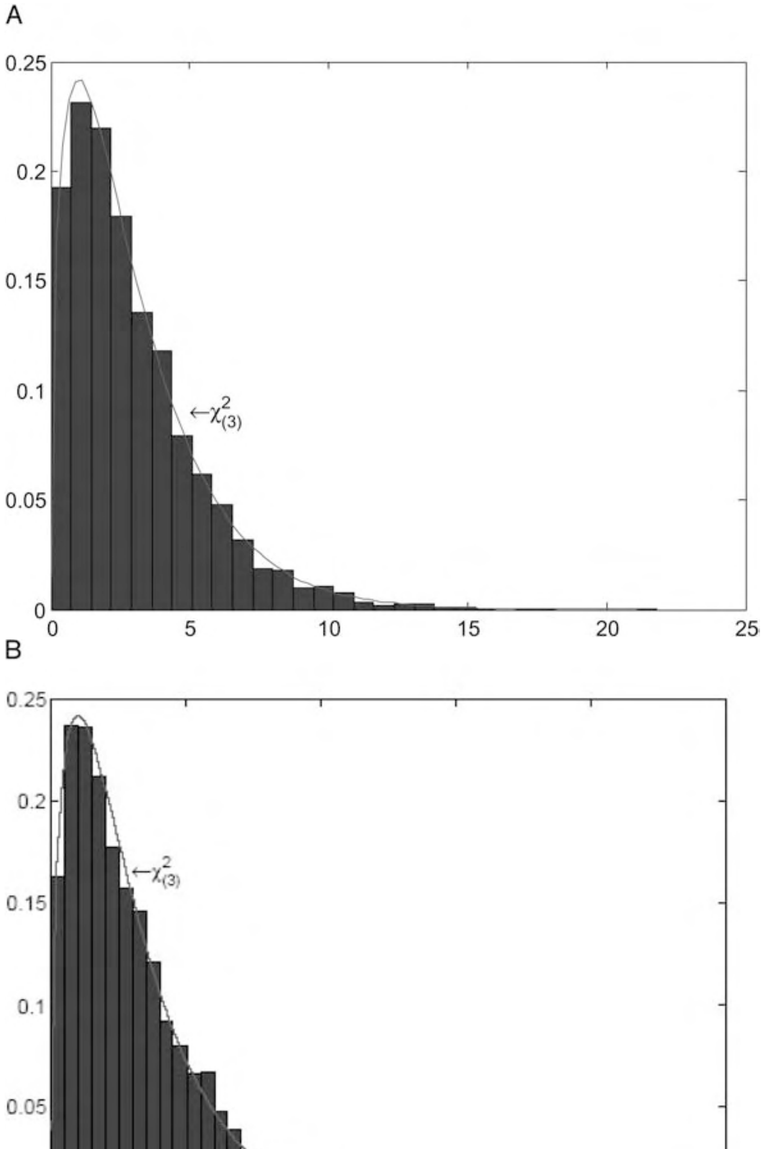

Figure 4 Histograms of nonlinear test statistics.

The noncentrality parameter λ_N can be approximated by (Appendix A) [123]:

$$\lambda_N \approx e^2 \delta_{HD}^T \left(I + \frac{1}{2}S\right)^T \left[\frac{1}{2n_A}(I+S)\Sigma^A(I+S) + \frac{1}{2n_G}\Sigma\right]^- \left(I + \frac{1}{2}S\right)\delta_{HD}\,, \tag{1}$$

where

$$e = \frac{P_D(f_{11} - f_{12}) + P_d(f_{12} - f_{22})}{P(A)}\ , \ \delta_{\mathrm{HD}} = [\delta_{H_1D}, \ldots, \delta_{H_mD}]^{\mathrm{T}}$$

and

$$S = C^{-1}H(P^A - P) = \mathrm{diag}\left(\frac{ef''(P_{H_1})\delta_{H_1D}}{f'(P_{H_1})}, \ldots, \frac{ef''(P_{H_m})\delta_{H_mD}}{f'(P_{H_m})}\right) .$$

The matrix S measures the strength of the nonlinearity of the nonlinear transformation $f(P)$ (Appendix A). Note that under the same alternative hypothesis, the traditional χ^2 test statistic, which is defined as:

$$T = (\hat{P}^A - \hat{P})^T \hat{\Lambda}_0^{-1}(\hat{P}^A - \hat{P})\ , \quad \hat{\Lambda}_0 = \frac{1}{2n_A}\hat{\Sigma}^A + \frac{1}{2n_G}\hat{\Sigma}\ ,$$

is a noncentral $\chi^2_{(r)}$ distribution with the noncentrality parameter:

$$\lambda \approx e^2 \delta_{\mathrm{HD}}^{\mathrm{T}} \left[\frac{1}{2n_A}\Sigma^A + \frac{1}{2n_G}\Sigma\right]^{-} \delta_{\mathrm{HD}}\ . \tag{2}$$

Comparing the noncentrality parameters λ_{N} and λ, we can see that the noncentrality parameter λ_{N} involves one more term S than the noncentrality parameter λ. The matrix S characterizes the nonlinearity of the nonlinear function. The power of the nonlinear test statistics depends on the strength of the nonlinearity of the nonlinear function through the matrix S. The matrix S is referred to as the strength matrix of the nonlinearity of the nonlinear function.

If the product terms of the haplotype frequencies in the variance-covariance matrices Σ^A and Σ are ignored, the matrices Σ^A and Σ can be approximated by $\Sigma^A = \mathrm{diag}(P^A_{H_1}, \ldots, P^A_{H_m})$ and $\Sigma = \mathrm{diag}(P_{H_1}, \ldots, P_{H_m})$. Then the noncentrality parameters λ_{N} andλ will be further reduced to:

$$\begin{aligned} \lambda_{\mathrm{N}} &\approx e^2 \sum_{i=1}^{m} \frac{\delta^2_{H_iD}\left(1 + \frac{e\pi_i}{2}\delta_{H_iD}\right)^2}{\frac{1}{2n_A}\left(1 + \frac{e\pi_i\delta_{H_iD}}{2}\right)^2 P^A_{H_i} + \frac{1}{2n_G}P_{H_i}} \\ \lambda &\approx e^2 \sum_{i=1}^{m} \frac{\delta^2_{H_iD}}{\frac{1}{2n_A}P^A_{H_i} + \frac{1}{2n_G}P_{H_i}}\ , \end{aligned} \tag{3}$$

where $\pi_i = \frac{f''(P_{H_i})}{f'(P_{H_i})}$. The parameter π_i is proportional to the curvature of a nonlinear function [5] and influences the noncentrality parameter λ_{N}.

From the above formulas, we can see that both noncentrality parameters λ and λ_{N} depend on the frequencies of the allele or haplotypes, penetrance, the measure of the LD between the marker alleles or haplotypes and the disease allele, as well as the number of the sampled affected and unaffected individuals. In addition, the noncentrality parameter of the nonlinear test λ_N also depends on the curvature, which measures the degree of nonlinearity of the nonlinear function.

Now we compare the power of several nonlinear test statistics with that of the standard χ^2 test statistic. The nonlinear functions for construction of nonlinear test statistics are listed in Table 1. The markers are assumed to be bi-allelic (i.e. SNPs). Specifically, we consider two scenarios: (i) a disease locus, and (ii) two marker loci and a disease locus which is located in the middle of two markers [123]. The calculation of the power is based on analytic methods which are based on calculation of the noncentrality parameter.

We first investigate the expected noncentrality parameters of the nonlinear tests statistics at the disease locus. We assume that the frequencies of two alleles at the disease locus in controls are both equal to 0.5. Figure 5 plots the expected noncentrality parameters of the nonlinear test statistics and the standard χ^2 test statistic as a function of the frequency of the disease allele in cases. From Figure 5 we can see three remarkable features. (i) The expected noncentrality parameters of all test statistics increase as difference in frequency of the disease allele between cases and controls increases. (ii) The expected noncentrality parameters of the most nonlinear test statistics in Table 1 (except for the statistic based on reciprocal transformation of the allele frequency) are larger than that of the standard χ^2 test statistic. (iii) The expected noncentrality parameters of the nonlinear test statistics in Table 1 (except for the statistic based on reciprocal transformation of the allele frequency) are almost indistinguishable.

We then investigate the power of the nonlinear test statistics at the disease locus. Figure 6(A–C) plots the power of the nonlinear test statistics and the standard χ^2 test statistic as a function of the disease allele frequency under three different disease models: (1) disease model with penetrance $f_{11} = 1$, $f_{12} = 0.2$ and $f_{22} = 0.1$; (2) disease model with penetrance $f_{11} = 1$, $f_{12} = 1$ and $f_{22} = 0.1$, and (3) genotype relative risk model, in which the genotype relative risk for genotypes *Dd* and *DD* is r and r^2 times greater than that of the genotype *dd* [82]. Several features emerge from these figures. (i) The power for most of the nonlinear test statistics is higher than that of the standard χ^2 test statistic, but the power of the test statistic based on the reciprocal function is lower than that of the standard χ^2 test statistic. The power curves of the exponential, sigmoid and quadratic functions are similar. (ii) The power of the nonlinear test statistics is influenced by the disease model. The shapes of the nonlinear test statistics in disease model (2) are different from that of the test statistics in disease models (1) and (3). (iii) The power of the test statistics depends on disease allele frequency. The shapes of the power curves in disease model (1) and (3) are roughly bell-shaped; however, the shapes of the

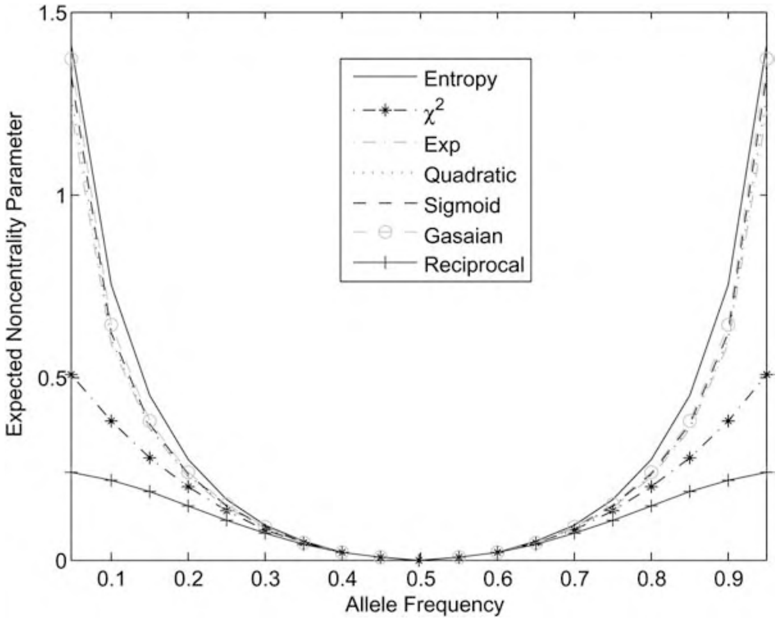

Figure 5 Expected noncentrality parameters as a function of allele frequency.

power curves in disease model (2) are skewed to the left. (iii) The strength of the nonlinearity of the nonlinear transformations also influences the power of the nonlinear test statistics. Figure 7 shows that the measure π_1 of nonlinearity for several nonlinear transformations as a function of disease allele frequency. The measure of the reciprocal function is a negative function of the disease allele frequency and is the smallest among the nonlinear functions being studied. Figure 6(A–C) also shows that the power of the reciprocal-based test statistic is the smallest among the nonlinear tests being studied. In many cases, the larger the measure of nonlinearity of the nonlinear transformation for allele or haplotype frequency, the higher the power of the nonlinear test statistic. However, since the power of the test statistics also depends on other parameters such as disease models, the correlations between the measure of the nonlinearity of the nonlinear transformation and the power of their corresponding nonlinear test statistics follow complex patterns.

Next, we study the power of the nonlinear tests using haplotypes at the marker loci. The markers are assumed to be bi-allelic (i.e. SNP). In particular, we consider two marker loci and a disease locus that is located in the middle of the two markers. The average haplotype frequencies in the affected and unaffected individuals are calculated by equations (1) and (4) in Akey and coworkers [2]. The power of the nonlinear test statistics and the standard χ^2 statistics using four haplotypes generated by two marker loci as a function

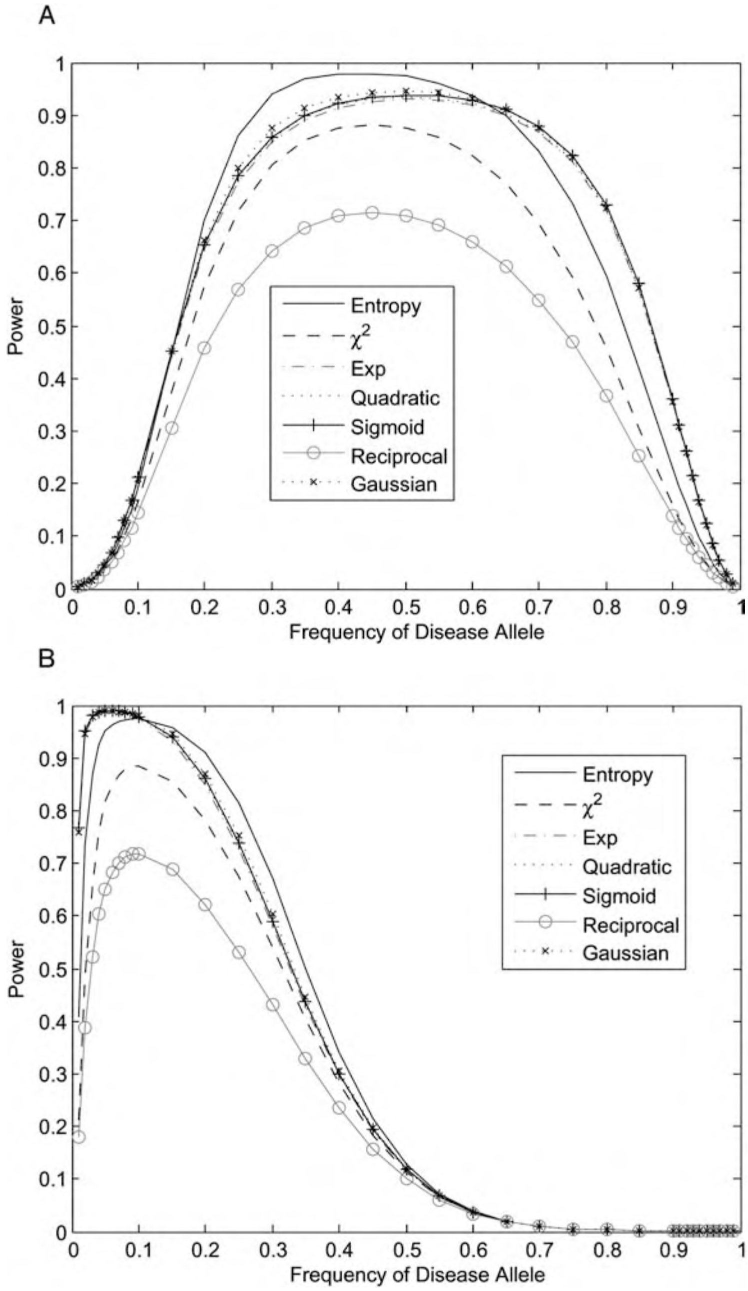

Figure 6 Power of nonlinear test statistics as a function of disease allele frequency.

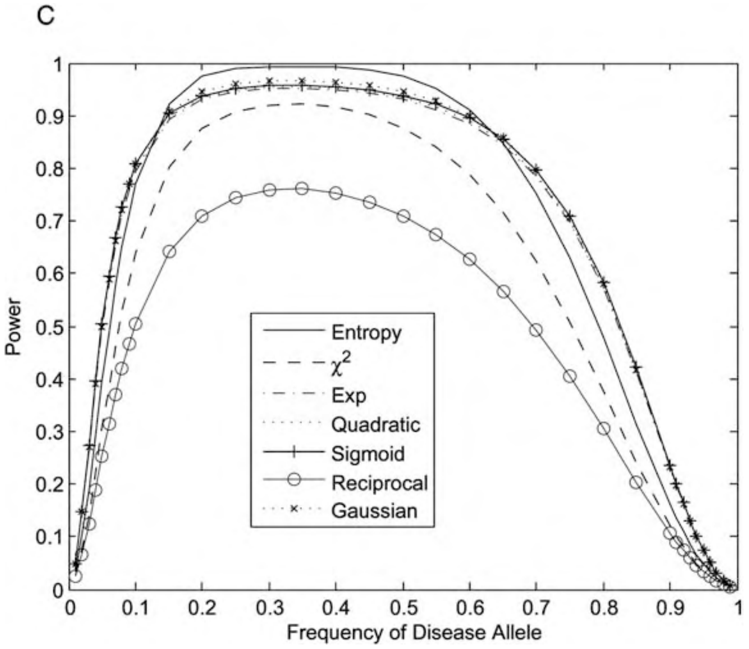

Figure 6 (continued)

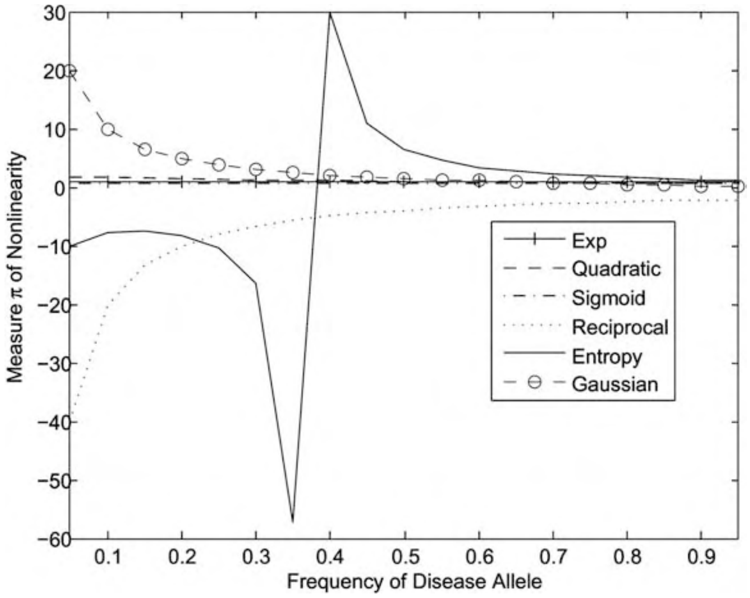

Figure 7 Measure π of nonlinearity as a function of disease allele frequency.

of the genetic distance between the disease locus and its flanking marker loci for recessive, dominance and genotype relative risk disease models is shown in Figure 8(A–C, respectively). The data demonstrate that the power of the nonlinear test statistics is higher than that of the standard χ^2 test, except for the nonlinear test based on the reciprocal. Similar to the scenario at the disease locus, the power of the nonlinear test statistics at the marker loci also depends on the disease model, haplotype frequency, disease allele frequency, the measure of the nonlinearity of the nonlinear functions, and the measure of LD between haplotypes at the marker loci and disease locus.

4 Similarity-based Statistics for Association Studies

We often observe that affected individuals share common haplotypes in the region surrounding disease mutations more often than unaffected individuals [36, 55, 116]. One way to test the excessive sharing of common haplotyes among affected individuals is to compare differences in haplotype frequencies between affected individuals and unaffected individuals [2]. Another way is to compare differences in haplotype similarity between affected and unaffected individuals [10,12,28,106,108]. Before introducing similarity-based statistics for association studies, we will study how to measure the haplotype similarity.

4.1 Similarity Measures

Several haplotype similarity measures have been developed to quantify degrees of haplotype sharing [106]. Here, we introduce three widely used measures of haplotype similarity.

Consider K marker loci which generate m haplotypes. Assume that n_A haplotypes are sampled from the affected individuals and n_G haplotypes are sampled from the unaffected individuals. Let H_i be one of the m haplotypes at the K marker loci. Let P_{H_i} and $P^A_{H_i}$ be the frequency of the haplotype H_i in the unaffected individuals and the affected individuals, respectively. Suppose that the number of H_i haplotypes in the unaffected individuals and affected individuals are n_i and n^A_i, respectively. Let Γ_{H_i} and $\Gamma^A_{H_i}$ be the similarity measure of the haplotype H_i in the unaffected individuals and affected individuals, respectively. A similarity measure of the haplotype H_i is defined as:

$$\Gamma_{H_i} = \frac{n_i}{n_G} \sum_{j=1}^{m} \frac{n_j}{n_G} S(H_i, H_j) = P_{H_i} S_i P \, ,$$

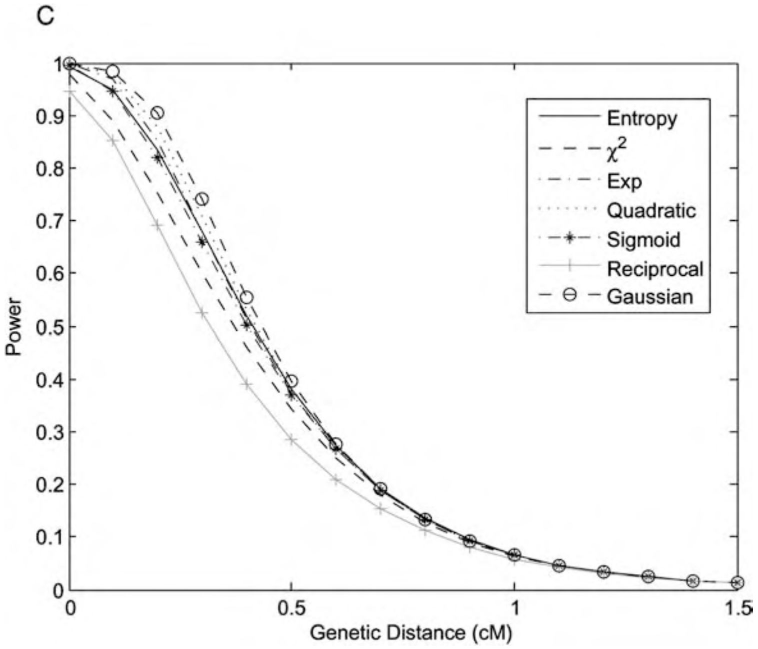

Figure 8 (continued)

where

$$P = [P_{H_1}, \ldots, P_{H_m}]^{\mathrm{T}} \;,\; S_i = [S(H_i, H_1), \ldots, S(H_i, H_m)] \;,\; S = (S(H_i, H_j))_{m \times m} \;,$$

referred to as a similarity matrix, and $S(H_i, H_j)$ is a measure to quantify similarity between the haplotype H_i and the haplotype H_j and will be defined below.

The similarity measure of all the haplotypes in the unaffected individuals, denoted by Γ, is defined as summation of the similarity measure of individual haplotype, i.e., $\Gamma = \sum_{i=1}^{m} \Gamma_{H_i}$. Then, we have $\Gamma = P^{\mathrm{T}}SP$. Similarly, for the affected individuals, we have $\Gamma = (P^A)^T S^A P^A$, where P^A, S^A and Γ^A are similarly defined as that for unaffected individuals.

4.1.1 **Matching Measure**

The matching measure $S(H_i, H_j)$ is defined as:

$$S(H_i, H_j) = \begin{cases} 1 & H_i = H_j \\ 0 & \text{otherwise} \;. \end{cases}$$

Therefore, for the matching measure, S is an identity matrix.

The matching measure considers only identical haplotypes as similar haplotypes and any nonidentical haplotypes are not similar, even if they share a

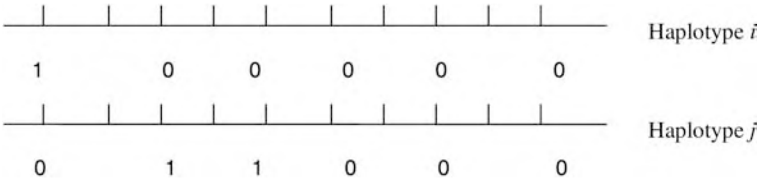

Figure 9 Scheme of length measure of similarity between haplotypes H_i and H_j.

large proportion of their sequence. To overcome such limitations, we need to develop other similarity measures.

4.1.2 Counting Measure

The counting measure $S(H_i, H_j)$ is defined as the number of alleles in common between haplotypes H_i and H_j. The haplotypes may not be identical, but share some common alleles. If the shared common alleles contain disease alleles, all haplotypes sharing disease alleles may be present more often in the affected individuals than the expected.

4.1.3 Length Measure

The length measure $S(H_i, H_j)$ is defined as the length of the longest continuous interval of matching alleles between haplotypes H_i and H_j. As shown in Figure 9, the length measure between haplotypes H_i and H_j is 7.

The length measure characterizes partial sharing identical by descent (IBD) between haplotypes.

4.2 Test Statistics

There are two types of test statistics: statistics based on the similarity measure of all haplotypes and statistics based on the similarity measure of part of the haplotypes. For the convenience of presentation, the former will be referred to as the overall similarity measure, the latter as the partial similarity measure.

We first consider test statistic based on the overall similarity measure. Define $\Sigma = \mathrm{diag}(P_1, \ldots, P_m) - PP^{\mathrm{T}}$ and $b = 2SP$. Then, $\mathrm{var}(\Gamma)$ and $\mathrm{var}(\Gamma^A)$ can be approximated by $\mathrm{var}(\Gamma) = \frac{4}{n_G} P^{\mathrm{T}} S^{\mathrm{T}} \Sigma S P$ and $\mathrm{var}(\Gamma)^A = \frac{4}{n_A} (P^A)^{\mathrm{T}} (S^A)^{\mathrm{T}} \Sigma^A S^A P^A$, where $\Sigma^A = \mathrm{diag}(P_1^A, \ldots, P_m^A) - P^A (P^A)^{\mathrm{T}}$, S^A and P^A are defined as before. We define statistic based on the overall haplotype similarity measure as:

$$T_{\mathrm{os}} = \frac{(\hat{\Gamma}^A - \hat{\Gamma})^2}{4\left[\frac{1}{n_G} \hat{P}^{\mathrm{T}} \hat{S}^{\mathrm{T}} \hat{\Sigma} \hat{S} \hat{P} + \frac{1}{n_A} (\hat{P}^A)^{\mathrm{T}} (\hat{S}^A)^{\mathrm{T}} \hat{\Sigma}^A \hat{S}^A \hat{P}^A\right]}$$

under the null hypothesis of no association, T_{os} is asymptotically distributed as a central $\chi^2_{(1)}$ distribution.

Now consider the test based on the partial haplotype similarity measure. Let $b_{ii} = S_{ii}P_{H_i} + \sum_{j=1}^{m} S_{ij}P_{H_j}$ and $b_{ij} = P_{H_i}S_{ij}P_{H_j}$ $(i \neq j)$. $\Gamma_H = [\Gamma_{H_1}, \ldots, \Gamma_{H_m}]^{\mathrm{T}}$ and $B = (b_{ij})_{m\times m}$. B^A and Γ_H^A for the affected individuals are similarly defined. Define the test statistic as $T_s = (\Gamma_H^A - \Gamma_H)^{\mathrm{T}}\Lambda^-(\Gamma_H^A - \Gamma_H)$, where $\Lambda = \frac{1}{n_G}B\Sigma B^{\mathrm{T}} + \frac{1}{n_A}B^A\Sigma^A(B^A)^{\mathrm{T}}$. Under the null hypothesis of no association, T_s is asymptotically distributed as a central $\chi^2_{(r)}$ distribution, where $r = \mathrm{rank}(\Lambda)$.

Above we also show that the similarity measure of the genome region is a quadratic function of the allele or haplotype frequencies. Therefore, similarity-based statistics are nonlinear test statistics.

5 Generalized T^2 Test Statistic

Although most researchers acknowledge that genetic variation provides valuable information for diagnosis, prevention and treatment of complex diseases, there is no universally accepted consensus on how genetic variation contributes to the cause of complex diseases [90, 91]. Two different basic view points on the genetic architecture of complex diseases lead to two different strategies for analyzing complex diseases.

The popular view on the mechanisms of the common diseases is to assume that a single marker or gene acts independently and can explain the pathogenesis of the disease. The widely used strategies for unraveling the genetic structure of a common disease are single-locus analysis, one locus at a time, assuming that each susceptible locus has a large independent main effect on disease risk. The strategies focusing on the single genes with large marginal effects on disease risk have resulted in only limited success in genetic studies of complex diseases [47]. Current research demonstrates that only a small proportion of the disease risk is due to the influences of variations in a single gene with large genetic effects. In the real world, complex diseases develop as a consequence of interactions between multiple DNA variants, and exposure to environmental agents varying over time and space, which are organized into networks. The single-gene paradigm for genetic analysis which has proven successful in dissecting genetic structures of Mendelian diseases may not lead to success in genetic studies of complex diseases.

There are an increasing number of researchers who advocate taking a systems-level approach to complex diseases. The new concept concerning complex disease is to assume that the development of disease should be considered as a dynamic process with gene–gene and gene–environment interactions contributing within a complex biological system which is hierarchically organized into complex gene interaction networks [90, 91]. Genetic mechanisms underlying complex diseases involve multiple genes which influence disease variation largely through genetic interaction networks in which the effect of one gene is enhanced or masked by effects of other genes [66]. Actions of genes through networks are consequences of complex molecular interactions occurring during biological processes such as metabolism, transcription, signal transduction and translations. It was reported that the principles underlying stable phenotypes in the presence of mutations comprise genetic network structure that are redundant and robust [39]. Consequently, the genetic effects on the phenotype can be observed only when multiple mutations hit the genetic networks. The phenotypic variations depend on the genetic interaction networks. Uncovering hierarchically organized gene interaction networks and their nonadditive relationships with disease susceptibility require developing novel statistics which can test association of a set of markers or networks with the disease.

The Hotelling T^2 statistic can be used to test association of multiple markers (or networks) with the disease [117].

5.1 Test Statistic

Consider a design in which n_A cases from an affected population and n_G control subjects from a comparable unaffected population are sampled. Suppose that there are k markers typed in the samples. The j-th marker has alleles B_j and b_j with population frequencies P_{B_j} and P_{b_j}, respectively. Define an indicator variable for the genotype of the j-th marker for the i-th individual from the affected population:

$$X_{ij} = \begin{cases} 1 & B_jB_j \\ 0 & B_jb_j \\ -1 & b_jb_j \end{cases} .$$

Similarly, we define an indicator variable, Y_{ij}, for an individual from the unaffected population. Let:

$$\begin{aligned} X_i &= (X_{i_1}, \ldots, X_{i_k})^{\mathrm{T}},\ Y_i = (Y_{i_1}, \ldots, Y_{i_k})^{\mathrm{T}} \\ \bar{X}_j &= \frac{1}{n_A}\sum_{i=1}^{n_A} X_{ij},\ \bar{Y}_j = \frac{1}{n_G}\sum_{i=1}^{n_G} Y_{ij} \\ \bar{X} &= (\bar{X}_1, \ldots, \bar{X}_k)^{\mathrm{T}},\ \bar{Y} = (\bar{Y}_1, \ldots, \bar{Y}_k)^{\mathrm{T}} . \end{aligned}$$

The pooled-sample variance-covariance matrix of the indicator variables for the marker genotypes is defined as:

$$S = \frac{1}{n_A + n_G - 2}\left[\sum_{i=1}^{n_A}(X_i - \bar{X})(X_i - \bar{X})^{\mathrm{T}} + \sum_{i=1}^{n_G}(Y_i - \bar{Y})(Y_i - \bar{Y})^{\mathrm{T}}\right] .$$

Hotelling's [51] T^2 statistic is then defined as

$$T^2 = \frac{1}{\frac{1}{n_A} + \frac{1}{n_G}}(\bar{X} - \bar{Y})^{\mathrm{T}} S^{-1}(\bar{X} - \bar{Y}) ,$$

Under the null hypothesis of no association of markers with the disease, the statistic T^2 is asymptotically distributed as a central $\chi^2_{(k)}$ distribution.

5.2 Nonlinear T^2 test

We can also develop a nonlinear T^2 statistic for testing the association of a set of markers with the disease. Let f be a nonlinear function. Then, $f(\bar{Y}) - f(\bar{X})$ is asymptotically distributed as the following multivariate normal distribution:

$$f(\bar{Y}) - f(\bar{X}) \sim N(f(\mu_Y) - f(\mu_X), \Lambda),$$

$$\mu_x = E[\bar{X}] ,$$

$$\mu_Y = E[\bar{Y}],\ \Lambda\frac{1}{n_A}C\Sigma_Y C^T + \frac{1}{n_G}B\Sigma_x B^{\mathrm{T}},\ C = \left(\frac{\partial f}{\partial \mu_Y^T}\right),$$

$$\Sigma_Y = n_A \mathrm{cov}(\bar{Y}, \bar{Y}),\ \mu_x = E[\bar{X}] ,$$

$$B = \left(\frac{\partial f}{\partial \mu_x}^{\mathrm{T}}\right),\ \Sigma_x = n_G \mathrm{cov}(\bar{X}, \bar{X}) .$$

The nonlinear T^2 statistic can be defined as:

$$T_{\mathrm{N}} = [f(\bar{Y}) - f(\bar{X})]^{\mathrm{T}}\,(\hat{\Lambda})^{-}\,[f(\bar{Y} - f(\bar{X})]$$

where $(\hat{\Lambda})^{-}$ is the generalized inverse of the matrix $\hat{\Lambda}$. Let $r = \mathrm{rank}(\hat{\Lambda})$. It can be shown [43] that under the null hypothesis of no association of the markers with the disease, the statistic T_{N} is asymptotically distributed as a central $\chi^2_{(r)}$ distribution.

6 Family-based Association Studies

Although population-based association studies are a powerful tool for genetic studies of complex diseases, their drawback is that they may create spurious association due to population substructure. Recently, genomic control has been proposed to adjust for the effect of population substructure [27, 29]. However, the adjustment depends on the assumed models and the population parameters [124]. Since the true disease models are unknown and the estimation of population parameters may not be accurate, genomic control cannot completely eliminate the effect of population substructure on association studies.

The transmission/disequilibrium test (TDT), introduced by Spielman and coworkers [94], and its extensions are widely used to test for linkage in the presence of association because they can avoid spurious association due to population substructure [34]. The original TDT and its early extensions use one marker at a time [59, 63, 84, 89, 93]. With availability of a large collection of SNPs and the rapid progress of efficient genotyping methods, the TDT has been extended to using haplotypes and multiple marker loci [10, 11, 18, 65, 77, 121, 122]. Although collection of nuclear family data is not easy for late onset diseases, TDT will still be a major tool for genome-wide association studies.

6.1 TDT at a Single Locus with Two Alleles

Throughout the chapter, we consider nuclear families with at least one affected child. For the time being, we consider a locus with two alleles B_1 and B_2 at the marker locus and assume that the parental genotypes are known. We also assume that parents are heterozygous at the marker locus. Let n_1 be the total number of transmissions of allele B_1 to affected children and $n_2$be the total number of transmissions of allele B_2. Then, the original TDT is defined as [94]:

$$\mathrm{TDT} = \frac{(n_1 - n_2)^2}{n_1 + n_2} . \tag{4}$$

The original TDT can be rewritten in terms of allele frequencies. Let $n = n_1 + n_2$, $\hat{p} = n_1/n$, and $\hat{q} = n_2/n$ be the frequencies of the transmitted alleles B_1 and B_2, respectively. Then, the TDT in Eq. (4) can be rewritten as:

$$\mathrm{TDT} = n(\hat{p} - \hat{q})^2 .$$

6.2 TDT at a Single Locus with Multiple Alleles or at Multiple Loci with Phase-known Haplotypes

The two-allele TDT can be generalized to multiple alleles or multiple loci with haplotypes. If the phases of haplotypes are known, the TDT formulations for multiple alleles or haplotypes are the same. For simplicity of presentation, we only consider haplotypes. However, conclusions obtained for haplotypes hold for multiple alleles. Assume that the number of haplotypes is k. Let n_{ij} be the number of times that heterozygous parents with genotype H_iH_j transmit haplotype H_i to an affected child. Since we consider only heterozygous parents, we assume $n_{ii} = 0$ for all i. Let $n_{i\cdot} = \sum_{j=1}^{k} n_{ij}$ be the number of times that haplotype H_i is transmitted to an affected child and $n_{\cdot i} = \sum_{j=1}^{k} n_{ji}$ be the number of times that it is not. The extension of the two-allele TDT is then given by [93]:

$$\mathrm{TDT}_m = \frac{k-1}{k} \sum_{i=1}^{k} \frac{(n_{i\cdot} - n_{\cdot i})^2}{n_{i\cdot} + n_{\cdot i}} \ . \tag{5}$$

This test statistic may not be distributed as a $\chi^2_{(k-1)}$ distribution [59,84,88].

To ensure that the multiple allele or haplotype TDT asymptotically follows a χ^2 distribution, TDT_m can be modified using score method [88]. Let $n = \sum_{i=1}^{k} \sum_{j=1}^{k} n_{ij}$. Let p_{ij} be the probability that a parent with genotype $H_i H_j$ transmits haplotype H_i to an affected child, $p_{i\cdot}$ be the probability that haplotype H_i is transmitted to an affected child and $p_{\cdot i}$ be the probability that haplotype H_i is not transmitted to an affected child. Their estimates are, respectively, given by:

$$\hat{p}_{ij} = \frac{n_{ij}}{n} \ , \quad \hat{p}_{i\cdot} = \frac{n_{i\cdot}}{n} \quad \text{and} \quad \hat{p}_{\cdot i} = \frac{n_{\cdot i}}{n} \ .$$

Let $\hat{p} = [\hat{p}_{1\cdot}, \ldots, \hat{p}_{k\cdot}]^{\mathrm{T}}$, $\hat{q} = [\hat{p}_{\cdot 1}, \ldots, \hat{p}_{\cdot k}]^{\mathrm{T}}$, $\hat{q} = [\hat{p}_{\cdot 1}, \ldots, \hat{p}_{\cdot k}]^{\mathrm{T}}$ and $d = \hat{p} - \hat{q}$. We can show that the variance-covariance matrix of d is given by:

$$\mathrm{cov}(d, d) = \Sigma / n \ ,$$

where:

$$\Sigma = \Sigma_p + \Sigma_q - \Sigma_{pq} - \Sigma_{pq}^{\mathrm{T}} \ ,$$

$$\begin{aligned}
\Sigma_p &= \begin{bmatrix} p_{1\cdot}(1 - p_{1\cdot}) & \ldots & -p_{1\cdot} p_{k\cdot} \\ \ldots & \ldots & \ldots \\ -p_{k\cdot} p_{1\cdot} & \ldots & p_{k\cdot}(1 - p_{k\cdot}) \end{bmatrix} \\
\Sigma_q &= \begin{bmatrix} p_{1\cdot}(1 - p_{\cdot 1}) & \ldots & -p_{\cdot 1} p_{\cdot k} \\ \ldots & \ldots & \ldots \\ -p_{\cdot k} p_{\cdot 1} & \ldots & p_{\cdot k}(1 - p_{\cdot k}) \end{bmatrix} \\
\Sigma_{pq} &= \begin{bmatrix} -p_{1\cdot} p_{\cdot 1} & \ldots & p_{1k} - p_{1\cdot} p_{\cdot k} \\ \ldots & \ldots & \ldots \\ p_{k1} - p_{k\cdot} p_{\cdot 1} & \ldots & -p_{k\cdot} p_{\cdot k} \end{bmatrix} \ .
\end{aligned} \tag{6}$$

By large sample theory [60], d is asymptotically as $N(p - q, \frac{1}{n}\Sigma)$.

Define the statistic:

$$\mathrm{TDT}_s = n d^{\mathrm{T}} \Sigma^{-} d \ , \tag{7}$$

where Σ^- is the generalized inverse of matrix Σ. Then, under the null hypothesis of no linkage, TDT_s is asymptotically distributed as a central χ^2 distribution with degrees of freedom r, where $r = \text{rank}(\Sigma^-)$.

6.3 Sib-TDT

6.3.1 Comparison of Genotype Frequencies

Assume that total N_s sibships are sampled. Let G be the number of observed genotypes among all individuals in the sample. Let m_{ij} be the number of individuals with the j-th genotype in the i-th sibship. Let N_i^A and N_i^C be the number of affected individuals and unaffected individuals in the i-th sibship, respectively. We denote the total number of individuals in the i-th sibship by N_i, i.e. $N_i = N_i^A + N_i^C$. Let t_{ij} be the number of individuals with the j-th genotype in the i-th sibship. Then, m_{ij} follows a hypergeometric distribution with mean:

$$e_{ij} = t_{ij} \frac{N_i^A}{N_i} ,$$

and variance:

$$V_{ij} = t_{ij} \frac{N_i^A}{N_i} \left(1 - \frac{N_i^A}{N_i}\right) \frac{N_i - t_{ij}}{N_i - 1} .$$

Let $\pi_{ij} = \frac{t_{ij}}{N_i}$, $\pi_i = [\pi_{i1}, \ldots, \pi_{iG}]^{\mathrm{T}}$, $t_i = [t_{i1}, \ldots, t_{iG}]^{\mathrm{T}}$, $e_i = [e_{i1}, \ldots, e_{iG}]^{\mathrm{T}}$, $m_i = [m_{i1}, \ldots, m_{iG}]^{\mathrm{T}}$ and $V_i = [\text{diag}(\pi_i) - \pi_i \pi_i^{\mathrm{T}}] \frac{N_i^A N_i^C}{N_i - 1}$.

The total observed genotype counts for the affected sibs across all families with its expected value under the null hypothesis of no association are given by:

$$m = \sum_{i=1}^{N_s} m_i$$

and:

$$e = \sum_{i=1}^{N_s} e_i .$$

Let N^A be the total number of affected sibs across all families. Let $P = \frac{m}{N^A}$, $\mu = \frac{e}{N^A}$ and $V = \frac{1}{(N^A)^2} \sum_{i=1}^{N_s} V_i$. When the sample size is large, P is asymptotically distributed as a multivariate normal distribution with mean μ and variance-covariance matrix V. Let $b_{jj} = -1 - \log P_j$, $b_{jk} = 0$, $j \neq k$, $B = (b_{jk})_{G \times G}$, $Y_j = -P_j \log P_j$, $Y = [Y_1, \ldots, Y_G]^{\mathrm{T}}$ and $\Sigma = BVB^{\mathrm{T}}$.

Define the test statistic:

$$T_{\mathrm{SG}} = (Y - \mu)^{\mathrm{T}} \Sigma^{-} (Y - \mu) ,$$

where Σ^{-} denotes the generalized inverse of matrix Σ. Under the null hypothesis of no association, statistic T_{SG} is asymptotically distributed as a $\chi^2_{(G-1)}$.

6.3.2 Comparison of Allele Frequencies

When the number of genotypes is large, an approach via the comparison of genotype frequencies will have low power. To avoid this problem, we compare allele frequencies. Allele counts are linear combinations of genotype counts [85]. Suppose that there are K alleles. The count of the l-th allele for the affected individuals in the i-th sibship is equal to $a_{il} = C_{il}^{\mathrm{T}} m_i$, where the j-th element of the vector C_{il} has the value 2, 1 or 0, depending on whether the corresponding genotype has 2, 1 or 0 alleles of type$l$ allele. Let $C_i^{\mathrm{T}} = [C_{i1}, \ldots, C_{ik}]$. Then, the observed allele count of the affected individuals in the i-th sibship and its expected values under the assumption of no association are given by $a_i = C_i m_i$ and $e_i^a = C_i e_i$. The covariance matrix is $V_i^a = C_i V_i C_i^{\mathrm{T}}$.

Define $m^a = \sum_{i=1}^{N_s} a_i$, $e^a = \sum_{i=1}^{N_s}$, and $V^a = \sum_{i=1}^{N_s} V_i^a$. Let $P^a = \frac{m^a}{N^A}$, $\mu^a = \frac{e^a}{N^A}$ and $\Sigma^a = \frac{BV^aB^{\mathrm{T}}}{(N^A)^2}$, where B is defined as that in the previous section.

Define $Y_j^a = -P_j^a \log P_j^a$ and $Y^a = [Y_1^a, \ldots, Y_k^a]^{\mathrm{T}}$. Then, the test statistic T_{Sa}, defined as:

$$T_{\mathrm{Sa}} = (Y^a - \mu^a)^{\mathrm{T}} (\Sigma^a)^{-} (Y^a - \mu^a) ,$$

is asymptotically distributed as a central $\chi^2_{(k-1)}$ under the null hypothesis of no association.

7 Nonlinear Transmission/Disequilibrium Test

Similar to population-based association studies, multiple-testing problems are also the major barrier to success of genome-wide TDT. By the same arguments as those for population-based genome-wide association studies, there is an urgent need to develop novel genome-wide TDT statistics with high power.

A natural way of developing powerful genome-wide TDT statistics is to apply a nonlinear transformation of the number of the transmitted and nontransmitted alleles or haplotypes for enlarging the difference in the number of transmitted and nontransmitted alleles or haplotypes. The common feature of the original TDT and its extensions is to compare the difference between the numbers of alleles or haplotypes transmitted and not transmitted from heterozygous parents to affected children, respectively. Therefore, amplifying the difference between the numbers of transmitted and nontransmitted alleles

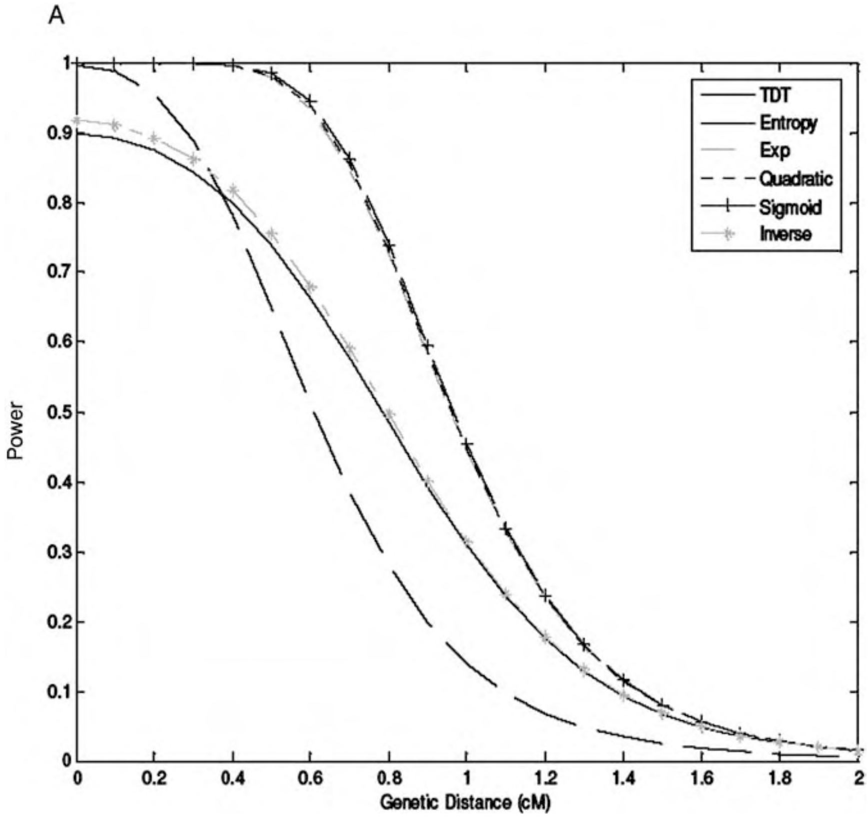

Figure 10 Power of nonlinear test statistics as a function of genetic distance.

or haplotypes is essential to improving the power of the TDT statistic. We hypothesized that this goal can be achieved by modifying the TDT statistics. Instead of comparing the difference between the numbers of the transmitted and nontransmitted alleles or haplotypes, the modified TDT compares the difference between a nonlinear transformation of these numbers. Such a transformation should satisfy two conditions: (i) statistics based on such a nonlinear transformation must still provide valid tests in the presence of population substructure and (ii) the nonlinear transformation should amplify the difference between the numbers of transmitted and nontransmitted alleles or haplotypes. The TDT based on the comparison of differences between the nonlinear transformations of the numbers of transmitted and nontransmitted alleles or haplotypes is referred to as nonlinear TDT.

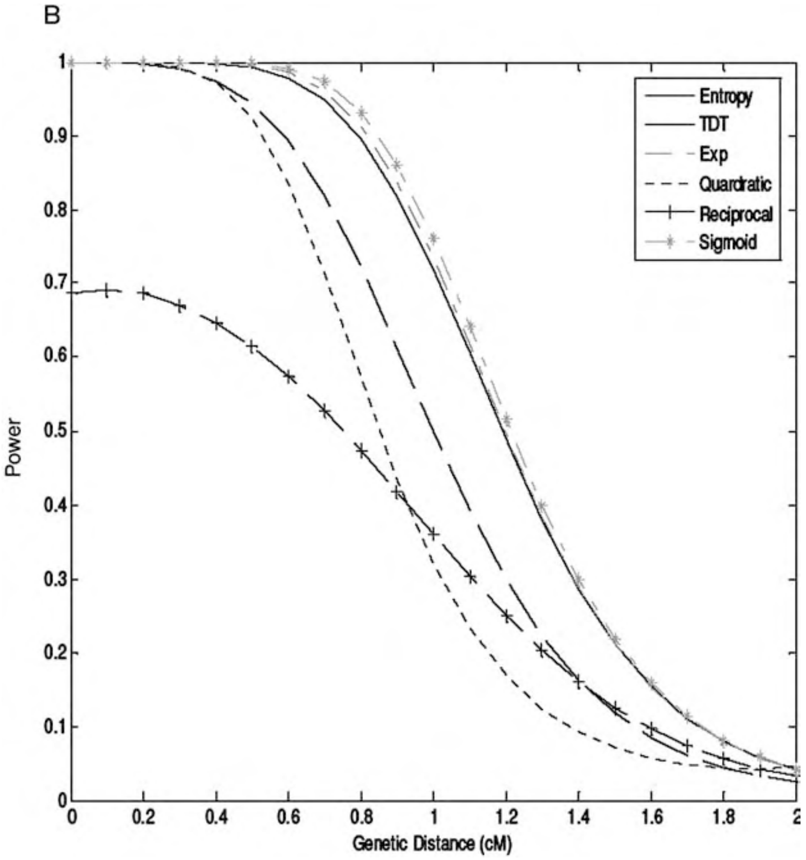

Figure 10 (continued)

7.1 General Procedures for the Construction of the Nonlinear TDT

For the simplicity, we consider family trios (one affected offspring with two heterozygous parents) and assume that all family members are genotyped at one or multiple marker loci. For haplotype analysis, we assume that the phases of the haplotypes are known. The results can be extended to sib-pair and general pedigrees with phase known and unknown haplotypes£®

7.1.1 A Single Locus with Two Alleles

Consider a locus with two alleles M_1 and M_2. Let n_1 be the total number of transmission of allele M_1 to the affected child and n_2 be the total number of transmission of allele M_2. Let $n = n_1 + n_2$, $\hat{p} = n_1/n$ and $\hat{q} = n_2/n$ be the estimated frequencies of the transmitted alleles M_1 and M_2, respectively. The nonlinear TDT for one locus with two alleles is defined as:

$$\mathrm{TDT}_{N_1} = \frac{n[f(\hat{p}) - f(\hat{q})]^2}{\hat{p}\hat{q}\{[f'(\hat{p}) + f'(\hat{q})]^2\}}\,, \tag{8}$$

where $f(\cdot)$ is a differentiable nonlinear function satisfying some regularity conditions such as entropy, exponential, polynomial, sigmoid and reciprocal functions. It can be shown that TDT_{N_1} is asymptotically distributed as a central $\chi^2_{(1)}$ distribution under the null hypothesis of no linkage or no association and asymptotically distributed as a noncentral $\chi^2_{(1)}$ distribution with the noncentrality parameter:

$$\lambda_{\mathrm{N}_1} = \frac{n[f(p) - f(q)]^2}{pq\{[f'(p) + f'(q)]^2\}}\,, \tag{9}$$

under the alternative hypothesis of presence of linkage and association.

7.1.2 **A Single Locus with Multiple Alleles or Multiple Loci with Phase-known Haplotypes**

The two-allele TDT can be generalized to multiple alleles or multiple loci with haplotypes. If phases of haplotypes are known, the TDT formulations for multiple alleles or haplotypes are the same. For simplicity of presentation, we only consider haplotypes. However, conclusions obtained for haplotypes also hold for multiple alleles. Assume that the number of haplotypes is K. Let n_{ij} be the number of times that heterozygous parent with genotype H_iH_j transmits H_i to an affected child. Since we consider only heterozygous parents, we assume $n_{ii} = 0$ for all i. Let $n_{i\cdot} = \sum_{j=1}^{k} n_{ij}$ be the number of times that haplotype H_i is transmitted to an affected child and $n_{\cdot i} = \sum_{j=1}^{k} n_{ji}$ be the number of times that is not. Furthermore, let $n = \sum_{i=1}^{k}\sum_{j=1}^{k} n_{ij}$. Let P_{ij} be the probability that a parent with genotype H_iH_j transmits haplotype H_i to an affected child, $P_{i\cdot}$ be the probability that haplotype H_i is transmitted to an affected child and $P_{\cdot i}$ be the probability that haplotype H_i is not transmitted to an affected child. Their estimates are given by $\hat{p}_{ij} = n_{ij}/n$, $\hat{p}_{i\cdot} = n_{i\cdot}/n$ and $\hat{p}_{\cdot i} = n_{\cdot i}/n$. Let:

$$\begin{aligned}
\Sigma_p &= \begin{bmatrix} p_{1\cdot}(1 - p_{1\cdot}), & \ldots, & -p_{1\cdot}p_{k\cdot} \\ \ldots & \ldots & \ldots \\ -p_{k\cdot}p_{1\cdot}, & \ldots, & -p_{k\cdot}(1 - p_{k\cdot}) \end{bmatrix} \\
\Sigma_q &= \begin{bmatrix} p_{\cdot 1}(1 - p_{\cdot 1}), & \ldots, & -p_{\cdot 1}p_{\cdot k} \\ \ldots & \ldots & \ldots \\ -p_{\cdot k}p_{\cdot 1}, & \ldots, & -p_{\cdot k}(1 - p_{\cdot k}) \end{bmatrix} \\
\Sigma_{pq} &= \begin{bmatrix} p_{11} - p_{1\cdot}p_{\cdot 1}, & \ldots, & p_{1k} - p_{1\cdot}p_{\cdot k} \\ \ldots & \ldots & \ldots \\ p_{k1} - p_{k\cdot}p_{\cdot 1}, & \ldots, & p_{kk} - p_{k\cdot}p_{\cdot k} \end{bmatrix}
\end{aligned}$$

$$\Sigma \quad = \quad \Sigma_p + \Sigma_q - \Sigma_{pq} - \Sigma_{pq}^{\mathrm{T}} \, . \tag{10}$$

Their corresponding estimates are denoted by $\hat{\Sigma}_p$, $\hat{\Sigma}_q$, $\hat{\Sigma}_{pq}$ and $\hat{\Sigma}$.

Let the vectors of the nonlinear transformation of the frequencies of the transmitted and nontransmitted haplotypes be $X = [f(\hat{p}_{1\cdot}), \ldots, f(\hat{p}_{k\cdot})]^{\mathrm{T}}$, $Y = [f(\hat{p}_{\cdot 1}), \ldots, f(\hat{p}_{\cdot k})]^{\mathrm{T}}$, respectively. Let B and C be the Jacobian matrices of X and Y, respectively, and define $b_{ii} = f'(\hat{p}_{i\cdot})$, $b_{ij} = 0$ for $i \neq j$, $B = (b_{ij})_{k \times k}$, $c_{ii} = f'(\hat{p}_{\cdot i})$, $c_{ij} = 0$ for $j \neq k$, $C = (c_{jk})_{k \times k}$. Let $\hat{B}$ and $\hat{C}$ be the estimates of matrices B and C, respectively. Let $\Lambda = B\Sigma_X B^{\mathrm{T}} + C\Sigma_Y C^{\mathrm{T}} - C\Sigma_{XY}B^{\mathrm{T}} - B\Sigma_{XY}C^{\mathrm{T}}$ and its estimates by $\hat{\Lambda}$. Then, the nonlinear TDT for haplotypes is defined as:

$$\mathrm{TDT}_{\mathrm{N}_2} = n(X - Y)^{\mathrm{T}} \hat{\Lambda}^{-} (X - Y) \, , \tag{11}$$

where $\hat{\Lambda}$ denotes a generalized inverse of the matrix Λ.

It can be shown that $\mathrm{TDT}_{\mathrm{N}_2}$ is asymptotically distributed as a central $\chi^2_{(r)}$ distribution under the null hypothesis of no linkage or no association and $r = \mathrm{rank}(\Lambda^{-})$. Under the alternative hypothesis that linkage and association between the marker and the disease loci exist, the statistic $\mathrm{TDT}_{\mathrm{N}_2}$ is asymptotically distributed as a noncentral $\chi^2_{(r)}$ distribution with the following noncentrality parameter:

$$\lambda_{\mathrm{N}_2} = n(\mu_{\mathrm{T}} - \mu_{\mathrm{NT}})^{\mathrm{T}} \Lambda^{-} (\mu_{\mathrm{T}} - \mu_{\mathrm{NT}}) \, , \tag{12}$$

where $\mu_{\mathrm{T}} = [f(p_{1\cdot}), \ldots, f(p_{m\cdot})]^{\mathrm{T}}$ and $\mu_{\mathrm{NT}} = [f(p_{\cdot 1}), \ldots, f(p_{\cdot k})]^{\mathrm{T}}$.

7.2 Power of the $N\backslash$ nonlinear TDT

A key component of power calculation is to compute noncentrality parameters. The noncentrality parameters of the χ^2 distribution of the nonlinear test statistics are formulated in Eqs. (10) and (13), which implies that the expected frequencies of the transmitted and nontransmitted alleles/haplotypes need to be calculated for power calculations.

We first study how to calculate the expected frequencies of the transmitted and nontransmitted alleles. It was shown that:

$$\begin{aligned} p_{i\cdot} \quad &= \quad p_i + b(1-\theta)\delta_{1i} \quad \text{and} \quad p_{\cdot i} = p_i + b\theta\delta_{1i} \, , \\ \text{where} \quad b \quad &= \quad \frac{(f_{11} - f_{12})P_D + (f_{12} - f_{22})P_d}{P(A)} \, , \end{aligned}$$

P_D and P_d and are the frequencies of the alleles D and d at the disease locus, respectively. f_{11}, f_{12} and f_{22} are the penetrance for genotypes *DD, Dd* and *dd*, respectively, with $f_{11} \geq f_{12} \geq f_{22} \geq 0$, $P(A) = f_{11}P_D^2 + 2f_{12}P_D P_d + f_{22}P_d^2$ represents the disease prevalence in the studied population. θ is the recombination fraction between the marker and the disease locus, M_i denotes a marker allele, p_i is the frequency of the marker allele M_i and P_{D_i} is the frequency of the haplotype DM_i, δ_{1i} is the measure of LD between the marker allele M_i and allele at the disease locus and is defined as $\delta_{1i} = P_{D_i} - P_D P_i$. Thus, the expected frequencies of the transmitted and nontransmitted alleles are given by $E[P_{i\cdot}] = P_i + (1-\theta)E(\delta_{1i}]$ and $E[P_{\cdot i}] = P_i + b\theta E[\delta_{1i}]$, where $E[\delta_{1i}] = \delta_{1i}(0)(1-\theta)^t$, $\delta_{1i}(0)$ is the measure of the initial LD when the LD was created, t is the time since the generations of the LD between the marker and the disease locus. Next, we calculate the expected frequencies of the transmitted and nontransmitted haplotypes. For simplicity of notations, we consider only three-locus haplotypes. The extension of the methods for three-locus haplotypes to haplotypes with more than three loci is straightforward, but involves more complex notation. To provide guidance for study design and intuitively illustrate the validity of the nonlinear statistics for testing the null hypothesis, we approximate the noncentrality parameter. We can show that the noncentrality parameter of the nonlinear test statistics can be approximated by:

$$\begin{aligned}\lambda_{\mathrm{N}_2} \quad \approx \quad & n\delta_{\mathrm{DM}}^{\mathrm{T}}(1-2\theta)^2 b^2 \left(I + \frac{1}{2}S\right)^{\mathrm{T}} [(I+S)\Sigma_p(I+S)^{\mathrm{T}} - (I+S)\Sigma_{pq} \\ & - \Sigma_{pq}^{\mathrm{T}}(I+S)^{\mathrm{T}}\Sigma_p]^{-} \left(I + \frac{1}{2}S\right)\delta_{\mathrm{DM}} \,,\end{aligned}$$

where $\delta_{\mathrm{DM}} = [\delta_{11}, \dots, \delta_{1k}]^{\mathrm{T}}$, $S = b(1-2\theta)C^{-}H\delta_{\mathrm{DM}}$, C is a Jacobian matrix as defined in the text, $H = [H_1, \dots, H_k]^{\mathrm{T}}$ and $H_l = \mathrm{diag}(0, \dots, 0, f''(P_{\cdot l}), 0, \dots, 0)$. The quantities b, θ and the matrices Σ_p, Σ_{pq} are defined as before.

To ensure that the distributions of the nonlinear test statistics are a central χ^2 distribution, we need to have:

$$(1-2\theta)\delta_{1i} = 0 \quad \text{for all} \quad i = 1, \dots, k \,. \tag{13}$$

This demonstrates that either $\theta = 1/2$ or $\delta_{1i} = 0$ for all $i = 1, \dots, k$ will lead to Eq. (13). Therefore, like the original TDT, the nonlinear TDT statistics can also be used to test either linkage or association. To detect linkage by nonlinear TDT, the LD between at least one marker allele and a disease allele must exist, i.e. only in the presence of association, the nonlinear TDT can be used to test linkage. The most properties of the original TDT will also hold for the nonlinear TDT statistics. We conduct preliminary power studies of nonlinear TDT and plot the power curves of the standard and nonlinear TDT for the recessive and dominance disease models in Figures 10A and 10B, respectively.

7.3 Real Examples

To further evaluate their performance, the nonlinear TDT statistics were applied to two real data sets. The first data set is a test of association of the

RET gene, which encodes a receptor tyrosine kinase, with Hirschsprung [8]. The second example is to test the association of Fcγ receptor genes (FcγRIIA, FcγRIIIA and FcγRIIIB) with systemic lupus erythematosus in 126 pedigrees [32]. SNPs in these three genes were typed. The results are shown in Tables 2 and 3. The results showed that the p-values of most nonlinear TDT statistics are much smaller than those of the original TDT statistic. These results suggest that developing nonlinear TDT statistics harbors great potential for establishing genome-wide linkage or association.

8 Perspective of Genome-wide Association Studies

Several large-scale genome-wide association studies in which 300 000 or 500 000 panels of SNPs will be typed are planned, including European initiatives, the National Institutes of Health (NIH) initiative for the Genetic Association Information Network, and the Genes and Environment Initiative [103]. To increase the power and reduce the cost of genotyping, two-stage study design for genome-wide association studies in which in the first stage all markers are typed in a fraction of samples and in the second stage a subset of markers showing significant association will be typed was proposed [86,110].

A key component of genome-wide association studies is to test interaction between genes and interaction between genes and environment. Complex diseases are caused by multiple genes, primarily through nonlinear gene interactions and gene–environment interactions. Complex gene interactions are organized into networks. Genetic interaction networks must be ubiquitous in common diseases, given the complex dynamic interactions of the genetic regulatory and metabolic networks. Despite growing consensus on the importance of testing for gene–gene interactions in genetic studies of complex diseases, the effect of gene–gene interactions has often been defined as a deviance from genetic additive effects, which is essentially treated as a residual term in genetic analysis and leads to low power to detect the presence of interacting effects. To what extent the definition of gene–gene interaction at population level reflects their biochemical or physiological interaction remains a mystery.

Testing of interactions including gene–gene and gene–environment interactions poses great challenge to genome-wide association studies because of the extremely large number of potential interactions. Should we incorporate testing of gene-gene interactions into genome-wide association studies? There is some doubt about the strategy to test for interactions at the expense of power for detecting main effects. Some suggest limiting the testing of interaction to pairs of markers that individually show significant association at some threshold. However, others argue that although both SNPs do not show significant evidence of association when analyzed individually, they do give significant evidence of interaction. It remains to be seen whether incorporating testing of interactions into genome-wide association studies will be useful.

We are entering a new era in genetic studies of complex diseases. Without question, the next few years will be an exciting time [122]. A dozen large-scale genome-wide association studies are under way. More and more powerful methods for genome-wide association studies are being developed. We can expect that a flurry of new association results will appear in the literature. The validation of association findings will continue to rely not only on the replication of independent samples, but also on functional studies of the SNPs. It is certain that genome-wide association studies, in conjunction with systems biology, will successfully dissect the complex structure of common diseases.

Appendix A

Let $f(P)$ be a vector-valued nonlinear function of random vector P. Assume that the nonlinear function $f(P)$ satisfies regularity conditions which ensure that Theorem 3.3A in Serfling [87] holds. Then, $f(\hat{P})$ is asymptotically distributed as a multivariate normal distribution $N(f(P), \frac{1}{2n_G} C\Sigma C^{\mathrm{T}})$, where

$$c_{ii} = \frac{\partial f P_{H_i}}{\partial (P_{H_i})}\ , \quad c_{ij} = \frac{\partial f(P_{H_i})}{\partial P_{H_j}}\ , \quad C = (c_{ij})_{m\times m}\ ,$$

$$\Sigma = \mathrm{diag}(P_{H_1}, \ldots, P_{H_m}) - PP^{\mathrm{T}}\ .$$

Similarly, $f(\hat{P}^A)$ is asymptotically distributed as $N(f(P^A), \frac{1}{2n_A} B\Sigma^A B^{\mathrm{T}})$, where

$$b_{ii} = \frac{\partial f(P^A_{H_i})}{\partial P^A_{H_i}}\ , \quad b_{ij} = \frac{\partial f(P^A_{H_i})}{\partial P^A_{H_j}}\ , \quad B = (b_{ij})_{m\times m}\ ,$$

$$\Sigma^A = \mathrm{diag}(P^A_{H_1}, \ldots, P^A_{H_m}) - P^A(P^A)^{\mathrm{T}}\ .$$

Therefore, under the null hypothesis $H_0 : P^A = P$, which implies $f(P^A) = f(P)$, $f(\hat{P}^A) - f(\hat{P})$ is asymptotically distributed as $N(0, \Lambda)$, where:

$$\Lambda = \frac{1}{2n_A} B\Sigma^A B^{\mathrm{T}} + \frac{1}{2n_G} C\Sigma C^{\mathrm{T}}\ .$$

Let $Z = f(\hat{P}^A) - f(\hat{P})$ and $r = \mathrm{rank}(\Lambda)$. Then, under the null hypothesis, $T_{\mathrm{N}} = Z^{\mathrm{T}}\Lambda^{-}Z$ is asymptotically distributed as a central $\chi^2_{(r)}$ distribution [43]. The alternative hypothesis is $H_a : P^A \neq P$. Under the alternative hypothesis, T_{N} is asymptotically distributed as a noncentral $\chi^2_{(r)}$ distribution with the following noncentrality parameter:

$$\lambda_{\mathrm{N}}[f(P^A) - f(P)]^{\mathrm{T}}\Lambda^{-}[f(P^A) - f(P)] \tag{A.1}$$

By Taylor expansion, we have:

$$f(P^A) - f(P) \approx C(P^A - P) + \frac{1}{2}(P^A - P)^{\mathrm{T}} H(P^A - P) \tag{A.2}$$

where $H_1 = \operatorname{diag}(0,\ldots,f''(P_{H_l}),0\ldots0), l = 0,\ldots,m$

$$(P^A - P)^{\mathrm{T}} H (P^A - P) = \begin{bmatrix} (P^A - P)^{\mathrm{T}} H_1 (P^A - P) \\ \vdots \\ (P^A - P)^{\mathrm{T}} H_m (P^A - P) \end{bmatrix}$$

Equation (A2) can be rewritten as:

$$\begin{aligned} f(P^A) - f(P) &\approx C\left[(P^A - P) + \frac{1}{2}C^{-}(P^A - P)^{\mathrm{T}} H (P^A - P)\right] \\ &= C\left[(P^A - P) + \frac{1}{2}C^{-} H (P^A - P)(P^A - P)\right] . \end{aligned} \tag{A.3}$$

Let $S = C^{-}H(P^A - P)$, then:

$$f(P^A) - f(P) \approx C\left(I + \frac{1}{2}S\right)(P^A - P) . \tag{A.4}$$

Substituting $f(P^A) - f(P)$ in Eq. (A4) into Eq. (A1) yields:

$$\begin{aligned} \lambda_{\mathrm{N}} &= (P^A - P)^{\mathrm{T}}\left(I + \frac{1}{2}S\right)^{\mathrm{T}}(C^{\mathrm{T}}\Lambda^{-}C)\left(I + \frac{1}{2}S\right)(P^A - P) \qquad \text{(A.5)} \\ &= (P^A - P)^{\mathrm{T}}\left(I + \frac{1}{2}S\right)^{\mathrm{T}}\left[(C^{-}\Lambda(C^{\mathrm{T}})^{-}\right]^{-}\left(I + \frac{1}{2}S\right)(P^A - P) . \end{aligned}$$

Recall that:

$$P^A - P = e\delta_{\mathrm{HD}} \quad \text{and} \quad B \approx C + H(P^A - P) \tag{A.6}$$

where $\delta_{\mathrm{HD}} = [\delta_{H_1 D},\ldots,\delta_{H_m D}]^{\mathrm{T}}$.

Thus:

$$\begin{aligned} C^{-}\Lambda(C^{\mathrm{T}})^{-} &= C^{-}\left[\frac{1}{2n_A}B\Sigma^A B^{\mathrm{T}} + \frac{1}{2n_G}C\Sigma C^{\mathrm{T}}\right](C^{\mathrm{T}})^{-} \\ &= \frac{1}{2n_A}C^{-}B\Sigma^A(C^{-}B)^{\mathrm{T}} + \frac{1}{2n_G}\Sigma \\ &= \frac{1}{2n_A}(I + S)\Sigma^A(I + S) + \frac{1}{2n_G}\Sigma . \end{aligned} \tag{A.7}$$

Substituting Eqs. (A6) and (A7) into Eq. (A5), we obtain:

$$\lambda_{\mathrm{N}} \approx e^2\delta_{\mathrm{HD}}^{\mathrm{T}}\left(I + \frac{1}{2}S\right)^{\mathrm{T}}\left[\frac{1}{2n_A}(I + S)\Sigma^A(I + S) + \frac{1}{2n_G}\Sigma\right]^{-}\left(I + \frac{1}{2}S\right)\delta_{\mathrm{HD}} . \tag{A.8}$$

Next we study geometric interpretation of the matrix S. Let $\gamma(P) = Z_1, \dots, Z_m]^{\mathrm{T}}$, where $Z_i = f(P_{H_i})$. Define the following parameter equations:

$$P^A = P + t\Delta P\,.$$

As t varies, $\gamma(P^A) = \gamma(P + t\Delta P)$ defines a curve C in the space. The tangent vector of the curve C at the point P is given by:

$$\frac{\mathrm{d}\gamma}{\mathrm{d}t} = \frac{\partial\gamma}{\partial P^{\mathrm{T}}}\Delta P\,, \quad \text{where} \quad \frac{\partial\gamma}{\partial P^{\mathrm{T}}} = \begin{bmatrix} f'(P_{H_1}) & 0 & \dots & 0 \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & f'(P_{H_m}) \end{bmatrix}.$$

Taking Z_i $(i = 1, \dots, m)$ as a new coordinate system, we obtain the change rates of the tangent vector of the curve over new coordinates:

$$\frac{\partial\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)}{\partial Z^{\mathrm{T}}} = C^{-}H\Delta P = S\,, \quad \text{where} \quad H = \begin{bmatrix} H_1 \\ \vdots \\ H_m \end{bmatrix}$$

$$\text{and} \quad H_i = \mathrm{diag}(0, \dots, f''(H_i), \dots, 0)$$

The change rate of the tangent vector of the curve characterizes the strength of the nonlinearity of the nonlinear function [5]. The vector S has the following form:

$$S = \mathrm{diag}\left(\frac{f''(P_{H_1})}{f'(P_{H_1})}(P^A_{H_1} - P_{H_1}), \dots, \quad \frac{f''(P_{H_m})}{f'(P_{H_m})}(P^A_{H_m} - P_{H_m})\right)\,.$$

If the product terms of the haplotype frequencies are ignored, we obtain $C^{-}\Lambda(C^{\mathrm{T}})^{-} = \mathrm{diag}(\Lambda_1, \dots, \Lambda_m)$, where

$$\Lambda_i = \frac{1}{2n_A}[1 + \pi_i(P^A_{H_i} - P_{H_i})]^2 P^A_{H_i} + \frac{1}{2n_G}P_{H_i}\,, \quad \pi_i = \frac{f''(P_{H_i})}{f'(P_{H_i})}\,,$$

$$I + \frac{1}{2}S = \mathrm{diag}\left(1 + \frac{\pi_1}{2}(P^A_{H_1} - P_{H_1}), \dots, \ 1 + \frac{\pi_m}{2}(P^A_{H_m} - P_{H_m})\right)\,.$$

Then, Eq. (A8) can be simplified to:

$$\begin{aligned} \lambda_{\mathrm{N}} &\approx e^2 \sum_{i=1}^{m} \frac{\delta^2_{H_iD}\left[1 + \frac{\pi_i}{2}(P^A_{H_i} - P_{H_i})\right]}{\Lambda_i} \\ &= e^2 \sum_{i=1}^{m} \frac{\delta^2_{H_iD}\left[1 + \frac{e\pi_i}{2}\delta_{H_iD}\right]^2}{\frac{1}{2n_A}\left(1 + \frac{e\pi_i\delta_{H_iD}}{2}\right)^2 P^A_{H_i} + \frac{1}{2n_G}P_{H_i}}\,. \end{aligned}$$

For the standard χ^2 test statistic, we have $\pi_i = 0$. Thus, its noncentrality parameter is given by:

$$\lambda \approx e^2 \delta_{\mathrm{HD}}^{\mathrm{T}} \left[\frac{1}{2n_A} \Sigma^A + \frac{1}{2n_G} \Sigma \right]^{-} \delta_{\mathrm{HD}} \quad \text{and} \quad \lambda \approx e^2 \sum_{i=1}^{m} \frac{\delta_{H_i D}^2}{\frac{1}{2n_A} P_{H_i}^A + \frac{1}{2n_G} P_{H_i}} \, .$$

39 Pharmacogenetics/Pharmacogenomics

Xing Jian Lou, Russ B. Altman, and Teri E. Klein

1 Introduction

Pharmacogenetics is the study of how variations in the genes of an organism affect its response to drugs. Since its inception in the mid-20th century [32, 45, 64, 69], the major goal of pharmacogenetics research has been to maximize drug efficacy and minimize drug toxicity. In recent years, with the sequencing of the human genome and the development of high-throughput genotyping methods, the ability to correlate genetic variations to drug responses has dramatically increased. Therefore, pharmacogenetics has been moving from the study of the impact of single-gene variations on drug response to the study of the entire complement of pharmacologically relevant genes (*pharmacogenes*), and how these genes and their variations interact with each other and the environment to affect drug response. Although "pharmacogenetics" and "pharmacogenomics" are often used interchangeably, the term *pharmacogenomics* is usually associated with the collection of data, including DNA sequence variations and mRNA expression, using large-scale and high-throughput methods. Pharmacogenomics research yields complex data that are relevant to many genes and difficult to integrate. Traditional methods of manual data collection and management are no longer cost-effective with the development of high-throughput pharmacogenetics and pharmacogenomics experiments. In this chapter, we review the challenges that pharmacogenomics brings to biomedical informatics as well as biomedical informatics tools that can catalyze the research and development of pharmacogenetics and pharmacogenomics.

2 An Overview of Pharmacogenetics and Pharmacogenomics

The concept of pharmacogenetics originated from the clinical observation that plasma or urinary drug concentrations were variable and could be inherited. Through more than 50 years of research, pharmacogenetics has

Bioinformatics – From Genomes to Therapies Vol. 3. Edited by Thomas Lengauer
Copyright © 2007 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-31278-8

provided knowledge on how the genetic variation of single genes affects the drug toxicity and efficacy for drug development and therapy. Despite this progress, many multidimensional relationships between genes, drugs, disease and environment remain unclear. Pharmacogenomics studies using genomic approaches are expected to accelerate the process of understanding these multiple interactions.

2.1 Background of Pharmacogenetics and Pharmacogenomics

The classic example of pharmacogenetics is as follows. A 4-year-old boy has acute lymphoblastic leukemia. His treatment protocol includes daily doses of oral 6-mercaptopurine (6MP). However, this treatment leads to excess toxicity, including severe life-threatening bone marrow suppression. The physician performs a genetic test for thiopurine S-methyltransferase (TPMT) and learns that the patient has two mutated copies of this gene that cannot metabolize 6MP into its usual inactive metabolite. Instead, the 6MP is metabolized by a different pathway that leads to toxic compounds, called 6-thioguanines. Based on this information, his physician greatly reduces his dose of 6MP and monitors the resulting response to the drug. The boy subsequently has an uneventful several-year maintenance period and achieves complete remission [21].

Before the genetic variations of TPMT, an enzyme that metabolizes 6MP, were discovered, physicians had long wondered why approximately one in 300 Caucasian patients had serious, sometimes lethal, myelosuppression during the treatment with regular dosages of 6MP [67, 68]. Now we know that this adverse drug response results from a lack of TPMT as a result of a genetic alteration. When there is insufficient TPMT, 6MP is metabolized to 6-thioguanine nucleotide (6TGN), a toxic 6MP metabolite, instead of its normal metabolite, 6-methly-MP [36–38, 68]. Severe side-effects and adverse reactions then occur under the "standard-of-care" treatment. There is also evidence that an increased activity of TPMT is associated with a decreased efficacy of 6MP [37].

Most initial pharmacogenetic discoveries involved a small number of polymorphisms (variations in genes, see also Chapter 37) in a single gene associated with a very dramatic change in the drug response. These simple, but striking, examples provided the foundation for our present understanding that inheritance can play an important role in individual variations in drug response by influencing efficacy, toxicity or both. Drug-metabolizing enzymes are divided into two large subgroups: phase I (functionalization) and phase II (conjugation) enzymes. Phase I reactions consist of oxidation, reduction and hydrolysis. These reactions usually lead to metabolites that are more polar than the parent compounds. In a phase II reaction, an endogenous hydrophilic moiety is attached to a target molecule, producing a metabolite that is more water soluble than the parent compound. Glucuronidation, sulfation, acetylation and conjugation to glutathione and amino acids are the major conjugation reactions. The most common variations associated with drug responses reported occur in genes coding enzymes of both phase I and phase II metabolism [66]. Polymorphisms in cytochrome P450 genes (such as CYP2D6, one of the phase I genes) are the most widely studied and best understood, because these polymorphisms affect the metabolism of a wide range of commonly used drugs [12, 53]. Polymorphisms in genes from phase II metabolism, such as TPMT and *N*-acetyltransferases (NATs), have also been shown to affect drug response. Transporter gene polymorphisms are also found to be associated with drug efficacy and toxicity [60]. Recently, there has been a focus on polymorphisms in genes that are the targets of drug therapy (and are not involved in metabolism). For example, mutations in the epithelial growth factor receptor (EGFR) gene have been shown to enhance tumor response to the EGFR tyrosine kinase inhibitor gefitinib (Iressa; AstraZeneca) [41, 46].

Like many other genetic phenomena, the response to many drugs is determined by the interaction of multiple genes at different loci [31, 47]. In addition, environmental factors including diet, age and lifestyle also play important roles in a person's response to drug treatment. Environmental factors need to be studied in the context of an individual's genetic make-up in order to understand their effects [24, 29]. Pharmacogenetics has thus expanded to pharmacogenomics and includes multidisciplinary research efforts, including genetics, molecular biology, cell biology, physiology, pharmacology, biochemistry, toxicology, clinical pharmacology, clinical pharmacy, epidemiology, pharmaceutical sciences and bioinformatics.

2.2 Influence of Pharmacogenetics and Pharmacogenomics on Drug Development and Therapy

Most pharmaceutical companies avoid developing drugs that are metabolized primarily by polymorphic enzymes such as CYP2D6 because of interindividual variation in response. However, this precaution is not always effective, especially when variations exist in the drug targets. Therefore, an important aspect of drug development is to develop pharmacogenetics tests to define the patient population that will benefit most from the drug treatment with minimal adverse reactions. Using pharmacogenetics tests to select the right patient group may significantly decrease the cost of drug development. Clinical trials focused on the right population (responders without adverse reaction) may decrease the trial size and increase the success rate. Although there is still debate about the cost-effectiveness of genetic screening before drug trials, there is evidence that genetic variations can be used to enrich for normal and hyper-responders to decrease the size of clinical trials [54]. A population-based study of genetic variations associated with increased risk of disease conducted by deCODE Genetics has also led to the discovery of a disease-specific pathway and shortened the time of target discovery through the phase II clinical trial to little more than 1 year [23,27,28].

On the therapy side, few currently available medicines actually treat *all* patients effectively. Some medicines are licensed on the basis of only 30% efficacy in clinical trials [57]. Physicians have therefore accepted in practice that many medicines are prescribed by trial and error. Patients first take one medicine and, if it is shown to be ineffective, are then prescribed another. Unfortunately, the adverse risks that are associated with medicines can be lethal and can be additive. Adverse reactions represent the fourth to the sixth leading cause of death in the US [7,51]. Therefore, it would be useful to determine, before prescribing a drug, whether a patient is likely to respond, and if that individual is at risk of adverse reactions. In the US there are only three pharmacogenetic tests that have been approved by the US Food and Drug Administration (FDA) to be used by physicians to personalize treatment decisions for maximizing efficacy and avoiding adverse reactions. AmpliChip of Roche is used to individualize the dosage of antidepressants, antipsychotics, β-blockers, and some chemotherapy drugs by detecting gene variations for the CYP2D6 and CYP2C19 genes. The TRUGENE HIV-1 identifies variations in the viral gene that make the virus resistant to some antiretroviral drugs. Most recently, the Invader UGT1A1 test of Third Wave Technologies was approved for identifying patients with specific mutations in the UGT1A1 gene. These patients may be at increased risk of adverse reaction to chemotherapy drugs such as irinotecan. Although the number of pharmacogenetic tests is currently limited, a lot of effort and resources have been put into this field by private, public and regulatory sectors such as the Roche decode alliance (http://www.decode.com) and the ScanBalt Clinical Research Network (http://www.scanbalt.org/sw229.asp). That two out of three pharmacogenetic tests were approved by the FDA in 2005 indicates the rapid progress and growth in this area.

3 Biomedical Informatics Resources Relevant to Pharmacogenomics

The explosion of biological information in the last decade has triggered the establishment of many successful biological databases in areas such as sequences [5,48], structures [15] and functions [4,33]. These databases provide basic data of relevance to pharmacogenomic. The Reference Sequence (RefSeq) Project at the National Center for Biotechnology Information (NCBI) (http://www.ncbi.nlm.nih.gov/RefSeq) provides a comprehensive and nonredundant set of sequences, including genomic DNA, transcript (RNA) and protein products for major research organisms. It also serves as a standard for sequence annotation such as exon, intron, alternative splicing isoforms, and 3′- and 5′-untranslated regions of genes [48]. The human genome browsers offered by University of California at Santa Cruz (UCSC) (http://www.genome.ucsc.edu), Ensembl (http://www.ensembl.org) and NCBI (http://www.ncbi.nlm.nih.gov/mapview/map_search.cgi) offer comprehensive information about gene location and genomic annotation. The Single Nucleotide Polymorphism database (dbSNP) at NCBI (http://www.ncbi.nlm.nih.gov/projects/SNP/index.html) and International HapMap Project [1,2] provide excellent sources for the locations and types of genetic variations of reported SNPs, including those submitted by The SNP Consortium [56,63] – an industrial group that is performing large-scale SNP screening.

The success of pharmacogenomics depends on the description of functional features (phenotypes) associated with gene products. These phenotypes range in detail from the molecular [19] to the individual [36] and population levels [41,43], including gene expression profiles, enzyme kinetic data, blood pressure and drug responses in a particular population of patients. Some progress has been achieved in the representation of these phenotypes. Efforts have begun in providing standards of metabolism and signaling pathway presentations [10,30,33] (BioPax: http://www.biopax.org/index.html, see also Chapters 20 and 22). Furthermore, existing standards for coding diagnoses (International Classification of Diseases: http://www3.who.int/icd/vol1htm2003/fr-icd.htm; MeSH: http://www.nlm.nih.gov/mesh), pathology (Systematized Nomenclature of Medicine – SNOMED: http://www.snomed.org) and procedures (Current Procedural Terminology: http://www.ama-assn.org/ama/pub/category/3113.html) in clinical medicine offer a good starting point for pharmacogenomics research. However, these clinical data representations do not provide the precision required for high-quality data retrieval. Also there is a fair amount of agreement within the pharmacology community on how to represent pharmacokinetic profiles. Programs such as ADAPT II [9] and NONMEM (http://c255.ucsf.edu/nonmem0.html) allow first- and second-order kinetics and associated parameters to be computed. A standard set of parameters, including the dissociation constant for binding of inhibitor to enzyme (K_i), the concentration of substrate that produces half-maximal velocity (K_m) and the maximal velocity of a reaction (V_max), have fairly consistent definitions and thus provide a good initial opportunity for modeling of the data (see also Chapters 20 and 22).

A set of controlled terms is called a standard vocabulary or controlled vocabularies. The Human Genome Organization (HUGO) Nomenclature Committee (HGNC) has created a reference set of symbols for human genes [65]. These symbols are used by almost all databases that involve genes or gene products (e.g. protein). Therefore, this nomenclature serves as a standard vocabulary for pharmacogenomics regarding genes. Controlled vocabularies are also very useful for indexing purposes. For example, whereas an abstract in Medline is free text, the list of Medical Subject Heading (MeSH) keywords from the Medline database (http://www.ncbi.nlm.gov/PubMed/) represents a controlled vocabulary. The advantage of a controlled vocabulary is that computer programs can be written to detect certain phrases and can be programmed to process data based on the occurrence of these phrases.

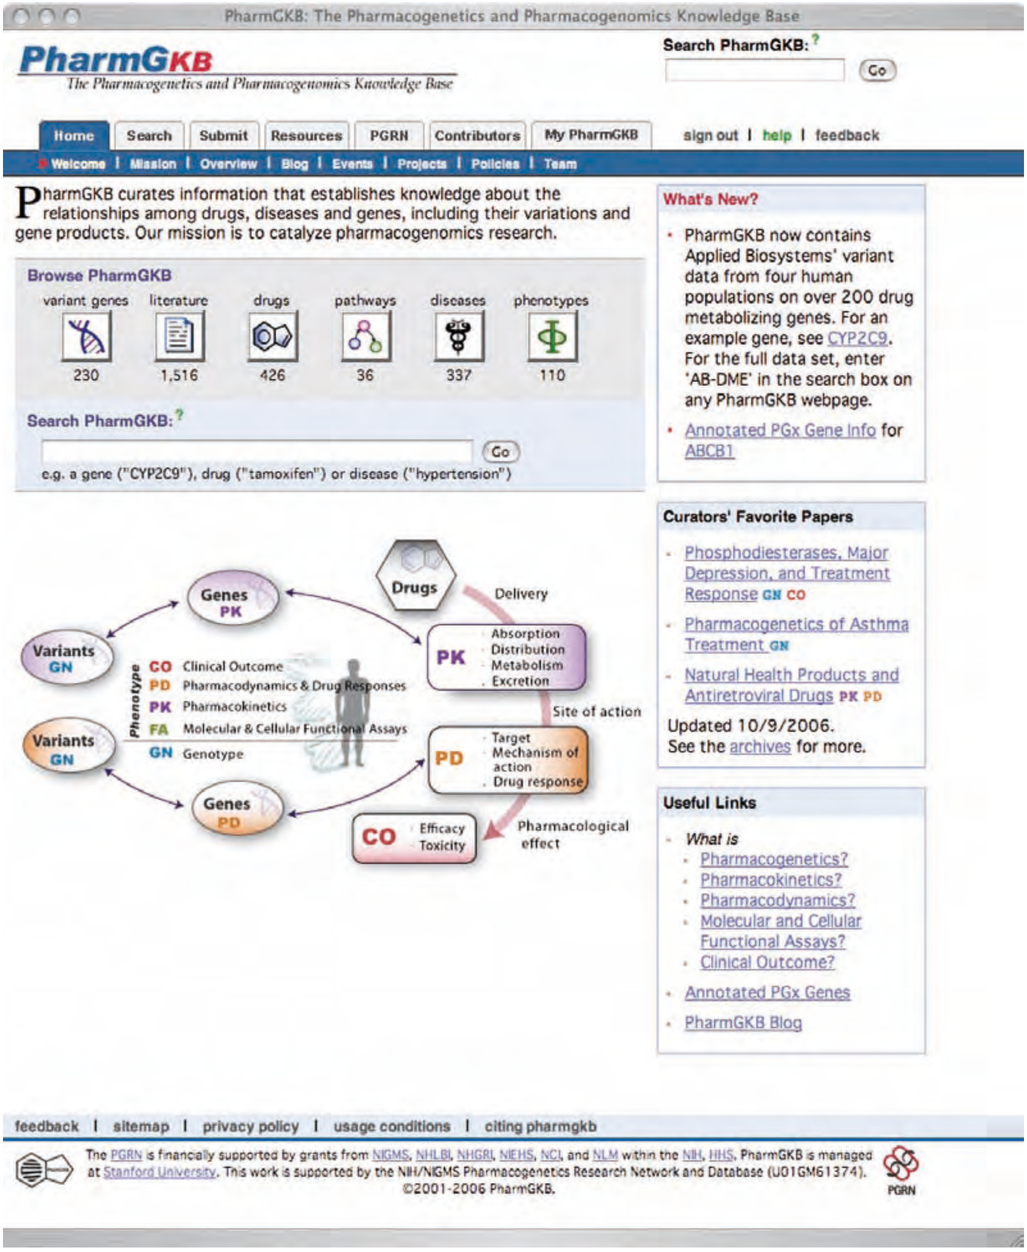
There have been a number of proposed standards for exchange sequence data, including standards that support GenBank submission such as BIOML (http://bioinformatics.genomicsolutions.com/BioML.html), Bioperl (http:// bio. perl.org) and GCG (http://www.accelrys.com/products/gcg_wisconsin_package). There has also recently been much effort in creating a standard for exchange of genetic polymorphism information, such as the PharmGKB eXtensible Markup Language (XML) schema (http://www.pharmgkb.org/schema/index.html) and the Polymorphism Markup Language (PML) [61]. The Microarray Gene Expression Data (MGED) society also has developed Microarray and Gene Expression Markup Language (MAGE-ML) – a data exchange format for microarray expression experiments [58]. MGED is an international organization of biologists, computer scientists and data analysts that aims to facilitate the sharing of microarray data generated by functional genomics and proteomics experiments. MAGE-ML specifies a set of Minimum Information About a Microarray Experiment (MIAME), including experimental conditions, the quality control parameters, the list of genes being assayed and the actual expression measurements (and background measurements) recorded, and is implemented using XML (see also Chapter 23). This format has been widely accepted by the microarray and gene expression community and can be used for pharmacogenomics studies as well.

While data exchange format and controlled vocabulary are well developed for microarray data and most of the sequence-related genomic data, many pharmacogenomic, especially phenotype, data related to function still lack such standards. The mouse genome initiative has created an ontology that provides a general framework for communication on mouse phenotypes (http://www.informatics.jax.org/searches/MP_form.shtml). With the objective of capturing information about phenotypes in any organism, in 2002, Ashburner also proposed the Phenotype And Trait Ontology (PATO: http://obo.sourceforge.net). Ontologies based on the PATO proposal are under development [20]

4 Building the PharmGKB

The Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB, http://www.pharmgkb.org) is a National Institutes of Health (NIH)-funded effort to build a centralized repository for genetic and clinical information on all individuals participating in pharmacogenomics studies as well as for molecular, cellular and pharmacological information on model systems that are used for pharmacogenomics research. The PharmGKB is currently being developed at Stanford University. It is web based, and supports the storage, integration and dissemination of data and knowledge about pharmacogenetics and pharmacogenomics. The home page of PharmGKB is shown in Figure 1. In brief, the PharmGKB classifies primary phenotype and genotype data sets submitted by the pharmacogenetics and pharmacogenomics community, described below, into five categories: (i) clinical outcome, (ii) pharmacodynamics and drug responses, (iii) pharmacokinetics, (iv) molecular and cellular functional assays, and (v) variation in genetic sequence. Users browse data by associated genes, drugs, diseases and pathways. These pathways show how drugs are metabolized (pharmacokinetics) and how drugs act (pharmacodynamics). In addition to primary genotype and phenotype data sets, PharmGKB collects information about gene–drug–disease interactions of relevance to pharmacogenetics from the literature. Using controlled vocabularies and standard exchange formats, PharmGKB integrates this data with relevant information from other databases, and provides browsing, searching and analytical functions to help scientists discover connections between genetic variations and alterations in drug responses and related phenotypes.

Different approaches are used at facilities within the pharmacogenetics and pharmacogenomics community to uncover the mechanisms underlying the inter-individual differences in the response to drug treatments. For example, some groups specialize on the study of genetic variations affecting the treatment of a particular disease (e.g. http://www.pharmgkb.org/network/members/parc.jsp), some groups focus on studying the influence of multiple genetic effects on a single drug (e.g. http://www.pharmgkb.org/network/members/cobra.jps), and others on the study of variations of a group of genes and their resulting effect on drug treatment (e.g. http://www.pharmgkb.org/network/members/pmt.jsp). Studied diseases include, but are not limited to, arrhythmia, hypertension, atherosclerosis, asthma, cancer and depression. Examples of investigated drugs include tamoxifen, statin, ACE inhibitors and irinotecan. Numerous functional polymorphisms on genes responsible for drug transport, metabolism and genes targeted by drugs are under investigation in pharmacogenetics and pharmacogenomics study centers.



PharmGKB curates information that establishes knowledge about the relationships among drugs, diseases and genes, including their variations and gene products. Our mission is to catalyze pharmacogenomics research.

e.g. a gene ("CYP2C9"), drug ("tamoxifen") or disease ("hypertension")

What's New?

- PharmGKB now contains Applied Biosystems' variant data from four human populations on over 200 drug metabolizing genes. For an example gene, see CYP2C9. For the full data set, enter 'AB-DME' in the search box on any PharmGKB webpage.

The PGRN is financially supported by grants from NIGMS, NHLBI, NHGRI, NIEHS, NCI, and NLM within the NIH, HHS. PharmGKB is managed at Stanford University. This work is supported by the NIH/NIGMS Pharmacogenetics Research Network and Database (U01GM61374).
©2001-2006 PharmGKB.

Figure 1 The PharmGKB home page. Contents of the Knowledge Base are highlighted in the gray shaded box.

In addition to the PharmGKB, there are other tools available for specialized topics in pharmacogenomics. For example, the Pharmacogenomics of

Arrhythmia Therapy group at Vanderbilt University has developed a data reduction algorithm [Multifactor Dimensionality Reduction (MDR)] for the detection of gene–gene, gene–drug or gene–environment interactions in relatively small sample sizes [22,52]. The number of analytical and computational approaches continues to grow with the challenges facing the pharmacogenomics community.

PharmGKB uses the SOAP (simple object access protocol) web-service standard method (http://www.pharmgkb.org/home/projects/webservices/index.jsp) to allow users to access these analytical and computational tools (see also Chapter 43 for bioinformatics web technology). For example, PharmGKB has demonstrated a service on the gene variant page that triggers code to gather all variants for that gene, format them as required by the haplotype inference algorithm PHASE and ship the data to the Channing Laboratory in Boston for computation. Users therefore are able to access data through the central repository of PharmGKB, but use tools developed by third parties to analyze such data through PharmGKB's web service.

General information in the PharmGKB is available to the public without restriction. However, genotypic and phenotypic information associated with individual human subjects is only available to users that have been granted access, i.e. "registered". Patient privacy policies are discussed in more detail in Section 4.3.3.

4.1 Establishing a Repository of Pharmacogenetics and Pharmacogenomics Information

Pharmacogenetics and pharmacogenomics research usually involves the analysis of multidimensional data obtained through different approaches and using different technologies. Integration is very important at many levels. For example, data on functional changes are meaningless if they are not associated with a particular genotype. The establishment of a central data repository and maintaining the relationships among these data provides a foundation for such integration.

4.1.1 The Data Model

A good data model is critical to the establishment of a successful pharmacogenomics knowledge base, because of the great diversity of information formats and the rapid evolution of the field. A data model contains important classes of objects in the domain of interest, the key attributes for these objects and the logical relationships among these objects.

The high-level objects in a pharmacogenomics data model are shown in Figure 2. Functional considerations for a database include the ability to accept data submissions from the user community, provide a preview of submitted

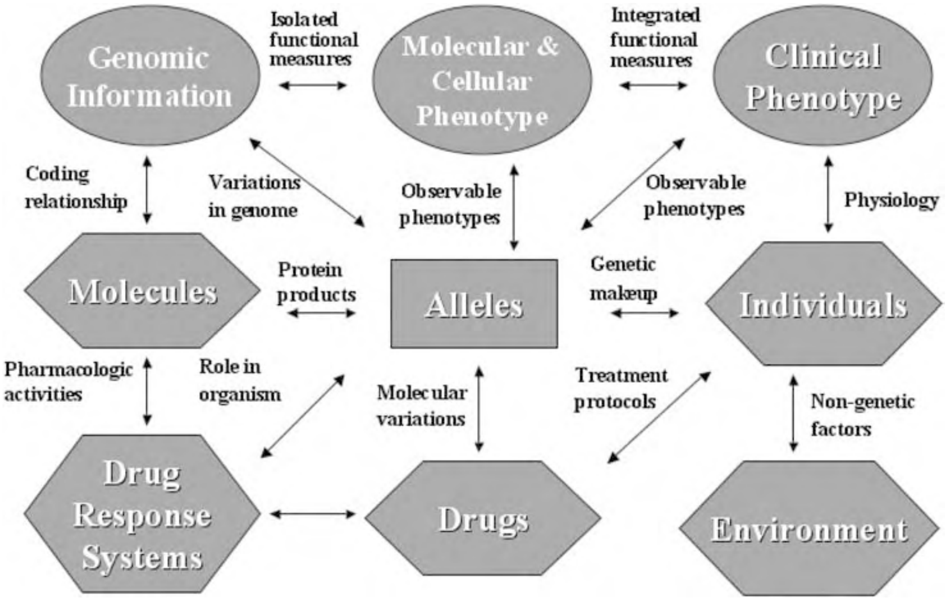

Figure 2 PharmGKB data model. Each gray box represents a class of objects that has a large tree of subclasses of objects underneath it for more specificity. The lines between the objects summarize the types of links that occur between instances of each type of objects.

data to the submitters for inspection and approval, provide access to all approved submissions to all registered users, provide a search capability to find major objects from any text field associated with the object, and track changes to the data and be able to retrieve a date dependent view of the data. More information about one sample pharmacogenomics relational data model can be viewed at http://www.pharmgkb.org/resources/references.jsp.

Relational database management systems are the most dependable and widely used architectures for building large databases. They provide built-in support for dynamic and hierarchical data modeling, including adding objects, associating particular attributes with each object and interlinking objects with named relationships. For example, PharmGKB is built using a relational database architecture upon which a middle layer (written in Java) contains all logic and a final presentation layer presents data to the user. The technical infrastructure of PharmGKB is detailed at http://www.pharmgkb.org/resources/references/architecture.jsp.

4.1.2 Primary Data

The main source of the pharmacogenomic primary data is from pharmacogenetics investigators. Information regarding the research interest and affiliations of all the groups to submitting to PharmGKB is available at http://www.pharmgkb.org/views/loadContributors.action.

Fundamentally, there are only two types of data generated from pharmacogenetic and pharmacogenomic research – genotype data and phenotype data. Genotype is the internally coded, heritable information carried by the organism. Variation in genotypes represents differences in sequence within a species, such as SNPs (a very common gene variation that only involves the change of a single nucleotide) the locations or the number of repeats, deletions, or critical splice sites (see also Chapters 36 and 37). Phenotypes are the observable properties of an organism produced by the interaction of the genotype with the environment. For pharmacogenetics, the "environment" is often defined via the exposure to a drug, although it may include other variables, e.g. describing smoking habits or alcohol consumption. However, because an individual's drug response is usually a consequence of interactions among many genes or proteins (encoded by genes), including transporters, enzymes and receptors in different cells, tissues and organs, "the observable properties of an organism" here can vary from the change in the expression of a transporter gene, across the increase or decrease of an enzyme's activity or the binding affinity of a receptor to how the individual feels, e.g. headache, diarrhea, etc. Different assays are designed to measure these different changes, including how these changes interact with each other and trigger a new change. Therefore, it is fair to say that there are as many phenotypes as assays that have been invented to measure them.

Individual primary phenotype files in PharmGKB are carefully curated with respect to clear documentation, scientific clarity, and privacy considerations. Approved files will be then labeled with:

- List of genes, drugs, diseases relevant to the file (using controlled vocabularies).
- List of index terms from the phenotype ontology.
- List of MeSH terms for additional indexing.

The approval and labeling procedure is an interactive process between curators and submitters. It is usually time consuming, but it is one of the necessary procedures to ensure the high quality of the data in the knowledge base.

4.1.3 Data from Literature

Thousands of papers related to pharmacogenetics and pharmacogenomics research have been published in the past decades. Numerous scientific discoveries and observations are recorded in these papers. Most of them are written in the text of natural language and stored in a database like Medline with a less-structured form to accommodate the heterogeneity of information.

Whereas natural language text has much power for expressiveness, it is difficult for computers to parse such language. For example, ideally a user would like to be able to compare results among some of the relevant papers then raise new hypotheses for further testing or to validate a discovery. Therefore, it is useful to retrieve information from these publications and store it in a database for facile comparison and integration. However, reliably retrieving information from these papers is a considerable challenge. Three approaches have been taken to solve this problem. First, one can use an online tool for the scientific community to submit published literature providing evidence for relationships between genes, drugs and diseases. We have developed a web interface that accepts HGNC gene names, MeSH disease names and VA-NDF, Apelon and USP DI® drug names as a summary of published literature finding. These annotations are associated with existing evidence (a PubMed ID or an URL) and a confidence measure for the evidence (select from low to high or unknown). Submitters are encouraged to categorize the submitted literature into one of the knowledge categories discussed in Section 4.2.1.

The second way to capture information in the literature is manual curation. Database curators routinely review the literature to find gene–drug–disease associations that should be captured. Curators survey the literature using PubMed, clinicaltrials.gov, the websites of the National Cancer Institute (NCI), National Heart Lung and Blood Institute (NHLBI) and Google.

While human (especially expert) knowledge is very important in collecting information in the pharmacogenetics and pharmacogenomics field, the process is very time consuming and therefore the amount of information collected through this method is relatively small. A third approach to acquire information from published literature is based on automatic computer algorithms to extract information automatically from text. We have developed a statistical and computational approach to identify all the articles in Medline citations that are associated with pharmacogenetics and pharmacogenomics research. This method can also be used to extract data pertaining to particular gene–drug relationships with 92% precision [55]. One can search for drugs that are associated with a gene of interest or *vice versa*. This tool is available at http://pharmdemo.stanford.edu/pharmdb/main.spy. For more details about tools for analysis of pharmacogenetics text, users can also visit http://bionlp.stanford.edu/genedrug. For automatic analysis of scientific texts, see also Chapter 33.

4.1.4 **Linking to other Data Resources**

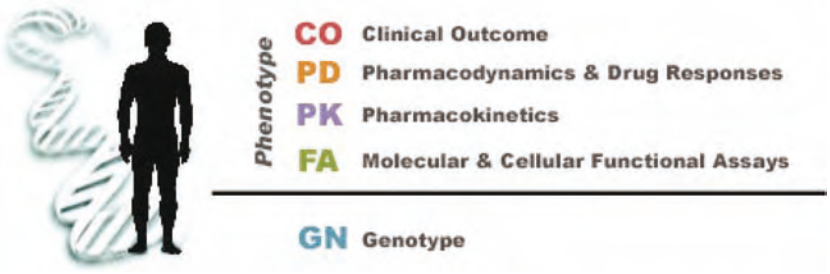
Many biological databases provide data that is complementary to the basic genotype–phenotype data sets collected for pharmacogenomics studies. The key to making appropriate links between database resources is to have common terminologies for referring to basic concepts such as genes and drugs.

For example, using shared vocabularies such as the HGNC gene symbols, one can link via URL directly to the following resources:

- UCSC Genome Browser [34]
- Entrez Gene [42]
- GenBank [5]
- Swiss-Prot [4]
- PubMed [17]
- OMIM [25]
- MedlinePlus (http://medlineplus.gov)
- Gene Ontology (GO; http://www.ebi.ac.uk/GOA)
- SOURCE [16]
- PromoLign [74]
- RefSeq [48]
- Ensembl [6]
- GENATLAS [18]
- GeneCards [50]
- MutDB [14]
- PharmGKB

4.2 Turning Data into Knowledge

It is critical for a public repository of pharmacogenetics and pharmacogenomics data to present core data sets upon which researchers in the field can apply new analyses, generate new knowledge and build new hypotheses. In order to provide such data sets, data need to be organized and classified first so that one can browse and search for individual data set easily. Relationships among data sets should be maintained and/or enabled. These relationships should also be presented in biochemical pathways to best summarize connected pharmacogenetic and pharmacogenomic knowledge for generating new hypotheses and making new discoveries.



Phenotype
CO Clinical Outcome
PD Pharmacodynamics & Drug Responses
PK Pharmacokinetics
FA Molecular & Cellular Functional Assays
GN Genotype

Figure 3 Categories of pharmacogenetics knowledge used by PharmGKB.

4.2.1 **Categorizing Data**

As discussed in Section 4.1.2, phenotype data obtained in pharmacogenetics/pharmacogenomics research are extremely diverse. We have previously categorized pharmacogenetics and pharmacogenomics information based on two principles [3]. (i) Pharmacogenetics and pharmacogenomics relate variations in genes to variations in certain phenotypes associated with drugs. Therefore, gene variations, phenotype variations and drugs should be used as major labels for most pharmacogenetic and pharmacogenomic data sets. (ii) Phenotypic data can be further classified based on the level (i.e. molecular or whole organism) at which they are collected. The indexing schema containing the five classified variation information types is shown in Figure 3. These five categories are not perfectly separable, but they provide a framework for categorizing pharmacogenetic and pharmacogenomic data and literature. If data sets touch upon more than one area, they are multiply classified. These five categories have been used for indexing the published literature, labeling phenotype and genotype data sets, and designing the user interface for different types of users. Specific definitions of the five categories of data sets can be retrieved at PharmGKB through preprepared "simple queries" (http://www.pharmgkb.org/search/query/index.jsp), as detailed in the following subsections

4.2.1.1 **Genotype** The most basic information about pharmacogenetics and pharmacogenomics is the observation of variations in individual genes, including the type of the variation (i.e. SNP, insertion, deletion, etc.), the location of the variation on chromosomes (using, for example, the UCSC's Golden Path position) and the frequency of the variation in the populations of interest. Information related to the potential importance of the genetic variation or how to analyze the variants is also part of the genotype data. This includes subject information such as gender and ethnicity, features (such as exons and promoters) of the region under investigation, alternative splicing, and protocols for the assay by which the variant was analyzed. For example, genotype file PS204853 in PharmGKB contains the measurement of four variants in *VKORC1* genes that are critical to the therapeutic dose of warfarin, and the measurement was performed in 340 subjects with different age, sex and ethnicity background.

4.2.1.2 **Clinical Outcome**

The main driving force of pharmacogenetic and pharmacogenomic research is to make an impact on clinical medicine through maximizing drug efficacy and minimizing drug toxicity. Therefore, the discovery of genetic variations (genotype) that cause measurable differences in clinical outcomes that are of concern to patients and their physicians such as how tolerable is the treatment (drug side-effects, adverse reactions) or how soon the patient improves (disease symptoms, laboratory test results) in response to the drug treatment are particularly meaningful. These clinical outcomes are obviously different from the measurements of drug response in a research setting. Sometimes they might not be detailed enough to illustrate the pharmacodynamic effect of a drug, but they can certainly alter medical practice or policy. An example of clinical outcomes can be viewed in file PS204373 at PharmGKB. The rejection of a heart transplant in pediatric patients can be potentially managed by using specific genotype information of the *MDR1* and *CYP3A5* genes because such genotype information is important for maintaining the patient's blood concentration during immunosuppressive therapy with the drug tacrolimus.

4.2.1.3 **Pharmacodynamics and Drug Responses**

Datasets of measurements at the whole-organism level are classified into pharmacodynamics data and drug responses, although usually pharmacodynamics data can include all outcomes associated with how drugs act. For example, changes in an individual's intestinal CYP3A4 protein levels after 2 days of receiving oral rifampin are associated with variations in the pregnane X receptor (*PXR*) gene (phenotype file PS200308 in PharmGKB).

4.2.1.4 **Pharmacokinetics**

The measurements of the absorption, distribution, metabolism or elimination (ADME) of a drug in association with genotyping belong to the pharmacokinetics category. Classic pharmacogenetic studies relied upon observing changes in drug metabolism in the context of genetic variants. Up to now, most of the important genetic variants associated with drug responses are in genes coding enzymes involved in drug metabolism and transporters in charge of drug transportation. Many data sets have demonstrated that genetic polymorphisms lead to variation in the pharmacokinetics of particular drugs. For example, genetic variation in *VKORC1* is responsible for phenotypic variation in the steady-state concentration of warfarin in plasma (phenotype file PS402853 in PharmGKB).

4.2.1.5 Molecular and Cellular Functional Assays

Many discoveries of pharmacogenetics and pharmacogenomics start from measurements establishing an association between genetic variation and a drug induced or inhibited reaction at the molecular and cellular level. For example, the phenotype file PS200308 in PharmGKB, the example used in Section 4.2.1.3, reports data about the binding ability of the variants PXR*1, PXR*2, PXR*3 and PXR*4 of the PXR protein to CYP3A4 in a transient plasmid expression system. Data obtained *in vitro* with artificial constructs belong to the category of molecular and cellular functional assays.

4.2.2 Establishing Genotype–Phenotype Correlation

Correlating genotype findings to phenotype results is a key step to understanding the impact of genetic variations on drug response. Therefore, providing reliable information that links genotypes to phenotypes is an important goal.

Pharmacogenomics data contains many levels of complexity, including information on individual subjects on whom pharmacogenetics and pharmacogenomics assays have been performed. Assays performed on individual subjects include all of the genotyping efforts (using DNA samples) and most of the phenotypic studies (all of the *in vivo* and some of the *in vitro* studies on derived cell lines). These subjects might participate in multiple studies in different institutes. Thus, it is possible that genotype data can be submitted by one institute, pharmacokinetic phenotype data can be submitted by a different institute, and pharmcodynamic and drug responses phenotype data can be submitted by yet another institute. While ensuring that the privacy of these individuals is protected, it is important to keep track of all subjects in association with the submitted genotype or phenotype results. This information provides a way to link genotype data sets to data sets with different types of phenotypes. Users can view the genetic variations in these individuals and the phenotypic consequences of those variations. This provides one of the most reliable ways to study the potential correlations between genotypes and phenotypes.

Statistical and computational tools are needed to assist users in finding correlation between genotype and phenotype. For instance, a simple genotype–phenotype association can look for "single SNP, single phenotype measurement" relationships. An implementation could compute correlations between genotypic data and phenotypic data for biallelic SNP sites. These correlations can be computed on individual study populations, as well as on all available subjects pooled together. For more detailed analyses, users must be able to download data sets and perform more sophisticated correlation analysis as needed.

4.2.3 Using Pathways to Summarize Current Pharmacogenetics and Pharmacogenomics Knowledge

Pathways provide an excellent way to summarize connected pharmacogenetic and pharmacogenomic knowledge. In particular, it is critical to manage pathways related to drug metabolism or action. Users require both graphic and computational representations of how drugs are transported and metabolized (pharmacokinetics) and how drugs act (pharmacodynamics). In PharmGKB, pathway knowledge is linked with the underlying data in PharmGKB. Drugs, metabolites and transporter genes are presented using standard icons. Pathway representations are interactive – every gene and drug in a pathway diagram is linked to a related page which reports more detailed information regarding the gene and drug. The arrows in a pathway diagram indicate that a gene is involved in some process and are linked with the appropriate literature annotation or primary data that establishes or confirms this relationship.

In addition to the pathway diagram, a text summary is provided to describe the content on the graph and, more importantly, the drug-related significance of the pathway, the limitations of that particular graphic representation and any additional information not able to be included in the pathway diagram. Related pathways, drugs and diseases (that are not directly involved in this pathway but are related) are also listed next to the pathway. An example of such pathways is shown in Figure 4.

As pathways rely on expert knowledge, the creation of drug-related pathways requires the collection of relevant information and assessment by experts from the pharmacogenetic research community. PharmGKB has developed a protocol for curation of pathways by pharmacogenetics experts. A PharmGKB curator is assigned to the process. On a well-defined timeline, a draft pathway is produced, there are one or more conference calls to discuss it, and, when there is general agreement, the final pathway is rendered by a graphical interface specialist and posted on the website. It is also stored in a database using a simple relational representation, compatible with the emerging pathway standards (such as BioPAX). The most time-consuming part of this process is the documentation of standard names for drugs and genes, and the collection of references to the supporting data for the links to be portrayed. The assembly of a pathway typically takes 2–3 months.

4.3 Providing Easy Access of Knowledge for the Research Community

Easy access of knowledge and data can be obtained via the web-based querying and browsing systems. Most data submission can also be web-based.

Different strategies and formats can be used for exchanging different types of data sets. An XML schema has been developed for genomic data sets. Rules and privileges can be set for different users for security purposes. In a pharmacogenetics and pharmacogenomics knowledge base, patient privacy can be well protected.

4.3.1 Querying System

The popularity of Google-style searches leads users to expect that the entire contents of a database can be searched for the occurrence of short text phrases. Many databases, including PharmGKB, index their contents for full-text search (using the Lucene [26] text search indexing engine). The challenge in this task is to present the results (which will be a mixture of web pages, data, publications and other types) to the user in a ranked and orderly way. Lucene ranks all results based on parameters and preferences that can be set by the developer. It also supports wildcards, boosting, approximate matches, and neighborhood searches (e.g. within 10 words).

Most database users do not use powerful search features, but instead prefer either Google-style text searches or queries predefined on the basis of templates. From a set of use-case scenarios from pharmacogenomics researchers, we have identified a collection of commonly occurring queries and coded these on a single web page. Each predefined query has two or three "fill in the blank" selections and a submission button. The results are then formatted in a manner that is sensitive to the nature of the question – an advantage of knowing the query that the user has selected.

4.3.2 Visualization and Browsing

In order to present a consistent predictable picture of the database to the user, it is important to use a simple set of web design principles. The main objects in pharmacogenomics are genes, drugs, diseases, pathways and submission group. In PharmGKB, the gene, drug and disease pages have been designed to have a similar look and feel. Data for which PharmGKB is the primary home is boxed to draw attention. Literature annotations are included at the bottom of each page, and with links among genes, drugs and diseases. External links

Details
Cytogenetic Location: 10q24.1
OMIM Phenotype: Tolbutamide poor metabolizer, Warfarin sensitivity
Product Name: cytochrome P450, family 2, subfamily C, polypeptide 9

GenAtlas ID: CYP2C9
GenBank ID: AY341248
GenBank ID: AY702706
GenBank ID: BC020754
GenBank ID: BC070317
GenBank ID: D00173
GenBank ID: L16880
GenBank ID: L16883
GenBank ID: M21939
GenBank ID: M21940
GenBank ID: M61855
NT_030059
Ref Seq NT Accession: NT_086775
SOURCE ID: CYP2C9
SWISS-PROT Accession: P11712
Web Resource: CYP2C9 Nomenclature

Figure 5 Gene page for *CYP2C9*. Named alleles are shown on the top of the page. Primary data are shown in the boxed area (left panel). The far right has links to external sources. The bottom of the page (right panel) lists all curated relations between drugs and diseases, and indicates what category of knowledge is used to establish the relationship. All gene pages have a similar layout.

usually appear on the right panel. The current gene page for *CYP2C9* is shown in Figure 5.

A genotype browser is critical for visualization and analysis of genotype data. These browsers typically display a genomic segment, while indicating the location of polymorphisms. The PharmGKB browser allows for zooming, sliding and display of the gene structure (Figure 6). Below the browser is a table of polymorphisms displaying summary data and links, including (most significantly) links to any measured phenotypes of the listed genotypes.

Phenotype files in PharmGKB are presented first with a short textual summary including the genes, drugs and diseases studied and the categories of pharmacogenetic knowledge – clinical outcomes, pharmacodynamics and drug responses, pharmacokinetics and molecular and cellular functional assays. In the Details Section, each column is labeled by a controlled vocabulary to facilitate indexing and retrieval. Each row contains individual subject data which are linked to all genotypes for that subject via a unique identifier. All subject data is completely de-identified prior to submission to PharmGKB. An example is shown in Figure 7.

Figure 6 Variant browser for *CYP3A4*. The genomic sequence is displayed with Golden Path numbering. Brown bands indicate the location of exons. SNPs are drawn as tick marks above the sequence bar, with height proportional to overall frequency and colored based on type of SNP (e.g. nonsynonymous). All SNPs are also displayed in the table below, with links to detailed frequency and population information. Haplotypes can be computed using web services at the top right.

4.3.3 **Privacy Protection**

Pharmacogenomics studies individual response to drugs and so individual data is critical. However, it is also critical to ensure the privacy of individuals from whom the genotype and phenotype data were collected [39, 40]. At PharmGKB, genotypic and phenotypic information associated with individual human subject is only available to registered users, who are associated with a *bona fide* research institution or company (or who are sponsored by other registered users). The most privacy-sensitive information has been de-identified or binned according to the method described by Lin and coworkers [39] in the database before it is released. Registration is free to the life science

Irinotecan and CYP3A5 Genotype

Investigator:	Mark J. Ratain, MD
Group:	PAAR-UChicago
Genes Studied:	CYP3A5
Drugs Studied:	irinotecan
Diseases Studied:	Neoplasms
Number of columns (phenotypes):	5
Number of rows (subjects):	30

Details

This study explores the relationship between irinotecan pharmacokinetics and the CYP3A5 gene.

Categories of Pharmacogenetic Knowledge

PK Pharmacokinetics

Disclaimer: Patients and doctors should NOT make treatment decisions based on the information in the PharmGKB as it is purely a research resource. Questions about the data should be directed to Mark J. Ratain, MD.

Genotype:
Phenotype:

Subject ID	PharmGKB Accession IDs for subjects in the PharmGKB.
Gender	Male, female, or unknown.
Race/Ethnicity	Race/Ethnicity as defined by the NIH Office of Management and Budget, followed by the self reported information in parentheses if available.
M4 mean peak height	Mean peak height of the de-ethylated metabolite of innotecan (M4) determined by HPLC.
NPC mean peak height	Mean peak height of 7-ethyl-10-(4-amino-1-pipendino)carbonyloxycamptothecin (NPC) determined by HPLC.

Subject ID	Gender	Race/Ethnicity	M4 mean peak height	NPC mean peak height	
PA126713938	Unknown	White (White)	A/G	30743.5	6908
PA126713970	Male	White (Caucasian)	G/G	8385.5	3750
PA126713974	Male	White (White)	G/G	10216.0	7768
PA126713977	Male	White (White)	G/G	24377.5	9748
PA126713985	Male	White (Caucasian)	G/G	27590.5	1762
PA126713987	Female	White (White)	G/G	47744.5	4665
PA126713988	Male	White (White)	G/G	25490.5	2259
PA126714032	Male	White (Caucasian)	G/G	15242.5	5363
PA126714034	Female	White (Caucasian)	G/G	41091.5	3289
Subject ID	Gender	Race/Ethnicity	M4 mean peak height	NPC mean peak height	
PA126714035	Male	White (White)	G/G	15583.5	7288

Figure 7 Phenotype data display. In addition to view the phenotype data set from this page, phenotype and related genotype data can also be down loaded by clicking the red arrow on the top right corner. All phenotype data set have a similar layout.

research community, but one has to first provide an identity and agree to fully comply with the usage policies, which include the prohibition of any attempt to re-identify study subjects.

4.3.4 Data Exchange Strategy

PharmGKB has developed a general purpose XML schema for genotype data submission and exchange. This schema contains a superset of information required by dbSNP and GenBank and is shared publicly. The XML captures information about reference sequences, polymorphism location and type (e.g. SNP, deletion, insertion etc.), study samples, populations and methods for determining polymorphisms (e.g. sequencing, restriction fragment length polymorphism). It also allows for specification of species, copy numbers, and gene structure/annotations. It is available at http://www.pharmgkb.org/schema/index.html. Changes occur on a 6-months basis and are associated with a sufficiently timely notice to allow associated code to be modified. PharmGKB has participated in the public process of defining standards for exchange of SNPs, such as PML [61], and has ensured that emerging standards are consistent with our XML.

The availability of an XML schema with clear semantics allows curators to run a full syntactic and semantic validation on submitted files upon receipt of a submission. The validation process ranges from data type checks to "common-sense" checks, such as that base numbers fall within specified ranges and that key required data items are provided. This XML schema has provided a high-throughput processing of genotype submissions and posting on the web.

In addition to supporting bioinformatics-savvy submitters who use XML, it is important to have options for users with little bioinformatics expertise. For example, user-friendly web pages for data entry using Excel files are also available on PharmGKB. Laboratories without bioinformatics infrastructure can use the online submission option for their genotype data sets. These web submission pages are based on the data representation used in the XML schema for polymorphisms.

5 Analytic Tools for Pharmacogenomics

The field of pharmacogenomics is so broad that it is difficult to list the key analytic functionalities that are required. However, we can summarize the key analysis tasks in pharmacogenomics, and the types of tools that are used.

The first challenge in understanding how a drug-related phenotype depends on genetics is to identify the genes that are likely to be involved. This may involve the creation of "candidate gene" lists based on analysis of the published literature on the drug or phenotype. It may also involve examining pathways of drug metabolism or action. Any bioinformatics tools that can infer gene function, and relate a function to a drug response could be useful at this stage of pharmacogenomic analysis. The analysis of gene expression (e.g. using microarrays) can also be used to suggest which genes may be involved in the response to a drug. Presumably, similar proteomic capabilities will emerge in the future. See Part VIII of this book for information on how to analyze gene and protein function with bioinformatics methods.

The discovery of genetic variation in genes that may be involved in drug response can be accomplished by resequencing multiple individuals and looking for variation. These analyses typically use the Phred/Phrap suite of programs to find evidence of multiple bases at a single position in the genome [35]. Other methods include mining of expressed sequence tag (EST) databases to find evidence of sequence polymorphism that is not likely to be due to sequencing errors [13].

Once a polymorphism has been detected, it is necessary to determine if it is likely to be functionally significant. Methods for assessing the likely functional significance of SNPs include the SIFT program [71], the MutDB resource [44] and others [8,62,70].

Phenotypes related to drug response are extremely variable. The key analytic challenge for phenotypes is to define them precisely, and to collect and record them well. The organization of phenotypes into ontologies is a critical need, because this allows the relationship between different phenotypes to be defined, in order to support indexing, search and aggregation. For example, "blood pressure" is a general phenotype that can be assayed in many ways. If the detailed relationship between these assays is recorded, then different blood pressure studies can be combined appropriately to achieve higher statistical power.

The key analytic challenge for pharmacogenetics is the discovery of genotype–phenotype relationships. If a phenotype is controlled primarily by a single gene locus, then a plot of the phenotype versus the allele observed at that locus is often a bimodal or trimodal distribution, with each mode corresponding to a different allele. If, however, the phenotype is controlled by a large number of loci from different genes, the distribution is likely to be unimodal and broad. Methods for finding the key genetic loci associated with a particular phenotypic measurement are the domain of statistical genetics and have been the subject of many recent reviews [11, 49, 72] (see also Chapter 37).

Recently, there has been a move to "whole-genome" association studies in which the phenotype is correlated to SNPs collected from a sample of genomic loci across the whole genome. The genotype SNPs are usually selected to be "tag SNPs" in linkage disequilibrium with a large number of other SNPs locally [59,73]. Once regions are found to be correlated with the phenotype of interest, they can be studied in a refined manner by genotyping the local SNPs and searching for those that are likely to be functionally significant, using the methods mentioned above. One strategy involves the combination of family-based linkage analysis to focus attention on a small number of genomic regions, association analysis with SNPs to find those SNPs in these regions that are most correlated with the phenotype of interest and then expression analysis to see if any of the genes showing potentially relevant polymorphisms show an expression change in response to a drug challenge. More information on this topic can be found in Chapter 37. Multiple other experimental methods can be used to focus attention on regions of the genome for which a variety of evidence points to involvement in modulating the response to a drug.

6 Future Perspectives on Informatics for Pharmacogenetics/Pharmacogenomics

PharmGKB is the first public pharmacogenetics and pharmacogenomics database to provide information about genetic variations in humans and the phenotypic consequences of those variations. By providing original data in standardized formats, and web interfaces to retrieve integrated information and for analyzing data, PharmGKB is providing solutions to many of the challenges that pharmacogenetic and pharmcogenomic researchers brought to biomedical informatics.

One of the major goals of pharmacogenomics is to predict drug response in individuals based on their genetic profile in order to provide the most effective individualized medicine. In the future, patients will be stratified based on genetic tests for their ability to respond to a therapeutic agent and their possibility of having adverse reactions. The process of drug development will also benefit from the ability to identify targeted patient populations with a high likelihood of success early in the process, while avoiding unexpected late failures. As the field increases its inventory of high-impact data sets and useful analytical tools, it should help catalyze the use of patient genetic information in medical practice.

Evolution of Drug Resistance in HIV

Niko Beerenwinkel, Kirsten Roomp, and Martin Däumer

1 Introduction

Evolution is the cornerstone of modern biology, because it provides a unifying principle for understanding diverse biological phenomena and for the quantitative analysis of molecular data. Evolutionary concepts also become increasingly important in medicine as witnessed, for example, by the progress in finding the genetic basis of complex diseases (Chapter 38) or by assessing polymorphisms in the human genome that are associated with drug effectiveness and tolerance (pharmacogenomics, Chapter 39). Evolutionary and population biology methods play a key role in understanding and controlling infectious diseases both within and among individuals [64]. The primary examples are infectious bacteria (Chapter 41) and viruses. In this chapter, we investigate the evolution of HIV. HIV is an attractive model system for evolutionary studies due to its short genome, large population size and high genetic diversity. The extreme replication dynamics of HIV allow for observing significant evolutionary changes over time. Understanding the evolution of HIV is necessary for controlling the spread of the AIDS pandemic, for developing effective therapies and vaccines, and for managing drug resistance.

The development of drug resistance is a major obstacle to the successful treatment of HIV infection. The evolutionary dynamics of HIV facilitate its escape from the selective pressure exerted by the human immune system and by combination drug therapy. This chapter presents computational methods for the design of optimal antiretroviral therapies against drug-resistant HIV strains. The focus is on using genomic information, i.e. the nucleotide sequences of the viral drug targets, to guide treatment decisions. Since every patient carries a unique virus population, the presented methods support individualized therapies, rather than the traditional one-drug-for-all paradigm. As opposed to the individual treatment factors based on human genetic variation (Chapters 38 and 39), here the rationale for unique treatment choices arises in the first place from the genetic variation in the infectious pathogen.

Thus, we present computational methods for a specific case of personalized medicine.

Section 2 reviews the biomedical background of HIV infection, antiretroviral therapy, and drug resistance. In Section 3, we discuss machine learning and statistical methods which are used to predict phenotypic drug resistance, as measured *in vitro,* from the viral genotype. The development of drug resistance is the subject of Section 4. We present methods for learning mutational pathways which the virus takes in order to escape from drug pressure and we discuss the concept of the genetic barrier to resistance. Section 5 focuses on estimating the *in vivo* effect of drug combinations conditioned on the baseline viral genotype. The described techniques draw on the results of previous sections and directly address the problem of selecting optimal drug combinations. In Section 6, the effect of immune pressure on the evolution of the virus is studied. We discuss some open problems in Section 7 and list related web resources in the final Section 8.

2 Biomedical Background

2.1 Biology of HIV

2.1.1 Epidemiology of HIV/AIDS

AIDS is one of the most serious infectious diseases having ever affected humankind. An estimated 40 million people are currently suffering from this disease [105]. Its mortality rate is close to 100% and resulted in more than 3 million AIDS-related deaths in 2004. In the same year, 5 million people became infected with the relevant pathogen, the HIV, and of these 95% live in developing countries. Despite the existence of controversial theories for explaining the origin of HIV, there is wide agreement that the virus entered the human population in a zoonotic transmission from African nonhuman primates, which were infected with the closely related simian immunodeficiency viruses (SIVs) [44]. It is estimated that HIV type 1 (HIV-1) and type 2 (HIV-2) were introduced into humans around 1930 and in the 1940s, respectively [58,61].

AIDS was first recognized in 1981 in the US. At that time several reports described an increase in the incidence of rare opportunistic infections such as *Pneumocystis carinii* pneumonia and mucosal candidiasis [43]. Common features among the affected patients were that they showed evidence of a general immune deficiency and that they were either homosexual men or intravenous drug abusers. Two years later HIV was isolated [1] and by the mid-1980s it became evident that two types of HIV (HIV-1 and -2), with slightly different genome architectures, were circulating in the human population.

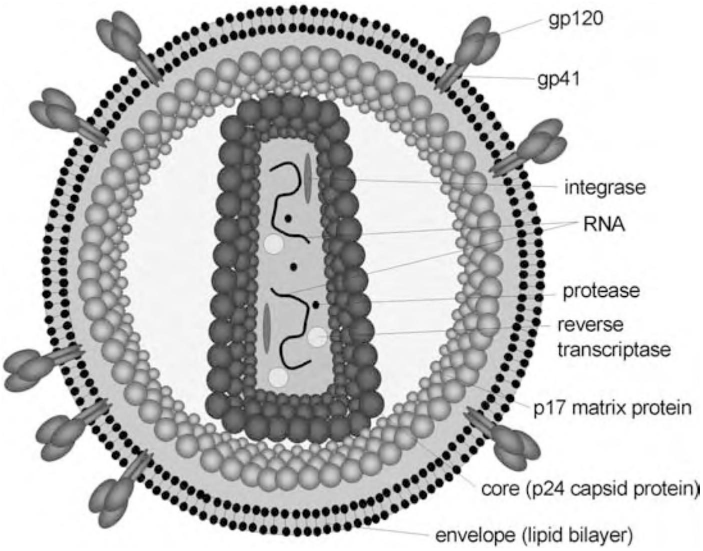

Figure 1 Schematic diagram of an HIV particle.

Both HIV-1 and -2 strains are divided into groups and subtypes. HIV-1 embraces the three genetically distinct groups M ("main"), N ("new") and O ("outlier"). Group M viruses, which cause 99% of HIV infections worldwide, are further subdivided into 11 genetically distinct subtypes, i.e. A1, A2, B, C, D, F1, F2, G, H, J and K [65]. Additionally, a major fraction of HIV-1 strains comprises intersubtype recombinants, designated "circulating recombinant forms" (CRF). The less virulent HIV-2 strains comprise six distinct phylogenetic lineages, i.e. subtypes A–F.

2.1.2 Structure, Genome and Replication Cycle

The HIV particle (virion) is roughly spherical and about 100–120 nm in diameter. Its outer envelope is composed of a lipid bilayer bearing numerous spikes (Figure 1). Each spike is composed of three heterodimers formed by glycoprotein 41 (gp41) and glycoprotein 120 (gp120) [40]. Beneath the outer envelope is a layer of matrix protein. The core of the virus particle has a hollow, truncated cone shape and is composed of another protein, p24, which contains the genetic material of the virus. Finally, inside the core there are two strands of RNA, consisting of about 9200 nucleotide bases, an integrase (p31), a protease (p10) and a reverse transcriptase (RT) (p51/66).

HIV is classified as a cytopathic retrovirus. Several characteristics differentiate retroviruses from other viral families. Their defining features are an RNA genome and the RT, an enzyme which facilitates the conversion of the RNA into DNA. HIV's genome consists of nine genes. Three genes, *gag*, *pol*

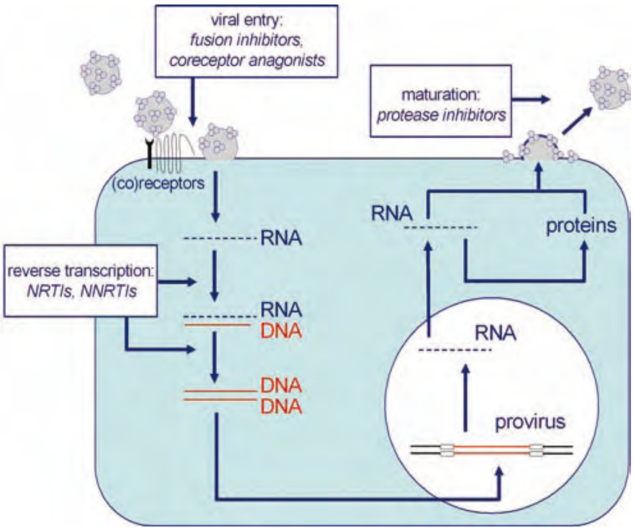

Figure 2 HIV replication cycle and targets of antiretroviral drug therapy.

and *env,* are common to all other retroviruses, the remaining six, the so-called accessory genes, *vif*, *vpr*, *tat*, *rev*, *nef* and *vpu*, are unique to HIV and SIV.

The life cycle of HIV can be divided into six steps: (i) binding to the target cell, (ii) penetration into the cell, (iii) reverse transcription, (iv) integration into the host's genome, (v) replication and (vi) budding of new virions (Figure 2). Gp120 facilitates binding and gp41 enables fusion of the viral envelope with the cell membrane. The primary host receptor for gp120 is CD4. CD4 receptors are most highly abundant on helper T cells, making these cells particularly susceptible to HIV infection. However, macrophages, monocytes, dendritic cells, Langerhans cells, hematopoietic stem cells, certain rectal-lining cells, and microglial cells are also susceptible. Subsequent to the initial binding of gp120 to CD4, binding to a cellular coreceptor, such as CCR5 or CXCR4, follows. Finally, binding to gp41 occurs enabling the penetration of the virus into the target cell.

Once inside the cell, the virus sheds its coat and transcribes its RNA into DNA. The resulting DNA is transported to the host cell nucleus and is integrated into the host cell's genome, forming what is referred to as the provirus. The virus can now remain dormant for an undetermined time period, the so-called latent phase, during which the viral genes are not expressed. Activation of the provirus is marked by the beginning of the transcription of HIV's structural genes and the formation of new virions. Transcription produces mRNA, which is translated into viral proteins, as well as single-stranded RNA (ssRNA), which is inserted into all new virus particles. The virus assembles into a new virion, which will bud out of the cell in order to enter new cells. The host cell membrane is modified by the insertion of gp41 and gp120. The viral ssRNA and core proteins assemble beneath the modified membrane, and, while budding, acquire the modified host plasma membrane as their envelope. Finally, the viral protease is required to process the precursor Gag–Pol polyproteins into mature HIV particles.

2.1.3 Basic Immunology and Course of Infection

HIV is able to infect several human cell types, but the most severe damage appears to result from the infection of cells that are of central importance to the immune system. The human immune system fights foreign invaders, removes dead and damaged cells, and destroys mutant and cancerous cells. The immune system is capable of fighting pathogens to which it has never been exposed employing a number of different cell types, which are all categorized as lymphocytes. B and T cells are two of the types of lymphocytes that recognize foreign substances or nonself. B cells produce and secrete antibodies in response to an antigen [76]. The three major types of T cells are cytotoxic or killer T cells (CTLs), suppressor T cells and helper T cells. CTLs eliminate virus-infected cells and are responsible for recovery from a viral infection. Suppressor T cells or cytotoxic T cells suppress the immune response after the antigen is eliminated. Helper T cells alert the immune system to antigens and signal other cells in the system to attack the antigen. Helper T cells do not kill cells, but interact with B cells and CTLs in order to help them attack foreign particles [98].

There are specialized receptors on the surface of each T cell to identify one of many millions of possible antigens that may invade the organism. Each T cell expresses a unique receptor that binds to the complementary antigen on the foreign particle to neutralize or destroy it. Killer and suppressor T cells carry the CD8 receptor (T suppressor cells are also called T8 cell) and the helper T cells (T4 cells) carry the CD4 receptor. Collectively, T8 and T4 cells regulate the body’s immune response to foreign antigens [98].

The primary infection elicits a rapid increase in CTL cells. It is estimated that approximately half of all T lymphocytes are involved. Rapid CTL cell division occurs over the first 2- to 3-week period. CTL levels peak and HIV-specific antibodies appear in the blood, leading to a drop in viral load, after which it is difficult to isolate the virus. This phase, referred to as clinical latency, is characterized by low viral replication and by a slow but constant decrease of the number of CD4$^+$ cells [36, 47].

The CTL response is essential for controlling the virus [67]. A strong CTL response correlates with low plasma viremia (amount of free virus in the blood) and a prolonged asymptomatic stage. The type of human leukocyte antigen (HLA, see Section 6), a kind of peptidic alarm system on cells, affects the effectiveness of the CTL response, as CTLs can only recognize an epitope bound to an HLA class I molecule.

CTLs have multiple antiviral mechanisms and it is currently unclear which of these mechanisms is most important for the control of viral infections. CTLs have the ability to lyse infected cells and to produce cytokines at sites of viral replication. Cytokines are low-molecular-weight soluble proteins that are produced in response to an antigen. They function as chemical messengers regulating the innate and adaptive immune systems (tumor necrosis factor-α, interleukin-1). Cytokines affect viral replication through their influence on T helper cell activation and proliferation. Certain chemokines, a group of cytokines, such as MIP-1α, MIP-1β and RANTES, are produced that suppress HIV replication by competing for or down-regulating the CCR5 coreceptor. However, at some point of the infection CTLs become incapable of controlling the virus. A possible factor contributing to this failure is the inability of other T cells to help. The immune system is able to reduce the number of viruses initially. Consequently, CTL-resistant HIV mutants are selected. These mutants are not easily recognized by HLA molecules. Since only those virions capable of escape survive and reproduce, eventually, the entire viral population consists of CTL escape mutants (Section 6). At this point the immune system is completely defenseless against the virus and HIV can freely reproduce, thereby further impairing the immune system. As a result, the increasing damage to the immune system leaves the infected individual susceptible to opportunistic infections.

2.2 Antiretroviral Therapy

2.2.1 Antiretroviral Drugs

The aim of antiretroviral therapy in HIV infection is to reduce the amount of replicating virus to as low a level as possible, thereby preventing the infection of new cells and further damage to the immune system. There are now 18 different drugs from four distinct drug classes in widespread use (Table 1). The first antiretroviral agent to become commercially available was zidovudine in 1987, followed by didanosine and zalcitabine in 1993. These drugs belong to the class of nucleoside analog RT inhibitors (NRTIs), which act on the RT (Figures 1 and 2). These drugs are analogues of thymidine or cytosine and are modified in the $3'$ position of the ribose molecule. NRTIs can be considered as prodrugs as they must be phosphorylated to become active. The incorporation of these drugs into newly synthesized DNA leads to premature chain termination as the drugs do not provide the $3'$ hydroxyl group to form the bond with the next nucleotide.

A dramatic decline in clinical progression of HIV disease and HIV-related deaths followed the introduction of protease inhibitors (PIs) in 1996. These

Table 1 Approved antiretroviral drugs in the four drug classes: NRTIs, NNRTIs, PIs and EIs (see text for details)

Drug class	Generic name	Abbreviation	Trade name
NRTI	zidovudine	ZDV	Retrovir
	didanosine	ddI	Videx
	zalcitabine	ddC	Hivid
	stavudine	d4T	Zerit
	lamivudine	3TC	Epivir
	abacavir	ABC	Ziagen
	tenofovir	TFV	Viread
	emtricitabin	FTC	Emtriva
NNRTI	nevirapine	NVP	Viramine
	delaviridine	DLV	Rescriptor
	efavirenz	EFV	Sustiva
PI	saquinavir	SQV	Invirase, Fortovase
	ritonavir	RTV	Norvir
	indinavir	IDV	Crixivan
	nelfinavir	NFV	Viracept
	lopinavir	LPV	Kaletra
	atazanavir	ATV	Reyataz
EI	enfuvirtide	ENF	Fuzeon

compounds act on the HIV protease enzyme, preventing the cleavage of essential viral precursor proteins. PIs are peptide-like molecules that mimic the Gag–Pol polyprotein and compete against it for the enzyme. The competitive inhibition of the viral protease leads to production of immature, noninfectious virus particles. Although PI therapy does not prevent the destruction of already infected cells, a further spread of infection into uninfected cell populations is prevented.

The nonnucleoside RT inhibitors (NNRTIs) are the third class of drugs currently available for treating HIV infection. NNRTIs also act on the RT enzyme, but differ in structure and mechanism of action from the NRTIs. The binding of an NNRTI close to the active site of the RT leads to a conformational change of the active site of the enzyme, and consequently to a reduced binding affinity for the RT's natural substrates, i.e. the nucleotides.

The fourth drug class comprises the so-called entry inhibitors (EIs), acting at the stage of viral attachment or host cell penetration. The only drug approved so far within this class is the fusion inhibitor enfuvirtide. Coreceptor antagonists are likely to enter phase III clinical trials soon.

The current standard of care is to treat HIV-infected individuals using a combination of at least three drugs out of two drug classes. This is commonly referred to as "highly active antiretroviral therapy" (HAART). Unfortunately, long-term use of antiretroviral treatment is associated with several limitations and drawbacks. Currently available antiretroviral drugs are unable to completely eradicate HIV, and virus continues to reside and to replicate latently in reservoirs. As a result, most patients will be on antiretroviral therapy for the rest of their lives, a situation that often causes continuous severe side-effects due to drug toxicity. Additionally, poor adherence to drug regimens has led to an increased rate of HIV drug resistance, resulting in viral strains that have reduced sensitivity to drug treatment [75].

2.2.2 Drug Resistance

The genetic and molecular basis of drug resistance is the enormous viral turnover coupled with an extremely high replication error rate, caused by the RT which lacks a proofreading mechanism. Mathematical modeling suggests that every possible point mutation in the viral genome may occur more than 10 000 times in an infected person per day [21]. Thus it is likely that mutants that are resistant to a single drug may naturally exist, whereas resistance to a drug combination requiring three or more specific mutations seems to be much more unlikely to preexist.

Resistance to antiretroviral drugs emerges when viral replication continues in the presence of selective drug pressure. For some drugs, such as the NRTI lamivudine and all NNRTIs, one point mutation is sufficient to induce high-level resistance, whereas other drugs like zidovudine and the PIs require the accumulation of multiple mutations to reach a high level of resistance. Thus, resistance to therapies consisting of combinations of different drugs develops in a gradual and stepwise manner (Section 4).

Single mutations or mutational patterns can result in resistance to an entire drug class. Therefore, a strain, which has emerged under the selective pressure of a specific drug, may be resistant not only to that drug, but also to other drugs from the same class that have never been applied. This phenomenon is referred to as cross-resistance. Cross-resistance affects almost all of the currently available drugs to varying degrees. Thus, resistance to one antiretroviral agent will affect the choice of other drugs from the same class.

2.3 Resistance Testing

Resistance to antiretroviral drugs can be measured using either genotypic or phenotypic assays. Genotypic assays detect mutations known to cause drug resistance. Phenotypic assays are drug susceptibility assays in which the virus is cultured in the presence of serial dilutions of an inhibitory drug. Both genotypic and phenotypic assays use HIV-1 RNA extracted from the patient's blood plasma for further testing, since this virus represents the phylogenetically most recent step in the viral evolution that is happening inside the patient.

2.3.1 Genotypic Resistance Testing

Genotypic resistance testing is generally performed by sequencing the drugs' target genes in order to detect mutations that confer drug resistance. The clinical usefulness of genotypic testing has been demonstrated in several prospective randomized trials [20, 26, 33]. Genotypic testing is used more commonly than phenotypic testing because of its lower cost, wider availability and shorter turnaround time. Furthermore, genotyping provides early evidence of drug resistance within a virus population. Genotypic assays detect mutations that are present as mixtures in relative proportions as low as 15–20%, even if the mutation does not affect drug susceptibility in a phenotypic assay. Moreover, genotyping can detect transitional mutations that do not cause drug resistance by themselves, but indicate the presence of selective drug pressure or the transmission of a resistant strain.

However, the interpretation of genotypic resistance tests remains challenging. Genotypic results are often interpreted by consulting "look-up tables" of drug resistance mutations. Regularly updated tables with a compilation of resistance associated mutations in protease, RT and the envelope protein gp41 can be obtained from the home page of the International AIDS Society – USA [51]. For example, within the protease more than 50 mutations at 33 different positions are listed. A more direct approach to the interpretation of genotypic data is based on rule sets encoded in computer programs that classify the virus as resistant, potentially resistant or susceptible to each drug (Section 3.2). Constructing these sets of rules is a lengthy and complicated process. Any additional information on drug resistance that is available requires frequent updating of the set of rules. Furthermore, extensive variation exists among the different available interpretation systems regarding drug activity and how drug resistance is scored [78, 88].

2.3.2 Phenotypic Resistance Testing

Similar to the procedure of genotypic assays, the first step in a phenotypic assay involves extraction of HIV-1 RNA from plasma, followed by reverse transcription and amplification of the genes of interest. These amplified genes are then used to generate recombinant viruses that can be tested for susceptibility to protease and RT inhibitors. Results of phenotypic testing are usually expressed in terms of the resistance factor (RF) which is the fold-change in susceptibility of the test sample compared with a fully susceptible control isolate.

Phenotypic testing in clinical settings is expected to be most useful for isolates with unusual combinations of resistance mutations or mutations not yet described and developing under new drugs. For example, the mutation L76V in the protease arises under several PIs in the background of other mutations that already confer high level PI resistance. Hence, current guidelines interpret such a genotype as multi-PI resistant. However, phenotypic analysis of strains harboring the L76V mutation revealed susceptibilities to saquinavir and atazanavir comparable to those of wild-type viruses, indicating that the L76V mutation has a resensitizing effect [70]. Phenotypic testing may also be useful in combination with therapeutic drug monitoring for designing salvage regimens in heavily treated patients whose viruses contain multiple drug resistance mutations.

However, the key question of whether a patient will respond to a particular drug or not remains open. Therefore, the primary challenge for interpreting phenotypic results is to predict clinical response by using data from clinical trials, studies or large cohorts in order to correlate genotypes and phenotypes (RFs) to virological response.

3 Prediction of Phenotypic Resistance from Genotypes

Phenotypic drug resistance can only be measured in a laborious virus assay (Section 2.3). On the other hand, genotyping is much more efficient, but the interpretation of the resulting sequence data is challenging. Computational methods can help interpret sequence data by predicting phenotypic traits from viral genotypes. Such genotype–phenotype relations are much easier to study if the phenotype is determined by a well-defined laboratory experiment, rather than from *in vivo* phenotypes that depend on many factors, which can confound the analysis. Therefore, predicting the *in vitro* resistance phenotype from the genotype is currently the most common approach to automatic sequence interpretation.

3.1 Drug Resistance Data

Models for resistance phenotype prediction are learned from data that have been generated in the course of routine resistance testing. Sequences are obtained from clinical samples derived from patients failing antiretroviral therapy. For each sample, the isolated virus has been genotyped (its drug targets have been sequenced) and phenotyped (tested for its replication capacity in the presence of a drug). Genotypes are represented by vectors, one entry for each position in the multiple protein sequence alignment taking one out of 21 values that represent the 20 amino acids and the gap symbol. Typically, the full protease (99 amino acids) and the 5$'$ part of the RT (amino acid positions 250–335) are sequenced. Some prediction methods require the input space to be a Euclidean vector space. In this case, each possible mutation or amino-acid change at each position is represented by an indicator variable.

Phenotypes are reported in terms of the RF, which is a single real-valued number. Coefficients of variation between 10 and 60% have been reported for this quantity [107]. On the other hand, the determination of genotypes by standard cycle sequencing is highly reproducible, but the common population sequencing strategy detects only those variants that are present in at least 15–20% of viruses in the population.

Predicting the resistance phenotype from the genotype means solving, for each drug, a regression problem. Predictors are the sequence positions of the drug target, and response is the resistance factor. Alternatively, we may consider the related binary classification problem induced by choosing a drug-specific cutoff to define a *susceptible* and a *resistant* class of viruses. Similarly multi-class classification problems arise by defining intermediate levels of resistance. Several statistical and machine learning methods have been applied to this high-dimensional, noisy data.

3.2 Methods of Phenotype Prediction

The VirtualPhenotype® (Virco, Mechelen, Belgium) is a quantitative phenotype prediction method based on a pattern search in a database of genotype–phenotype pairs [59]. From a query sequence, all mutations for a predefined set of sequence positions are extracted and all phenotypes in the database matching this pattern are retrieved. The predicted phenotype is the average resistance factor of these matches. Thus, this approach can be regarded as a nearest-neighbor method, where similarity is coached in terms of sharing a predefined set of mutations. The regression problem has also been approached by linear stepwise regression [110] and by artificial neural networks [32, 108]. For example, Wang and Larder [108] use a one-hidden layer neural network to predict resistance to lopinavir from a selection of protease sequence positions. Support vector machines (SVMs) have been applied in the regression and classification setting to all drugs [3, 11]. Since the SVM learning strategy is particularly well suited for high-dimensional data, this approach does not require the selection of a subset of mutations. The performance of linear SVMs was not improved significantly by the use of standard nonlinear kernels.

Other methods are advantageous if the goal is not only to maximize predictive power, but also to derive insight about the genotype–phenotype relation from the learned model. For example, decision tree (or recursive partitioning) methods yield models that are directly interpretable by human experts [10, 90]. Decision trees can elucidate the effect of mutational patterns on the resistance phenotype. For example, analysis of 450 genotype–phenotype pairs revealed concise models incorporating only four to seven sequence positions. Moreover, decision trees can model the effect of a mutation in the context of other mutations. In particular, some decision trees display resensitization or hypersusceptibility effects. For example, zidovudine resistance induced by mutation T215Y in the RT may be reverted by mutations L74V/I and M184I/V. The latter substitution can also resensitize tenofovir-resistant strains [112]. Likewise, the mutation N88S in the protease gene has been found to increase the susceptibility to amprenavir.

Other methods are more concerned with the statistical modeling of genotype–phenotype relations that yields procedures for hypothesis testing. Foulkes and DeGruttola [38] use cluster analysis to identify groups of similar genotypes and to define superclusters of phenotypically similar genotype groups. They introduce a statistical framework that allows for the calculation of the probability that a sequence from one supercluster is more resistant to a certain drug than a sequence from another supercluster. DiRienzo and coworkers [29] build prediction models in a forward-stepwise manner. This approach can identify specific mutational patterns that are most influential in predicting phenotype. Combinations of codons are tested for significant concordant or discordant associations with the occurrence of a mutation. Both statistical approaches have been applied to the PI indinavir.

Finally, several clinical and virologic research groups have set up scoring systems for relating sequence variations to drug resistance or the likelihood of therapy failure [80, 85, 91, 104, 106]. Based on lists of mutations that have been linked to drug resistance (Section 2) these authors provide hand-made classifiers. Prediction models are encoded as sets of rules that have been derived from the scientific literature and personal experience. These systems predict resistance to a drug in terms of one of two to five levels ranging from *susceptible* to *resistant*.

3.3 Comparisons

The performance of classifiers is usually assessed in terms of their accuracy, i.e. by the percentage of correctly classified cases in a test set. However, accuracy provides only a very limited picture of the characteristics of the trained classification model. For example, scoring classifiers are more appropriately analyzed by means of receiver operating characteristic (ROC) curves [92]. Figure 3 displays four different measures of interest for a linear SVM model that has been trained on 650 protease sequences in order to separate samples resistant to saquinavir from those susceptible to saquinavir. Figure 3(a) shows density estimates of the predicted scores for the resistant and the susceptible subgroups of viruses. Although the two classes are fairly well separated, there is some overlap. In choosing a cutoff for the prediction of resistance and susceptibility, respectively, the accuracy of the classifier will vary as shown in Figure 3(b). This dependency can be analyzed in more detail by plotting

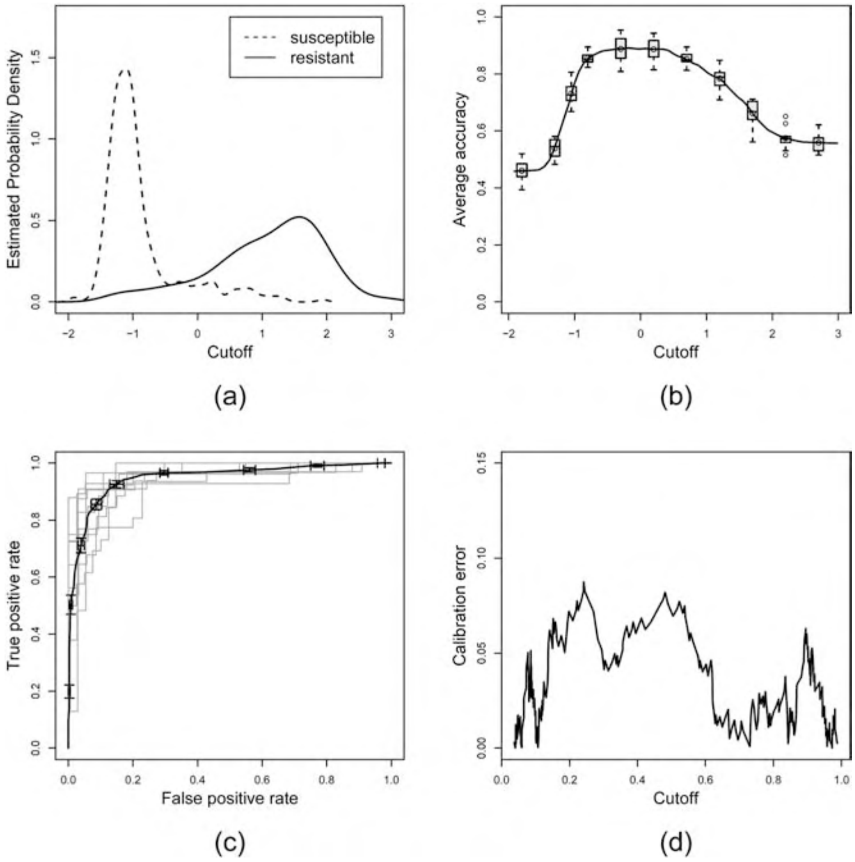

Figure 3 Performance measures for a scoring classifier that separates viruses resistant to saquinavir from those susceptible to saquinavir: density estimates of the predicted scores for the two classes (a), accuracy as a function of the cutoff used for prediction (b), ROC curve (c) and calibration error of predicting class membership probability as a function of the cutoff (d).

the false positive rate against the true positive rate. The resulting ROC curve is displayed in Figure 3(c). Finally, a scoring classifier (a method that classifies samples based on a score by choosing a cutoff) can also be used to estimate the confidence of predictions. It is important to assess whether these estimates are well calibrated. The percentage of resistance predictions at a certain confidence level should be close to that level of confidence. For example, if 80% confidence is estimated for resistance predictions at a certain cutoff, then a well-calibrated classifier would, at this cutoff, assign about 80% of the samples to the resistant class. Figure 3(d) shows the classifier’s performance in calibrating the confidence estimates [93].

Depending on the concrete application scenario, a low false-positive rate or low false-negative rate may be more desirable than minimizing the overall accuracy. For example, for heavily pretreated patients, it can be very difficult to identify active drugs for a new regimen. In this situation, a high sensitivity in detecting potentially active drugs may be required. On the other hand, for untreated patients one may want to take a more conservative approach and exclude all inactive drugs from the initial therapy with very high probability. ROC curves and related performance measures can help identifying such classifiers.

4 Development of Resistance-associated Mutations

The evolution of HIV has received considerable attention over the past 15 years not only because of its relevance for treating HIV-infected patients, but also because HIV provides an excellent model system for testing evolutionary theories. The general interest in the population genetics of HIV stems from its extraordinary evolutionary dynamics, which permit the observation of effects that occur on timescales several orders of magnitude larger in cellular organisms.

4.1 Viral Evolution

The intra-patient virus population is characterized by high rates of mutation and turnover together with high virus titers. In this situation the large majority of virions and productively infected cells turn over every day. Erroneous reverse transcription introduces substantial diversity into the population. It is estimated that any single RNA genome copied from a template molecule contains an average of 0.1–1 mutation relative to the template. The census population size (the actual number of viruses) within an untreated patient can reach 10^7–10^8 infected cells. However, the effective population size (the number of viruses in an idealized population that would show the same amount of genetic variation under random genetic drift) has been estimated to be much smaller, namely between 10^3 and 5×10^5 cells per host [16, 86]. This quantity determines the dominating mode of evolution as follows. A large effective population size implies deterministic evolution driven by mutation and selection, whereas a small effective population size implicates stochastic evolution driven by random genetic drift. The randomness in small populations is due to the finite sampling effects that arise in choosing individuals for reproduction. In very large populations even small fitness differences are recognized and the outcome of the evolutionary process is predictable. There is support for both evolutionary regimes, even in the special case of evolution under drug therapy.

Multi-nucleoside resistance, i.e. resistance to multiple NRTIs, can develop along different evolutionary pathways. This fact has been interpreted as evidence for stochastic evolution. For example, viruses in patients treated with zidovudine and didanosine follow one of two mutually exclusive pathways, apparently by chance [17]. Similarly, resistance to the PI indinavir develops by the accumulation of four to seven of approximately 12 different mutations. However, almost no two isolates from treated patients have been shown to contain the same combination of mutations. Likewise, resistance to ritonavir was observed to develop uniquely in each of five patients treated with that drug suggesting stochastic evolution of resistance patterns [74].

Apparent deterministic evolution can also be observed during the development of drug resistance. For example, single-nucleotide changes produce the mutations M184V and K103N that confer a high level of resistance to the NRTI lamivudine and the NNRTI nevirapine, respectively. These mutants are selected in over 90% of patients after a few weeks or even days of monotherapy. Convergent evolution has also been observed in protease sequences isolated from patients that were under multiple drug therapies for at least 2 years. Out of five intra-patient virus populations that had escaped selective drug pressure, identical amino acid replacements were observed in all five patients at two different sites [23].

Despite these cases in favor of deterministic evolution, selection appears to be detected less frequently than one would expect from HIV facing strong immune responses and antiviral therapy. This may indicate a more prominent role of genetic drift, but it might also be a limitation of the methodology to detect selection. The most popular test for detecting selection compares, for each site under consideration, the number synonymous mutations to the number of nonsynonymous mutations. In practice, the test can suffer from averaging the test statistic over a sequence region thereby limiting its power if selective pressure acts only on a few sites [100]. Alternative tests are based on the coalescent (a modeling framework in which two viral lineages converge in a common ancestral sequence, going backwards in time) [101] or on a Bayesian approach to sequence evolution [73].

In addition to classical phylogenetic and population genetics methods, rapidly evolving RNA populations have also been modeled as molecular quasispecies. This concept has been developed by Eigen and coworkers [34, 35] in order to describe populations of self-replicating RNA molecules as an ensemble of closely related genomes. The mutant spectrum depends on individual replication rates and hence reflects the surrounding fitness landscape. Since selection operates on this mutant cloud rather than on an individual strain, evolution is biased by the internal structure of the quasispecies. In particular, selection may favor clouds of genotypes interconnected by mutation over isolated genotypes, even if the average fitness of the cluster is lower than that of the individual. The suitability of quasispecies models for real RNA virus populations is subject to current debate [30,34,48,49,111].

Apart from random genetic drift, mutation and selection, there are additional factors that have a significant impact on evolving virus populations. For example, migration occurs within hosts via infection of multiple cells, tissues and organs. Migration also occurs between hosts as viruses spread into different human subpopulations and geographic regions. Migration results in complex spatial patterns and implies the necessity of studying structured populations [45]. Another important factor is homologous recombination, which can occur when a cell is coinfected with two different strains [53]. In HIV-1, recombination has been shown to occur approximately two to three times per genome per replication cycle. This is about 10 times as much as the mutation rate and an extremely high rate of recombination given the small genome size [52]. Recombination often biases parameter estimates of evolutionary models, but explicit modeling of recombination is notoriously difficult. Likewise, the role of recombination in the development of drug resistance is not well understood [15].

4.2 Learning Mutational Pathways

In the context of HIV drug resistance we are particularly concerned with the determinants and mode of the development of genetic changes that confer phenotypic resistance. If drug pressure is continuous and uniform, viral evolution is characterized by the accumulation of resistance-associated mutations. This accumulation occurs in a nonuniform, stochastic fashion and gives rise to coexisting evolutionary pathways. Understanding this evolutionary process is important for estimating how close a virus is to escaping from drug pressure. Mutagenetic trees, a family of probabilistic graphical models, have been developed for estimating the rate and order of occurrence of resistance-associated mutations in the viral drug targets.

Consider a set of n specific amino-acid changes (mutations) that develop under drug treatment. A mutagenetic tree for these n mutations is a connected branching on $\{0, \dots, n\}$ rooted at 0. Each vertex $v \neq 0$ represents the binary random variable X_v that indicates the occurrence of mutation v. Associating probability parameters θ_v with the tree edges one obtains a directed acyclic graphical model with transition matrices:

$$\Big(\Pr(X_v = b | X_{\mathrm{pa}(v)} = a)\Big)_{a,b=0,1} = \begin{pmatrix} 1 & 0 \\ 1-\theta_v & \theta_v \end{pmatrix},$$

where $\mathrm{pa}(v)$ denotes the parent of v in the tree. The first row of this matrix reflects the model assumptions that in the underlying evolutionary process mutations are nonreversible and that a mutation can occur only if all of its ancestor mutations have already occurred. By definition, mutagenetic trees are stochastic models, but parameter values θ_v close to 0 or 1 result in near deterministic behavior.

A mutagenetic tree defines a probability distribution on the set of all possible mutational patterns. In particular, this model family includes linear-path models (chains) and the model of complete independence given by the star topology. The complete family of mutagenetic tree models can be characterized by their algebraic invariants [6]. The key observation is that the binary state vectors that are compatible with the model, i.e. the mutational patterns which have positive probabilities, form a finite distributive lattice. This combinatorial structure allows for a simple enumeration scheme of (a basis of) all invariants.

Mutagenetic trees can be reconstructed from data as maximum-weight branchings of the complete graph on $n + 1$ vertices. This combinatorial optimization problem can be solved efficiently by Edmonds' maximum-weight branching algorithm. The weight functional used in this algorithm involves only pairwise probabilities, which can be estimated from cross-sectional data. This method has been shown to be consistent in the sense that if the data comes from a mutagenetic tree model, the procedure is guaranteed to recover the true tree [27].

The single-tree model has been extended to mixture models of mutagenetic trees that combine several weighted trees [8]. The first tree component is a star with uniform probabilities that models the spontaneous and independent occurrence of mutations. All other components represent dependencies between mutations and are estimated from the data. The mixture model is learned by an expectation maximization (EM) algorithm that iteratively estimates the expected values of the missing data (i.e. the association of samples to the trees) and the structure and parameters of the trees. For model selection (choosing the number of tree components) either cross-validation or a modified Bayesian Information Criterion can be used that is based on an estimate of the structural redundancy between tree components [113]. Mtreemix, a software package for statistical inference with mutagenetic trees and mixtures of these, is available on the internet and described in [9].

4.3 Genetic Barrier

In order to estimate the rate of development of mutations, we assume independent Poisson processes for the occurrence of mutations with parameters λ_v. If the observed sampling time (i.e. the time on therapy) is also modeled

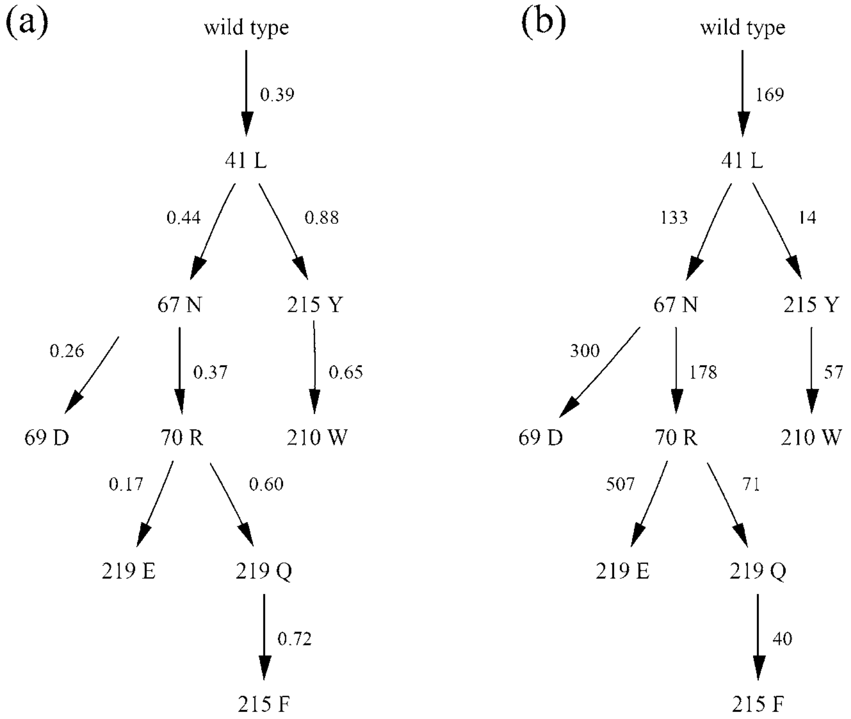

Figure 4 Mutagenetic tree for the development of resistance to zidovudine. Vertices denote amino acid changes from the wild-type; edges are labeled with conditional probabilities (a) and expected waiting times in weeks (b), respectively.

exponentially with rate λ_S, then:

$$\theta_v = \frac{\lambda_v}{\lambda_v + \lambda_S} .$$

This relation allows for the translation of the estimated conditional probabilities between mutations into the expected waiting time for the mutation to occur. Furthermore, the probabilities of the occurrence of any mutational pattern can be computed for any fixed mean waiting time. Hence, using these timed mutagenetic trees we can compare models that have initially been estimated from data sets sampled after different mean waiting times [4]. Figure 4 shows a mutagenetic tree and the corresponding timed mutagenetic tree for the development of drug resistance in the HIV RT under therapy with zidovudine. The model displays two characteristic pathways, namely the 70-219 and the 215-41 pathway [14].

The genetic barrier summarizes how difficult it is for a virus population to escape from drug pressure by developing mutations. This quantity can be estimated by means of mutagenetic trees and the phenotype predictions introduced in Section 3 [4]. Suppose we have estimated a mutagenetic tree model for the development of resistance to a certain drug. In particular, this model can be used to compute transition probabilities between mutational patterns. Using a classifier restricted to the set of n mutations we predict each mutational pattern to be either *susceptible* or *resistant*. The genetic barrier is defined as the probability of not reaching any resistant state after a fixed time period under therapy. This quantity can be calculated as the sum of the probabilities of all mutational patterns predicted as susceptible. Thus, a higher genetic barrier indicates that the virus is less likely to become resistant. In fact, a low genetic barrier has been proposed as the cause of the early virological failure, which has been observed with some combinations of otherwise very potent antiretroviral drugs [41].

For example, the genetic barrier to resistance to the nucleoside RT inhibitors zidovudine, lamivudine, and didanosine of the wild type virus has been computed under three different regimens: zidovudine mono-therapy (ZDV), double therapy with zidovudine plus lamivudine (ZDV + 3TC), and double therapy with zidovudine plus didanosine (ZDV + ddI). The genetic barriers to zidovudine resistance are ordered as ZDV + 3TC $>$ ZDV $>$ ZDV + ddI for the respective regimens. For lamivudine resistance we find ZDV $>$ ZDV + ddI $\gg$ ZDV + 3TC, and for low level didanosine resistance ZDV $>$ ZDV + ddI $>$ ZDV + 3TC. Thus, unexpectedly, zidovudine resistance appears to develop faster upon adding didanosine and a combination containing didanosine maintains a higher genetic barrier to didanosine resistance than a regimen sparing didanosine. These findings have been shown to be consistent with and to partly explain clinical data from a multi-cohort study assessing the risk of virological failure under these regimens [4, 22].

4.4 Transitions between Sequence Clusters

Foulkes and DeGruttola [39] have modeled the evolution of drug resistance as transitions between discrete states that are defined as clusters of sequences with similar patterns of mutations, rather than individual mutational patterns as used in the mutagenetic tree models. K-means clustering was applied to identify these states. A Markov model was used to estimate transition rates between states. One approach treats the state at a given time point as known, whereas another approach treats this as a latent variable. The second approach allows for consideration of the effect of minority species on the evolution of the viral populations. Both methods have been applied to protease sequences of HIVs cloned from the plasma of 170 patients who participated in a clinical study of efavirenz combination therapy. Multiple viral clones were available from each plasma sample at each measurement time point. In general, sequences of state membership that involved staying in the same state over time had the highest *a posteriori* probabilities.

NNRTI mutation data from the same clinical study was analyzed with an extended mutagenetic tree model that accounts for longitudinal and clonal samples [5]. In this mutagenetic tree hidden Markov model (HMM), progression of the virus population in time is modeled as a sequence of unobservable states, which are inferred from observed clonal samples. The hidden states, which are compatible with the given tree topology, represent the state of the population. Clonal variation is modeled by a simple error process that allows for false positives and false negatives, i.e. for observed mutations despite a wild-type population state and for wild-type residues in the presence of a mutant population state, respectively. Analysis of the NNRTI data has shown that the rates of occurrence of mutations, λ_v, can be estimated much more precisely from longitudinal than from cross-sectional data.

5 Selecting Optimal Combination Therapies

Even in the era of HAART, treatment failure is not uncommon and clinicians are frequently faced with the problem of selecting a new potent drug combination after failure of the current regimen. Preexisting drug resistance mutations can be the cause of therapy failure. In any case, viral replication under suboptimal therapy leads to the emergence of drug resistant variants (Section 2). The accumulation of resistance-associated mutations limits remaining treatment options which are available. Moreover, because of broad cross-resistance within drug classes, treatment changes cannot be based on the assumption that the virus will remain susceptible to the unused drugs. Even for therapy-naive patients not all drugs can be assumed to be active because of increasing rates of transmission of resistant viruses. The viral genotype may provide more information on the expected outcome of the new regimen than the past treatment history alone. In the following we discuss genotype-based methods for the selection of drug combinations that are estimated to maximize clinical response.

The computational task of identifying optimal antiretroviral drug combinations with respect to a given viral genotype is a typical bioinformatics problem (such as sequence alignment) in the sense that the objective function of the optimization problem is not known. In fact, we need to know the *in vivo* effect of any drug combination on any mutational pattern in order to find the best regimen. Typical clinical parameters of interest are the virus load and the number of T4 cells (Section 2). Estimating these response functions is much more challenging than actually selecting the optimal drug therapy. Indeed, the number of drug combinations is only on the order of thousands, and hence they can be enumerated. By contrast, HIV's high genetic diversity induces a much higher number of mutational patterns. Furthermore, clinical response is influenced by several factors in addition to resistance, including patient adherence, immunological status, and baseline virus load.

5.1 Clinical Databases

One way to estimate the activity of a therapeutic regimen against a viral strain is to learn this effect from observational clinical databases. This is straightforward, if we fix a combination therapy or a narrowly defined type of therapy. In this case, the same machine learning methods presented in Section 3 can be used to predict virological response. For example, King and coworkers [57] use decision trees in order to predict response to lopinavir–ritonavir-based regimens. However, if the drug combination is not fixed, direct learning from observed cohort data is limited by the amount of data necessary to derive useful models, because here the complexity of the problem depends on both mutational patterns and drug combinations. For example, Wang and coworkers use a neural network model in this situation. They estimate an approximate required database size of more than 9500 patient samples to predict virological response, if 12 drugs and 49 mutations are assumed [28, 109].

Furthermore, the distribution of drug combinations in clinical databases is heavily skewed. It reflects drug approval times and preferred treatment strategies over time rather than the full variety of potential combination therapies [2]. Thus, training on such data sets is likely to result in models that capture the features of only a few frequently observed combinations. Therefore, those datasets are not appropriate for exploring the product space of all mutational patterns and drug combinations.

5.2 Simple Scoring Functions

An alternative approach to general response prediction is to score drug combinations on the basis of single-drug effects. This implies the assumption of a model of how the effect of a drug combination depends on the single-drug effects. For example, we may use a classifier for resistance phenotype prediction and count the number of *active* drugs in a combination, i.e. the number of drugs for which the virus is predicted susceptible. This model has been used in a retrospective analysis of 332 therapy changes accompanied by genotypic resistance tests [24]. SVM-based phenotype predictions were used to define one group of patients with two or fewer active drugs and a second group of patients with three or more active drugs. Using a Cox proportional hazards model it was demonstrated that patients in the group with at most two active drugs were at significantly higher risk of virological failure (defined as two consecutive virus load measurements of more than 500 copies mL^{-1} after 24 weeks of therapy) [2].

Counting the number of active drugs in a combination therapy entails two problems. First, we have to choose a cutoff value for each drug. Second, we do not account for intermediate levels of resistance. The inherent difficulty in selecting appropriate cutoffs and the apparent loss of information can be avoided by considering the real-valued fold-change in susceptibility. However, the dynamic range of resistance factors varies by as much as two orders of magnitude between different drugs. Thus, resistance factors and their predictions are not comparable between different antiviral agents.

In order to overcome this limitation different normalizations have been proposed. In one approach, the degree of resistance is quantified relative to the biological variation of fold-change values observed among untreated patients. This distribution is normal with individual parameters for each drug. Hence, the *z*-score of a resistance factor is the number of standard deviations it differs from the mean in therapy-naive patients. Another normalization is based on phenotype predictions from genotypes obtained from both untreated and treated patients. The resulting distributions exhibit large differences in location and deviation of modes for the different drugs, but also reveal a common bimodality. Thus, we model this density by a Gaussian mixture model:

$$\lambda \times N(\mu_1 \sigma_1) + (1 - \lambda) \times N(\mu_2, \sigma_2)\,, \quad \lambda \in [0, 1]\,,$$

and estimate its parameters by the EM algorithm. This two-state model provides a data-derived definition of *susceptible* and *resistant*. By linearizing the log-likelihood ratio between these two classes, we obtain the *activity score*, which approximates the conditional probability of membership in the susceptible class given the viral genotype [7]. Thus, the activity score provides a normalized and comparable measure of resistance and it can be extended to multi-drug therapies by summing over all drugs in the combination.

5.3 Look-ahead Techniques

The genetic barrier of the virus to resistance to each of the compounds of the regimen also provides a normalized score. The genetic barrier estimates the likelihood of viral escape rather than the current level of resistance. Summing these values provides an estimate of how easy it is for the virus to escape from the selective pressure of the combination therapy. As shown in Section 4.3, this *genetic barrier score* is generally different from the genetic barrier of the drug combination, but the genetic barrier cannot be obtained for all drug combinations as it needs to be estimated from many samples derived from patients under the same regimen.

Despite these simplifications, both the activity score and the genetic barrier score have been shown to be predictive of virological response [2, 12]. In particular, classifiers based on these scores can learn concepts that are specific for the combined effect of drug combination and mutational pattern. Thus, this approach is promising for identifying individually optimized drug combinations.

In a related approach the likelihood of the virus to escape from selective pressure of a drug combination is estimated more conservatively. Applying a heuristic greedy search, the mutational neighborhood of the viral strain under consideration is explored. Successively, point mutations are introduced, the activities of the regimen against the resulting *in silico* mutants are estimated, and those variants are kept that reduce the activity of the regimen most. This strategy can be implemented efficiently by organizing the mutated sequences in a data structure called a priority queue that orders the sequences by activity. If the activity is estimated by a linear model, the new activity for a one-point mutant can be obtained by a cheap update of the previous activity avoiding a full computation of the linear function for each visited mutant. The estimated "worst case" activities at each level of depth of the sequence space search were used as inputs to a linear model and yielded significant predictions of virological success (defined as a drop in viral load of at least 2 $\log_{10}$ copies mL^{-1} after 3 months of therapy) [7].

5.4 Rules-based Approaches

As mentioned in Section 3.2 several rule-based systems aim to predict clinical response from genotypes. Based on these rule sets two computational approaches have been developed. The CTSHIV (Customized Treatment Strategy for HIV) system is a rule-based expert system designed for finding optimal resistance-avoiding combination therapies [60]. The system operates on a set of resistance-inferring rules which are applied to a patient's viral strains and nearby mutants. Drug combinations are scored by identifying the most resistant mutant and the least-resisted drug for this mutant in the respective drug combination. Nearby mutants are generated by a backward-chaining search. The optimal solution is computed by a branch and bound algorithm.

Another approach applies fuzzy logic methods to a set of expert rules [25]. Rule weights are learned from observed clinical outcomes. The resulting system has been shown to have improved results over the set of rules alone.

6 Host Genetic Profiles and Viral Evolution

6.1 Immunobiological Background

Host genetic profiles play an important role in the course and outcome of viral diseases such as HIV-1. These genetic profiles have a significant impact on the susceptibility or resistance to infection, the rate of disease progression and therefore the clinical manifestations of the disease. However, the rapid rate of viral evolution allows the virus to adapt to specific host genetic profiles. The increased understanding of the interplay between the host and the virus has provided important insights into the large variation in responses to HIV-1 infection, where some patients are extremely resistant to even becoming infected and whereas others progress to AIDS in a very short time period.

6.1.1 HLA Genes

The human major histocompatibility complex (MHC) is called the HLA system and consists of a large gene region on the short arm of chromosome 6 which contains over 100 genes [50, 97]. These genes encode proteins which are essential for adaptive and innate immunity. Of central importance in the protection against pathogens are the HLA class I genes (particularly *HLA-A*, $-B$ and *-C*) and HLA class II genes (particularly *HLA-DR*, *-DQ* and *-DP*). Class I genes encode molecules that are expressed on all nucleated cells, at varying levels and bind endogenously derived antigens and present them to T8 cells (Figure 5), leading to a cytotoxic T cell response. Class II molecules are mainly expressed on antigen-presenting cells (APCs) such as B lymphocytes, macrophages and dendritic cells. Class II molecules bind peptides of extracellular origin and present them to T4 cells, resulting in cytokine production and T cell help in antibody production. Supporting the activities of these molecules are the class III complement proteins and the inflammatory cytokine genes, which are also located in the HLA region.

HLA class I and II genes are extremely polymorphic. As of January 2005, 1179 class I alleles and 725 class II alleles had been named and the growth in the total number of observed alleles is projected to continue for some time [82]. Additionally, *HLA-B* has been confirmed as the most polymorphic gene in the human genome [71]. Allelic variation occurs both within and between different ethnic groups (http://www.allelefrequencies.net). Linkage disequilibrium (see also Chapter 38), where the alleles at one HLA locus are not randomly distributed with respect to the alleles at another HLA locus, has been described between different loci in the HLA region [68]. Due to the high number of polymorphisms in the HLA genes, most individuals are likely to be heterozygous at the most polymorphic loci. The expression of HLA alleles

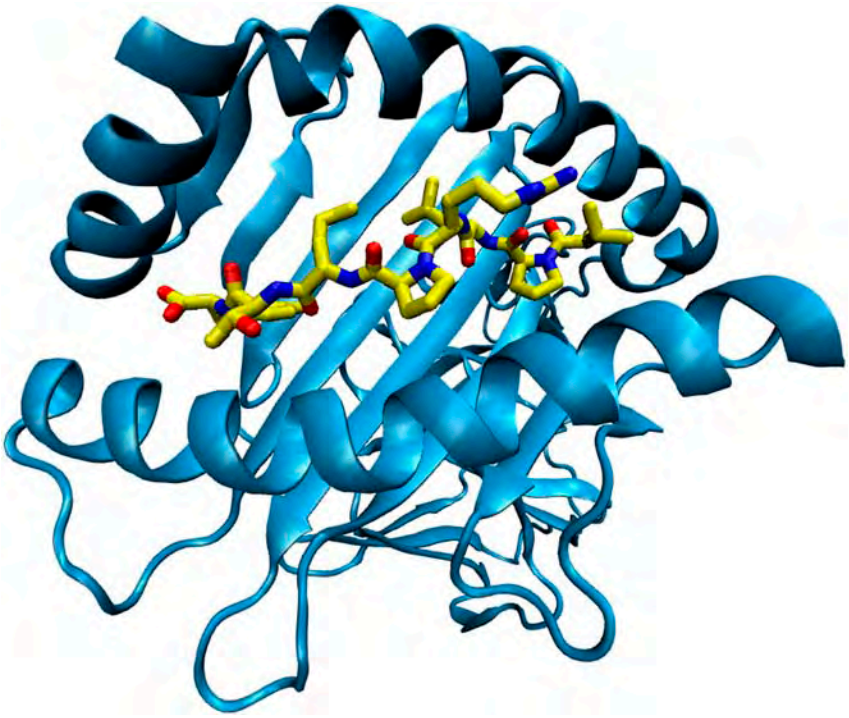

Figure 5 The crystal structure of the HLA-B*3501 allele complexed with peptide VPLRPMTY from the NEF protein (75–82) of HIV-1 [95]. The HLA molecule is shown as a blue ribbon diagram and the peptide is shown in yellow, with red oxygen atoms and blue nitrogen atoms.

is codominant, as both alleles of a locus are expressed on a cell's surface and each allele is able to present peptides to T cells.

Polymorphisms in HLA molecules are primarily concentrated among amino acids which are responsible for the binding of the foreign peptide. These amino acids are located on the floor or on the inner walls of the peptide-binding cleft. The polymorphisms cause the clefts to have different size and chemical characteristics in different allele variants. Therefore, although all HLA molecules can bind large and diverse sets of peptides, different HLA molecules have preferences in their binding affinities and specificities. Groups of *HLA-A*, -*B* and -*DR* alleles, called supertypes, have been identified which share specific binding preferences for peptides or supermotifs of a similar size, charge and amino acid composition [66,89].

Numerous studies have identified a role for HLA genotypes in HIV-1 progression and these will be discussed in detail below.

6.1.2 Chemokine Receptors

Many inflammatory and immunoregulatory cells are strongly influenced by the interaction between secreted chemokines and the chemokine receptors which are expressed on their cell surfaces. Particular attention has been focused on these receptors and their ligands because of their important role in general immunity and in the process by which HIV-1 penetrates into cells.

Two receptor–ligand families have been shown to have prominent roles in the HIV-1 infection process: the CCR and CXCR families. Two receptors which are members of the CCR family are CCR2 and CCR5. CCR5 binds the CC-motif ligands MIP-1α, LD78b (or CCL3L1), MIP-1β, RANTES, MCP-2 and HCC-1. A member of the CXCR family, CXCR4, binds SDF-1 which is encoded by the *CXCL12* gene [55].

Viruses that exclusively use the CCR5 coreceptor for cell entry are known as R5 strains and those that use CXCR4 are known as X4 strains. The binding to CCR5 typically predominates in initial infection. As the infection progresses, the virus begins to use CXCR4 instead of or in addition to CCR5. As CXCR4 is present on many more T4 cells than CCR5, this switch in coreceptor usage enables the virus to infect a far greater number of T4 cells and is associated with accelerated disease progression.

Genetic variations in the third variable loop (V3 loop) of the viral envelope protein gp120 have been associated with the switch in coreceptor usage from CCR5 to CXCR4. Machine learning methods similar to those described in Section 3.2 have been applied to predicting coreceptor usage from V3 sequence data [92]. Six statistical learning methods operating on the entire V3 loop were evaluated using cross-validation. Classifiers based on SVMs showed significantly higher area under the receiver operating characteristic curve (AUC) than other methods, with the exception of position-specific scoring matrices (PSSMs), for which the difference did not reach significance. At varying specificities, which were controlled by choosing appropriate cutoffs, SVMs dominated all other methods in terms of sensitivity. Predictions of coreceptor usage on a large longitudinal dataset agreed well with published data and showed smooth score trajectories, indicating applicability of scoring classifiers to monitoring the accumulation of coreceptor-associated sequence alterations. These models allow for careful monitoring of coreceptor usage, which is an important prerequisite for the use of coreceptor inhibitors.

Individuals who are homozygous for a 32-bp deletion in CCR5 (*CCR5-Δ32*) are almost completely protected from HIV-1 infection because of the inability of the virus to bind to the coreceptor. Rare exceptions occur when homozygotes are infected with X4 viruses that do not require CCR5 for penetration. Heterozygotes are as likely to be infected, but demonstrate a slower rate of disease progression. A number of polymorphisms in the CCR5 promoter in various ethnic groups have also been associated with increased likelihood of infection and more rapid disease progression.

In CCR2, a valine to isoleucine polymorphism (*CCR2-V64I*) has been associated with a favorable prognosis in heterozygous HIV-1-infected individuals, although the mechanism by which this occurs is still ambiguous. Studies into effects of the 3′A variant at position 801 in the untranslated region of the *CXCL12* gene which encodes SDF-1 (*SDF-1-3′A*) on HIV-1 disease progression have been less consistent. CCL3L1 is one of the ligands of CCR5. The copy number of the gene shows interindividual and interpopulation differences and influences the level of the chemokine. Possession by an individual of a copy number which was significantly lower than average for their respective racial or ethnic background has recently been associated with enhanced HIV and AIDS susceptibility [42].

6.2 Epitope Prediction

Epitopes are defined as the parts of antigens which interact with receptors of the immune system. In order to continue developing techniques which will help detect, monitor and fight diseases, it is important to know as much about the intrinsic structure of the relevant epitopes as possible. Due to the large number of epitopes and HLA molecules, prediction methods are an important tool supporting the generation of new insights into this complex process.

6.2.1 Problem Definition

Peptides which are presented by HLA class I molecules are selected in a multistep process consisting of (i) the cleavage of proteins in the cytosol into peptides by the proteosome, (ii) the N-terminal trimming in the cytosol or later in the endoplasmic reticulum (ER) by aminopeptidases, (iii) the transport of peptides into the ER by TAP proteins and (iv) the loading of the peptides onto class I molecules. These peptide–HLA complexes transit through the constitutive secretory pathway, in which transport vesicles move from the *trans*-Golgi network to the plasma membrane [83].

The peptides bound by class I molecules are generally 8–11 amino acids in length. Binding is stabilized by contacts between atoms in the free N- and C-termini of the peptide and conserved sites found at each end of the cleft in class I molecules. These interactions limit the length of the peptide accepted for binding and, therefore, the binding cleft is often described as being closed. Variations in length of the peptide seem to be accommodated by kinking of the peptide backbone.

By contrast, a number of different pathways have been describe by which HLA class II molecules become loaded with peptides. Typically, exogenous proteins are internalized by the cell or endogenous proteins resident in the endosomal system. Alternatively, antigens presumably excluded from the endosomal system, such as proteins located in the cytosol or nucleus, can be presented by class II molecules [103]. The conventional processing pathway features enzymatic unfolding, fragmentation and loading of internalized exogenous antigens within the endocytic compartment. An alternative pathway includes processing that is proteasome and TAP-dependent [102].

HLA class II molecules bind peptides that are more variable in length, approximately 11–17 amino acids long and possibly much longer. The ends of the peptide are not bound and the peptide lies in the binding groove in an extended conformation. It is held in position by its side chains, which protrude into pockets in the class II molecule's binding groove that are lined by polymorphic residues. Additionally, the peptide is stabilized by interactions between the peptide backbone and conserved amino acids of the binding groove. As HLA class II molecules are more permissive in their peptide binding than class I molecules, it is more difficult to predict which peptides will bind to particular class II molecules.

Recent research appears to suggest that there is a lack of absolute topological restrictions on HLA class I and II molecules, implying that, in principle, any protein can be presented by either molecule class. Therefore, the differences between class I and II could possibly be distinguished mainly on the basis of their binding characteristics and physiological roles [103].

6.2.2 **Methods**

The ability of predicting which regions of a target protein make good epitopes is important for the understanding of immunological processes and vaccine design. A broad variety of prediction tools have been developed in recent years, some of which deal with particular parts of the pathways, by which peptides are loaded onto HLA molecules, such as TAP transport, or alternatively with whole pathways.

Several methods have been developed for predicting proteasome cleavage. In a recent comparison it was found that the best method, NetChop, captures roughly 70% of the C-termini correctly [87]. NetChop uses neural networks trained on *in vitro* data in addition to class I ligand data.

Two approaches have been used to predict selective TAP transport. Cascaded SVMs, using two layers of SVMs, were designed to include features of the sequence and of amino acids [13]. Alternatively, a method was developed using an additive scoring function to analyze and extend the TAP-binding motif [31]. The method assumes that each amino acid makes an additive and constant contribution to the biological activity regardless of amino acid variation in the rest of the peptide. Possible interactions between amino acids are accounted for by cross-terms. This approach is also called two-dimensional quantitative structure–activity relationships (2D-QSARs) and it relies on solving the linear regression problem by using partial least squares (PLS). PLS forms new variables, named principal components, as linear combinations of the initial variables and then uses them as predictors of the dependent variable which is the TAP binding affinity.

Due to the closed nature of the binding cleft in HLA class I molecules and the well-defined epitope length, many more methods have been developed for predicting class I epitopes than class II epitopes. A comparison of some of the methods that have been used in class I epitope prediction has been made [114]. The compared methods were based on binding motifs, binding matrices, hidden Markov models (HMMs) and artificial neural networks (ANNs). The selection of the optimal method depended on the amount of available data, the biases of the data set and the intended purpose of the prediction. For datasets with more than 100 known binding peptides, HMMs and ANNs were found to be the methods of choice.

A relatively small number of prediction tools have recently been developed for class II epitope prediction. A method involving the use of motif block alignments, generated by aligning peptides known to bind specific class II molecules, were used to generate PSSMs to which a position-based weighting method was applied [79]. A novel Gibbs motif sampler method designed for recognizing weak sequence motifs has also been developed [72]. An earlier approach used a matrix-based prediction algorithm, employing an amino acid/position coefficient table deduced from the literature [94,99].

6.3 Analysis of Escape Mutations

Genetic resistance is an important aspect of the viral adaptation to the host. Its analysis is an important component of the study of HIV-1 disease. The HLA genotype of an individual appears to play an important role in the progression of the disease.

A number of large, population-based HLA class I association studies (see also Chapter 38) have been conducted [96]. The studies were done in large Caucasian and African cohorts with subtype B and C infections. They have associated *HLA-B*57* and alleles of the *HLA-B*58* supertype with low viremia and a delayed onset of AIDS. *HLA-B*27* has been consistently associated with slow progression in non-African populations. The alleles that are part of the *HLA-B*7* supertype, including *HLA-B*35*, have been associated with high viremia and fast progression.

When regions of HIV viral proteins are presented as peptides, or epitopes, by HLA molecules, an immune response may be triggered. Therefore, the less likely it is for a particular peptide to be presented by an HLA molecule, the lower the overall immune response of the patient against that particular peptide will be. In certain HLA genotypes, a mutation away from the HIV consensus sequence might be beneficial in promoting immune escape. The ability of the virus to mutate rapidly [77] enables it not only to develop resistance mutations to antiretroviral therapy, but also to adapt to the HLA genotype of the infected individual. This type of mutation is often called an escape mutation.

Once an escape mutation has occurred it has three potential evolutionary fates. It may revert to the consensus or wild-type amino acid on transmission to an individual of another HLA genotype. In this case, it will remain a target for the immune system. Alternatively, the escape mutation might be stable and the epitope that contains it will no longer be a target for the immune system. Such an escape mutation will reach fixation in a population over time as all other amino acid variants at that position are eliminated leaving only the escape mutation. The original epitope therefore also no longer exists and has become extinct. Finally, the escape mutation might not revert to consensus, but could still be contained in an epitope that is presented. In this case, the frequency of mutation will equilibrate in the population and there will be no clear consensus [62].

Several studies have examined escape mutations at a population level. An analysis of the RT gene in a large HLA-diverse cohort of Australian HIV-1-infected individuals revealed that HLA-specific polymorphisms were most evident in sites of least functional or structural constraint and were often associated with particular host HLA class I alleles. Both positive and negative HLA associations were found using standard statistical methods including a preliminary power calculation and odds ratio analyses, followed by the fitting of logistic regression models [69]. The majority of the strongest associations were confirmed in a cohort of HLA-diverse European patients using similar statistical methods [84]. In addition to this, six novel associations were identified. A study of the HIV-1 Gag polyprotein focused on two HLA alleles associated with long-term HIV control. Two escape mutations within a dominant HLA-B*57/HLA-B*5801-restricted epitope were present in about 80% of HLA-B*57/HLA-B*5801-positive individuals, but in no HLA-B*57/HLA-B*5801-negative individuals. Transmission of the mutant viruses into HLA-B*57/HLA-B*5801-negative recipients resulted in a reversion to the wild-type sequence of one of the escape mutations. The second mutation was maintained after transmission [63].

A recent analysis of the percentages of amino acid positions, at which polymorphisms away from population consensus were significantly associated with the HLA-A, -B and -C allelic groups, found that there is great variability across the HIV-1 genome. The use of McNemar tests showed that some genes have no statistically significant associations, whereas others have over 2% of their amino acids involved in significant associations [56]. Other work has shown that defined T8 cell epitopes tend to cluster in regions with distinct characteristics: conserved regions appear to have more epitopes, highly variable regions that lack epitopes bear cumulative evidence of past immune escape that may make them relatively refractive to T8 cells, and epitopes are more highly concentrated in alpha-helical regions of HIV-1 proteins [115].

A comparison of the relative contributions of HLA-A and -B alleles to the T8 cell-mediated immune response was performed using a large cohort of treatment-naive infected individuals from southern Africa. A panel of 410 overlapping synthetic peptides, spanning the entire expressed HIV genome, was generated and used to characterize the T cell responses to these peptides in interferon-α enzyme-linked immunospot (ELISPOT) assays [54]. There were marked differences in the frequency of targeting of individual peptides: some were targeted by no individuals, others where targeted by more than 25% of the cohort. Of the 30 most highly targeted peptides, 67% were HLA-B-restricted. The authors concluded that the principal focus of HIV-specific activity is at the HLA-B locus. The HLA-B gene frequencies in the population are those most likely to be most influenced by HIV disease, which is consistent with the observation that B alleles evolve more rapidly than A alleles [56]. The genetic epidemiological associations between HIV and HLA class II loci have not been as strong as those described for class I loci [18].

The observation of the influence of immune pressure on HIV-1 epitopes during HAART, showed that T8-mediated immune pressure can continue to effect viral evolution after the initiation of drug therapy [19]. Five treatment-naive patients, who achieved sizeable reductions in viral load upon initiation of HAART, were followed for 20 weeks. Each patient's response to 95 screening epitopes was evaluated prior to beginning HAART, with each of the five subjects responding to between one and three epitopes. The total number of optimized epitopes was ten and no epitope was located at a position where known resistance mutations occur. Two of the five patients displayed evidence of T8 cell-dependent antiviral pressure. In one patient, the epitope changed from an apparent escape variant prior to the initiation of therapy, to the sequence that is best recognized by the T8 response after the initiation of therapy and then to a new escape variant during continued therapy. In another study [37], a long-term-nonprogressing HLA-B*27 child managed to maintain viral loads of less than 400 copies mL^{-1} for almost a decade under a dual-nucleoside therapy until an escape mutation emerged with an immunodominant B*27-restricted CTL epitope. Subsequently, the child experienced a re-emergence of HIV-1 viremia accompanied by marked number of the CTL epitopes targeted.

Future treatment strategies for both treatment-naive and pretreated patients should not only involve the analysis of resistance mutations in order to help define treatment options, but to also take into account the influence of escape mutations since they can also play a causal role in the loss of immune control.

It may also be possible that the HLA-type of an individual has an impact on the choice of a particular mutational pathway, i.e. the sequence and type of resistance mutations a patient develops.

7 Conclusions

Computational methods for analyzing HIV drug resistance are likely to gain further importance in the future. The huge number of mutational patterns, on the one hand, and the large number of drug combinations, on the other hand, call for computational support in data management, analysis and clinical decision making. Moreover, therapeutic success appears to depend on viral genotype, therapy and host HLA type in a complicated manner that is unlikely to be captured by simple hand-made rules. Thus, the careful construction, validation and application of statistical models of therapy outcome may provide the basis for medical intervention planning. With an increasing number of drugs, optimization methods for finding optimal drug combinations will also play an increasingly important role. Hence, we expect sound statistical modeling and efficient optimization to be the key to individualized antiretroviral therapies in the future.

8 Web resources

8.1 Los Alamos HIV Databases (http://www.hiv.lanl.gov)

The Los Alamos National Laboratories maintain four different databases related to HIV infection [46]. The Sequence Database contains HIV and SIV sequences partly annotated with information on patient, sample, phenotypes and experimental techniques. The Resistance Database is a compilation of all mutations in HIV genes known to confer resistance to anti-HIV drugs. The Immunology Database offers a comprehensive, annotated listing of defined HIV epitopes. Finally, the Vaccine Trials Database provides a complete overview of HIV and SIV vaccine trials and their outcomes.

8.2 Stanford HIV Drug Resistance Database (http://hivdb.stanford.edu)

The Stanford HIV Drug Resistance Database is a curated database of sequences coding for the molecular targets of anti-HIV therapy [81]. It includes drug susceptibility data and therapy histories where publicly available. The database has been designed for the study of evolutionary and drug-related variation in the genome of HIV. The public website comprises query forms and a tool for the interpretation of genotypic resistance tests, based on various sets of expert rules.

8.3 Geno2pheno (http://www.geno2pheno.org)

Geno2pheno is a web service that provides two types of phenotype predictions from HIV DNA sequences. Geno2pheno[resistance] predicts phenotypic drug resistance to all approved antiretroviral agents using different classification and regression methods. The output also comprises normalized resistance scores (see Section 6.2) [3]. Geno2pheno[coreceptor] operates on the V3 loop of the envelope protein gp120 and predicts which coreceptor the virus can use to enter target cells [92].

8.4 IMGT/HLA Databases (http://www.ebi.ac.uk/imgt/hla)

The IMGT/HLA database is the official database of the WHO Nomenclature Committee for Factors of the HLA System [82]. It acts as a central repository for HLA gene and allele sequences. It has also recently incorporated data collected for the dictionary of HLA alleles and their serological equivalents. The database provides the basic tools needed to retrieve allele information and to perform sequence alignments. The database continues to grow with approximately between 150 and 200 sequences being added annually.

Analyzing the Evolution of Infectious Bacteria

Dawn Field, Edward J. Feil, Gareth Wilson, and Paul Swift

Nothing makes sense except in the light of evolution.
T. Dobzhansky, 1973

1 Introduction

The sequencing of hundreds of genomes is providing new insights into the evolutionary processes that lead to the emergence and maintenance of traits related to virulence and pathogenicity. In this chapter, we discuss how bioinformatic approaches to genome analysis can be guided by evolutionary principles and complemented by phylogenetic studies of population and species. When combined, the fields of molecular evolution and bioinformatics provide a powerful set of conceptual, analytical and practical tools for mining information from genomic sequences. Likewise, pathogens are fascinating subjects for evolutionists because of the intense selective pressures associated with host–pathogen interactions. Those interested in mechanisms of pathogenesis, epidemiology, and the development of new antimicrobials and vaccines can often benefit from an understanding of the evolution of infectious bacteria.

Bioinformatics has its roots as much in molecular evolutionary theory as it does in statistics, mathematics and computing. This is because the theory of evolution provides a unifying principle with which to gain meaning from molecular data. Here, we provide an overview of how evolutionary theory helps us to better understand a biological phenomenon of pressing relevance – *pathogenesis*. We discuss the relevance of evolution to the study of infectious bacteria by reviewing key evolutionary concepts and some of the most commonly used methods and tools in molecular evolutionary biology. First, we give an overview of molecular evolutionary theory, review the number and nature of the genomes available from infectious bacteria, and provide a practical overview of relevant software and databases. We then address four areas in which an evolutionary perspective has profoundly impacted

ISBN: 978-3-527-31278-8

our understanding of infectious bacteria. These areas are the detection of the determinants of virulence, the determination of relationships between isolates, the ubiquity and importance of lateral gene transfer and its role in niche adaptation, and the evolution of adaptive traits as a direct result of coevolution with the host. Finally, we examine the future outlook for the burgeoning field of evolutionary pathogenomics.

1.1 Introduction to Molecular Evolutionary Theory

There are many opportunities for applying evolutionary theory directly to the bioinformatic analysis of genomes. For example, the assignment of function based on homology, perhaps the most widely used concept in bioinformatics, is based on molecular evolutionary theory. If gene A is homologous (related by evolutionary descent) to gene B, it is likely to have a similar function, since both genes evolved from a common ancestor. This process of characterizing novel sequences can also be extended to the inference of similar structural properties (homology modeling; see Chapter 10). While there are potential dangers associated with assigning function (or structure) purely on the basis of sequence similarity, the value of this approach should not be underestimated.

There are three main foci to molecular evolutionary studies: the origin of life, the evolutionary history of the subsequent expansion of life forms and the manner in which molecules evolve. Reconstructing the evolutionary history and the relationships between all extant bacteria falls into the field of phylogenetics and requires knowledge of how sequences evolve. It is beyond the scope of this chapter to review all the methods and tools currently employed in phylogenetic and population genetics studies. Rather, we cover some of the key methods and tools. For a comprehensive review of phylogenetics, the reader should refer to Chapter 4.

Molecular phylogenetic tree building has a long history and developed from methods based on morphology. Evolutionary relationships can be reconstructed using a variety of molecular methodologies that involve comparisons of 16S rDNA genes, complete proteomes, restriction length fragment patterns (RFLPs), housekeeping genes, repetitive sequences, single nucleotide polymorphisms (SNPs) and other polymorphisms (Table 1). The choice of method is determined by both the question to be addressed (i.e. epidemiological or evolutionary), as well as basic features of the bacteria in question. Currently, multilocus sequence typing (MLST) is of particular importance because of its reproducibility and the ease with which data can be compared between laboratories [17, 43]. This method is based on the DNA sequencing of six to eight housekeeping, or "core", genes. Such genes are preferred as phylogenetic markers because they are conserved across strains, have relatively uniform levels of genetic variability making it easier to pool information across loci and are under strong stabilizing selection such that the majority of polymorphisms detected are likely to have arisen as the result of neutral mutations. Each unique allele encountered in a species can be given a number thus allowing for the development of strain-specific "profiles". MLST data can be used to uniquely type each processed isolate, thus facilitating epidemiological studies and the characterization of clonal complexes [25].

There are three general principles currently employed in the development of methods for reconstructing phylogenetic trees. The first uses a distance matrix built from the differences between sequences or sets of loci to build a tree. The second uses the principle of parsimony, which assumes that the correct tree is the one that requires the smallest number of past mutation events. The third, maximum likelihood, uses an explicit model of sequence evolution to judge which tree is most likely (the tree with the largest log likelihood score) given a particular data set. Despite these differences, there is strong agreement that, regardless of method, high-quality data should always produce the same tree. With lower quality, or less phylogenetically informative, data, different methods can vary in their reliability.

Constructing a tree is only the first step in inferring evolutionary relationships. It is then useful to place some estimate of confidence on the tree (*bootstrapping*), test whether the tree meets certain assumptions of the Neutral Theory and whether it contains evidence of past recombination events. The Neutral Theory states that the majority of mutations are neutral and do not influence fitness [38]. The power of this theory comes from its ability to define "null models" based on how sequences evolve under neutral assumptions. Statistically significant deviations from the expectations associated with these null models can therefore be taken as evidence for potential "non-neutral" evolutionary forces.

The observation that neutral genetic variation accumulates at a relatively constant rate has led to the formulation of the molecular clock hypothesis. If the mutation rates of neutral characters (e.g. synonymous sites in coding regions) have been empirically determined and an independent date for the divergence of two lineages is available (in the case of eukaryotes this is usually based on fossil evidence), the molecular clock can be calibrated for a particular group of organisms. The assumption of a molecular clock allows the age of a last common ancestor to be calculated, and enables the dating of nodes within a phylogenetic tree and tests for non-neutral departures from expectations. At all times, it is important to bear in mind that all trees are hypotheses and should be treated as such.

Short-term evolutionary events occur within populations and the field of population genetics is closely allied to the field of molecular evolution. Many tools and approaches are shared across these two fields, but population ge-

Table 1 A variety of molecular markers can be used to explore the phylogenetic relationships, population structure and epidemiological patterns of infectious bacteria: overview of the molecular evolutionary studies that can be employed

Method name	Application	Reference	Conclusions of study
16S rDNA	identification of uncultured pathogenic bacteria by placing new 16S sequences into the bacterial tree	60	positive identification of the uncultured bacterial species, *T. whipplei*, that causes Whipple's disease
Comparison of whole proteomes	pairwise comparison of all predicted proteins in different species to reconstruct bacterial phylogenetic trees	58, 68	strong phylogenetic signal in resulting tree and concordance with 16S rDNA tree
Ribotyping	generation of a tree of more than 500 nontypeable *H. influenzae* to examine range of variation of potential vaccine epitopes	8	use of a phylogenic strategy for vaccine development is proposed and validated
MLST	generation of trees for housekeeping genes and examination of levels of congruence between trees to determine frequency of recombination	26	unexpectedly high levels of recombination in some species; variation in levels of recombination across species
Sequence surveys	generation of sufficient sequence data to date emergence of human pathogens and examine the nature and rate of recombination	24	last common ancestor of *H. pylori* existed 2500–11 000years ago and size of recombinant fragments is unusually small
Multilocus variable number tandem repeat analysis (MLVA)	multiplexed polymerase chain reaction analysis of repetitive regions for strain identification and epidemiological studies	37	human commerce has contributed to observed geographic dispersal of *B. anthracis*
SNPs, insertion deletions, tandem repeats	Sequencing of a second strain of *B. anthracis* to find polymorphic markers	59	rare polymorphic sites are present in this genetically monomorphic species which are suitable for tracking infectious disease outbreaks

netics, which is concerned with the changes in the frequency of alleles, is more mathematical in nature. The application of population-genetic theory in genomics is still in its early days, but this new frontier in genomics holds great promise for future discovery, especially as multiple strains from a single species are sequenced and "resequencing" of large quantities of DNA becomes possible using custom microarrays [81].

Evolutionary theory also provides a range of assumptions useful in mining biologically significant patterns from genome sequences. For example, it can be used to examine the magnitude and type of selection acting upon a gene. There are several tests for selection based on comparing the ratio of synonymous to nonsynonymous substitutions between sequences [50]. Recently, an exciting method was developed that purported to detect selection in a single genome sequence [56]. However, it appears that this method may be sensitive to underlying assumptions regarding mutational processes acting at the DNA level, thus re-emphasizing the power and importance of comparative approaches in molecular evolutionary studies [50]. Furthermore, a recent study comparing multiple genomes of several bacterial species or genera demonstrated that the proportion of nonsynonymous changes decreases over time, thus it is critical to place inferences of selection within a temporal (time-dependent) perspective [62].

1.2 The Quantity and Quality of Data Available

The genomic data currently available for the evolutionary analysis of infectious bacteria are vast and rapidly expanding. It is widely recognized that our genome collection is strongly biased toward the tiny fraction of total bacterial biodiversity that enters into relationships with human hosts and leads to disease. Of the first 220 bacterial isolates sequenced, 117 are capable of causing disease. We now have genome sequences for an array of medically important microbes including those with the potential to cause epidemics, serious outbreaks of disease on a local level, commensals (bacteria that occasionally cause disease) and opportunistic pathogens that cause disease only in compromised hosts. Access to genomic data has revolutionized our understanding of the fluid nature of bacterial genomes, emphasized the importance of the evolutionary perspective when interpreting results, and spawned the new and exciting field of phylogenomics [22].

As our taxonomic sampling of genomes becomes more representative of the biodiversity in nature, so the application of evolutionary principles to the analysis becomes more powerful. The second and fourth bacterial genomes were Mycoplasmas, and the sixth and 18th genomes were both *Helicobacter pylori* strains [7]. The potential scope for comparative genomic studies has exploded since that time. At the time of writing, of the 220 bacterial isolates sequenced, 132 are from species with a single sequenced representative, while the remaining 88 isolates come from 33 species. Among these 220, the best sampled species are all capable of causing disease. These include *Staphylococcus aureus* (6), *Streptococcus pyogenes* (5), *Chlamydophila pneumoniae*

(4), *Escherichia coli* (4) and *Bacillus anthracis* (4). There are also well-sampled groups like the Mollicutes [35] and Campylobacteria [23].

1.3 A Practical Overview of Online Resources

Combining evolutionary theory and bioinformatic approaches provides a powerful conceptual and practical toolkit for the study of infectious bacteria. Databases and software useful in the study of evolutionary pathogenomics are listed in Table 2. This list is far from exhaustive, but provides a starting point for exploring the genomes of infectious bacteria, allowing the user to examine levels of conservation between genomes, construct phylogenetic relationships between sequences, and detect the presence of virulence factors and horizontally transferred sequences.

Likewise, Table 3 lists some of the more widely used taxonomic and phylogenetic resources available. The true phylogeny of bacteria is still contentious, but there are two primary sources of taxonomic information, the printed Bergey's Manual and the electronic National Center for Biotechnology Information (NCBI) taxonomy. These formalized bacterial taxonomies are a classification which is not always a true reflection of phylogenetic relationships, but a best approximation given methods available in the past. Bergey's Manual is the most authoritative source for bacterial taxonomy. It offers what it terms a "taxonomic outline", which includes all named bacteria and is now largely based on phylogenetic information derived from molecular studies of 16S ribosomal RNA genes [53]. 16S rDNA genes are widely used to reconstruct phylogenetic relationships because ribosomal RNA genes are a universal feature of prokaryotic genomes. This outline can be downloaded as a .pdf file from the web and is found in the printed volumes of Bergey's Manual. In contrast, the NCBI Taxonomy provides an online, browsable taxonomy that contains bacteria for which there is at least one sequence in GenBank [77]. While not claiming to be an authoritative source of taxonomic information, this taxonomy is based on Bergey's Manual and the contribution of a wide range of experts. It is widely used in bioinformatics, in large part, because each taxonomic group is linked electronically to all associated data held at NCBI.

Another excellent source of information on the relationships between bacteria is the Ribosomal Database Project (RDP-II), which contains over 100 000 bacterial small-subunit rDNA gene sequences in aligned and annotated format [15]. Tools available at the RDP allow the user to browse a taxonomic (phylogenetic) hierarchy of isolates and select sequences for phylogenetic analysis or download. Alternatively, newly sequenced rDNA sequences can be uploaded into the RDP, to be aligned against existing data. There are now a variety of free (phylip, MEGA, splitstree) and commercial (PAUP,

Table 2 Databases and software resources for evolutionary pathogenomic studies

Comprehensive comparative genomic databases	
Comprehensive Microbial Resource (CMR) (http://www.tigr.org/tigr-scripts/CMR2/CMRHomePage.spl)	provides access to a wide range of information and analyses about all complete bacterial genomes
Virulogenome (http://www.vge.ac.uk/index.html)	access to complete and incomplete genomes, including Artemis applet and ACT comparisons
Databases of the genomes of infectious bacteria	
Molligen (http://cbi.labri.fr/outils/molligen)	web site dedicated to mollicute genomes which allows blast searching and whole genome alignment
Oral Pathogens database (http://www.oralgen.lanl.gov)	databases of bacterial oral pathogens
Pathema (http://www.tigr.org/pathema/index.shtml)	in-depth curated analysis of pathogen genomes
Pathogen Sequencing Unit (http://www.sanger.ac.uk/Projects/Pathogens)	sequenced genomes of organisms relevant to human and animal health with related tools
STDGen and the Oral Pathogens database (http://www.stdgen.lanl.gov)	databases of genomes responsible for sexually transmitted diseases
Multiple genome alignment tools	
A Genome Comparison Tool (ACT) (http://www.sanger.ac.uk/Software/ACT)	a DNA sequence comparison viewer
Mauve (http://gel.ahabs.wisc.edu/mauve)	multiple genome alignments in the presence of large-scale evolutionary events
Multi-LAGAN (http://lagan.stanford.edu/lagan_web/index.shtml)	one of several packages in the LAGAN tool set for multiple alignment of genomes
MultiPipMaker (http://pipmaker.bx.psu.edu/ pipmaker)	summarizes similarity between multiple sequences using percentage identity plots
Multiple Genome Aligner (MGA) (http://bibiserv.techfak.uni-bielefeld.de/mga)	computes multiple genome alignments for large, closely related DNA sequences
Phylogenomic databases	
PyPhy (http://www.cbs.dtu.dk/staff/thomas/pyphy)	large-scale reconstructions of phylogenetic relationships of complete microbial genomes
Phylogenomic Display of bacterial genes (Phydbac) (http://igs-server.cnrs-mrs.fr/phydbac)	web interactive tool that displays phylogenomic profiles of bacterial protein sequences

MacClade) software packages available for phylogenetic analysis of 16S and other sequences, and Joe Felsenstein's website provides a comprehensive list of these resources (Table 3). For more on software for phylogenetic analysis, see Chapter 4.

Increasingly, there are now tools for the analysis of MLST data [36, 70]. The MLST websites (http://www.pubmlst.org and http://www.mlst. net) are portals to these resources, and offer access to all data sets (e.g. profiles and allele sequences) and a customized computing platform that contains a range of prepackaged software for bioinformatic and phylogenetic research

Table 2 (continued)

Curated databases of virulence factors	
Virulence factor database (VFDB) (http://www.mgc.ac.cn/VFs)	curated information about the virulence factors of 16 of the best-characterized bacterial pathogens
Databases of horizontally transferred sequences	
BAE-Watch (http://www.pathogenomics.bc.ca/BAE-watch.html)	database of pathogen proteins with unusually high similarity to eukaryote proteins
GenomeAtlas (http://www.cbs.dtu.dk/services/GenomeAtlas)	genomic atlases with views of compositional biases useful in detecting regions of foreign DNA
IslandPath (http://www.pathogenomics.bc.ca/IslandPathExamples.html)	identification of horizontally transferred genes and genomics islands, including pathogenicity islands

An expanded number of resources can be found in the annual issues of *Nucleic Acids Research* dedicated to descriptions of databases (January) and web servers (http://July).

(BioLinux). There are already online MLST databases for a variety of infectious bacteria, including *Burkholderia pseudomallei* (and related species), *Campylobacter jejuni*, *Campylobacter coli*, *Enterococcus faecium*, *Haemophilus influenzae*, *H. pylori*, *Moraxella catarrhalis*, *Neisseria meningitidis*, *Streptococcus agalactiae*, *S. aureus*, *Salmonella enterica*, *Staphylococcus epidermidis*, *S. pneumonia* and *Streptococcus pyogenes.* Groups interested in generating MLST data for new species are encouraged to contact the researchers hosting these sites as most of the database components can be easily reused [12].

2 Identification and Study of Determinants of Virulence and Pathogenicity

Whole-genome sequencing reveals the entire genetic complement of an isolate, and, in the case of pathogens, may reveal key aspects about phenotypic traits associated with disease and the mechanisms by which they evolved. Evidence from genomic analysis is helping to address "big-picture" questions such as, "What makes a pathogen?", "Why does pathogenicity evolve?", "Can the ability to cause disease be lost over time?" and "Where do diseases originate and why do they appear?". A crucial step in this complex process of discovery is the use of genome sequences to identify classical virulence factors. This is largely done through homology, but can be complemented by a range of *in silico* approaches which attempt to find novel virulence factors using non-homology-based reasoning. This reasoning is primarily based on clues including evidence of surface exposure, high copy number, repetitive nature, high mutation rate or uniqueness to pathogens.

Table 3 An overview taxonomic and phylogenetic of resources for studying the evolution of infectious bacteria

Resource	Description
Taxonomy	
Bergey's Manual of Systematic Bacteriology (http://www.cme.msu.edu/bergeys)	"taxonomic outline", including all species, type strains and 16S rDNA sequence data
NCBI Taxonomy (http://www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html)	taxonomy for sequences in GenBank with links to related resources in NCBI databases
The Taxonomy Browser (http://www.msu.edu/%7Egarrity/taxoweb)	original data analysis tool for visualizing the taxonomic relationships among prokaryotes
16S ribosomal sequence phylogenies	
Ribosomal Database Project II (http://rdp.cme.msu.edu/html)	database of ribosomal sequences and related tools for sequence alignment and phylogenetic analysis
ARB (from Latin "arbor" meaning "tree") (http://www.arb-home.de/	community standard for managing 16S data sets and building phylogenetic trees
Sequence alignment software packages	
Clustal (http://www.ebi.ac.uk/clustalw)	web interface to widely used sequence alignment program
Tcoffee & 3Dcoffee (http://igs-server.cnrs-mrs.fr/Tcoffee/tcoffee_cgi/index.cgi)	web interface to software for alignment of sequences and structures
Phylogenetic software	
CVTree (Composition Vector Tree Method) (http://cvtree.cbi.pku.edu.cn:1977/cvtree/index.php)	uses similarities in word frequencies between proteomes to build phylogenetic trees
Horizstory and Lumbermill (http://coffee.biochem.dal.ca)	a pair of phylogenetic tools to compare multiple trees and detect lateral gene transfer events
Joe Felsenstein's web pages (http://evolution.genetics.washington.edu/phylip/software.html)	comprehensive collection of links to software for phylogenetic and population genetic analysis
MEGA (Molecular Evolutionary Genetics Analysis) (http://www.megasoftware.net)	estimates evolutionary distances, reconstructs phylogenetic trees and computes statistical quantities
MacClade (http://macclade.org)	facilitates studies of character evolution using phylogenetic trees
PAUP (Phylogenetic Analysis Using Parsimony) (http://paup.csit.fsu.edu)	the most widely used and comprehensive commercial phylogenetic software package
Phylip (Phylogeny Inference Package) (http://evolution.genetics.washington.edu/phylip.html)	widely distributed free phylogeny package which implements a variety of methods
SplitsTree (http://bibiserv.techfak.uni-bielefeld.de/splits)	test whether a data set creates a bifurcating tree, outputs relationships between sequences as networks
TreeView (http://taxonomy.zoology.gla.ac.uk/rod/treeview.html)	a program for viewing phylogenetic trees
MLST related resources	
Multilocus Sequence Typing (http://mlst.net)	MLST home page
PubMLST (http://pubmlst.org)	portal which provides access to MLST resources
START (Sequence Type Analysis and Recombinational Tests) (http://pubmlst.org/software/analysis/start)	software that performs strain-specific profiles, lineage assignment and tests for recombination/selection
eBURST (http://eburst.mlst.net)	clustering algorithm to examine patterns of descent within closely related strains

2.1 Homology-based Detection

The first aim of the sequencing of the genome of a pathogen is the identification of determinants of virulence. Determining what makes an isolate capable of causing disease is a complex process. The most direct method is to look for "classical" virulence factors. This is usually done by searching new genomes for genes with homology to known virulence factors. Approaches based on homology work because it is statistically improbable that two sequences showing a high degree of sequence similarity are not related through descent [3]. Hundreds of virulence factors belonging to known gene families have been found through this method since bacterial genome sequencing began, attesting to the power of this approach. Any new sequence can be compared against the virulence factor database (VFDB) a database of known virulence factors for 16 of the best characterized bacterial pathogens [13].

2.2 Pattern-based Detection

There are several methods of finding genes involved in virulence without recourse to known homologs. For example, knowledge of the statistical properties of DNA has proven a powerful method of detecting "foreign" DNA and this is useful because horizontally transferred sequences often include determinants of virulence. Foreign regions of DNA can be detected by their skewed G + C composition, third position G + C content, codon composition or other higher level patterns. These sequences range in size from short fragments to large regions with many genes known as pathogenicity islands. The evolutionary character and importance of pathogenicity islands has recently been reviewed [64].

The statistical properties and distributions of sequences in a genome can also be used to develop searches for specific types of sequences. For example, it is known that transmembrane regions contain more hydrophobic amino acids than would be expected by chance. Therefore, algorithms have been developed to find surface-exposed transmembrane proteins *de novo* based on this fact, e.g. in the development of vaccines [55]. (See also Chapter 9 on the topic of identifying transmembrane regions in proteins.) Other genes, like the large family of PE/PPE glycine-rich genes in *Mycobacterium tuberculosis* which make up about 10% of the genomic sequence, are unusual for their abundance and repetitive structure, suggesting *a priori* that they might play a role in the generation of antigenic variation [16]. These genes initially lacked homology to any known genes, but over time have been found in other *Mycobacterium* spp. and appear to be involved in virulence [42].

Another intriguing example of the detection of an unexpected (statistically unlikely) pattern is the discovery of sequences capable of acting as "molecular switches". Rapid, reversible genetic change (phenotypic variation or phase variation) is now known to be mediated by a number of different molecular mechanisms including slipped-strand mispairing, site-specific DNA rearrangement and DNA shuffling [30, 74]. These categories of mechanisms for genetic change represent a wide repertoire of potential mutations. Slipped-strand mispairing leads to small insertion–deletion events at short direct repeats, or microsatellites, while site-specific rearrangements are "triggered" by the presence of particular sequence motifs and DNA shuffling occurs when homologous section of DNA switch location or orientation within a genome. Such loci have been termed "contingency loci" [49] collectively. These "switches" are most often found in surface-exposed genes and genes that mediate key interactions with the host environment. They appear to have evolved both to provide genetic variation to evade host defenses and to facilitate rapid adaptation to different micro-niches within the host [4].

From a computational perspective, short direct repeats, or microsatellites, are the class of molecular switches that are most easily detected in new genome sequences. These loci, also known as simple sequence repeats (SSR), are composed of units of 1–6 bp. The high rate of slipped-strand mispairing at such loci results in the hypermutability of these sequences. Due to their ability to undergo rapid, reversible mutation they make highly efficient molecular switches [49] capable of altering the translation and transcription of genes, when found in coding regions or promoters, respectively. The discovery of a large number of such loci in the first sequenced bacterial genome, *H. influenzae* [33], has resulted in the search for such loci now being part of the routine analysis of novel pathogenic genomes. Chapter 8 gives a detailed account on methods for finding repeats in genome sequences.

The likelihood that novel SSRs are evolving in a nonrandom fashion can be evaluated by examining the total length (as longer loci are both more statistically improbable and more mutable [19]) as well as genetic context (i.e. the ability of an insertion or deletion event in an SSR to cause a frameshift within a known coding region or the location of an SSR in a promoter region) of each repeat. Candidate loci can be further evaluated through population-level surveys of variability in the "switch region" [46]. The best candidates can then be examined using empirical methods (such as knockout strains [33]) to explore their potential role in virulence and bacterial adaptation.

2.3 Comparative Genomic Methods of Detection

Good sampling of related genomes increases the power to detect differences and similarities between genomes. Given whole genomes, it is possible to search for genes shared between pathogens and nonpathogens, genes found only in pathogens, and genes that are never found in pathogens. This practice of “differential genome display” came into practice as soon as the complete genomes of pathogens and nonpathogens, i.e. *H. influenzae* and *E. coli*, became available [34]).

This approach works when pathogens share the genes responsible for a particular trait, but this is not always the case, as exemplified by the study of motility in Mycoplasmas. The Mycoplasmas are now one of the best phylogenetically represented groups of bacteria. They have minimal genome sizes, and yet display a variety of phenotypes, host preferences and degrees of pathogenicity. This group of bacteria is therefore ideal for comparative genomic studies in a phylogenetic framework. For example motility is a trait that has proven notoriously difficult to understand at the molecular level [35]. When a simple comparison between proteomes of motile and nonmotile Mycoplasmas failed to reveal candidate genes, the alternative was tested, i.e. that genes for motility were shared by motile and nonmotile species, but had been deactivated in nonmotile genomes [35]. Similarity searches revealed candidate genes that were better conserved among motile genomes than nonmotile genomes, suggesting relaxed selection acting on nonfunctional instances of these genes. Furthermore, the authors attempted to define a “required core set” of genes always found in full in motile genomes, but only ever found in part in nonmotile genomes. Both of these “filters” provided only circumstantial evidence of motility genes. Inspection of the 16S tree for the Mycoplasmas shows that motile and nonmotile species do not form two separate (monophyletic) evolutionary groups. The difficulties encountered in defining the genes responsible for motility may reflect the fact that motility has evolved independently more than once in Mycoplasmas [35]. A general overview of methods of comparative genomics is given in Chapter 37.

2.4 Taxonomically Restricted Genes (TRGs) and Orphans

TRGs are found in isolated lineages and it is therefore plausible that they are responsible for niche-specific traits, including those involved in virulence and pathogenicity. Among TRGs, “orphans” (predicted proteins that lack similarity to any known proteins) are of particular interest [78]. It has been claimed that the number of orphan genes discovered in complete genome sequences has been one of the biggest surprises of the genomic era so far [21]. Explanations for the large numbers of orphan genes in complete genomes include the suggestion that we have not sequenced enough genes from enough organisms to find other members of these gene families [73], that orphans may be noncoding sequences incorrectly annotated as predicted proteins [66] or that orphan genes belong to known gene families, but have not been identified as such owing to extensive sequence diversification [18]. An exciting frontier within the area of improved gene prediction is the use of transcriptomic and proteomic data to validate genomic annotations. For example, the first example of a "proteogenomic" approach to genome annotation found no evidence of expression of many smaller-than-average genes predicted using *in silico* methods alone, suggesting that many "orphans" do not encode real proteins [35]. Such empirical data is essential to correct errors of annotation and validate true orphans.

Despite the contribution of undersampling and error to the numbers of orphans found in public databases, the number of bacterial orphans appears to be increasing [78]. There is also mounting evidence that a proportion of orphans are real genes [18, 65]. For example, evidence of transcription was obtained in a study of 19 out of 25 proposed orphan genes in the *E. coli* K12 MG1655 [2]. An interesting possibility is that orphans are real genes captured by bacterial isolates through horizontal transfer from phage (and plasmids). This possibility is discussed further in Section 4.1 [18].

3 Putting Isolates of Infectious Bacteria into a Phylogenetic Framework

As described above, the use of phylogenetic and population genetic analysis can be used to address a wide range of questions concerning the biology and control of infectious bacteria (Table 1). Phylogenies can be used to "place" new isolates of pathogens, identified by their 16S sequences, onto the tree of life [60]. They can also be used to track the emergence of hypervirulent or antibiotic-resistant isolates [25], to explore the origins of pathogens and place dates on their emergence [24] or to test whether specific traits have evolved more than once [35]. Comprehensive phylogenies encompassing enough strains to adequately represent the genetic diversity of a named species can be used to guide a variety of subsequent studies. For example, to select a maximally divergent set of strains to test for evidence of recombination [26] or to examine the potential phylogenetic conservation of candidate epitopes for the development of vaccines [55, 79].

One of the most interesting conclusions about the nature of pathogens to be drawn from evolutionary studies is the fact that pathogenicity has evolved multiple times. Pathogens are often found next to nonpathogens on the bacterial tree and closely related isolates can differ greatly in their degree and nature of pathogenicity. For example the 16S sequence of *Yersinia pestis* and *Yersinia pseudotuberculosis* are identical [72], and the former appears to have evolved from the latter only 1500–20 000 years ago [1]. Despite their recent divergence, these species have very different potentials to cause disease. While *Y. pestis* is infamous for causing devastating disease (The

Plague), its close relative *Y. pseudotuberculosis* is rarely capable of causing disease or death.

It has become increasingly clear that different sections of bacterial genomes evolve at different rates. Studies must be designed in such a way that the rate of evolution of a chosen "marker" matches the question asked and provides the correct level of discrimination. For example, to resolve relationships between distantly related bacteria the 16S rDNA marker is preferable [53] because it is universally conserved. However, 16S sequences are often monomorphic among closely related strains and are therefore unsuitable for population-level studies. For isolates with complete genomes, it is now possible to construct trees based on complete proteome comparisons – an approach which removes the requirement for all isolated to share the same sequences. For example, trees can be built using the numbers of shared genes found in pairwise comparisons among proteomes [68] or on frequencies of amino acid motifs ("words") [58].

For examining the relationships between isolates within a species, more rapidly evolving loci are required. There are now a variety of methods available that assay genetic diversity capable of distinguishing closely related isolates. For example, ribotyping has been used to validate the utility of bacterial epitopes for use in vaccine development [8]. Ribotyping and similar methods that depend on the digestion of DNA by restriction enzymes are excellent for economically processing large numbers of strains from a single species, but have the drawback of generating "anonymous" banding patterns that lead to ambiguities in scoring the similarities and differences between strains. MLST, as mentioned above, is probably now the most widely applied method.

In some cases, though, MLST is unable to distinguish between isolates under examination, especially isolates from recently emerged pathogens. In the case of *Y. pestis*, for example, fragments of five housekeeping loci were examined and all were found to be monomorphic [1]. The three main biovars (strain types) of *Y. pestis* can be distinguished by assaying markers evolving more rapidly than housekeeping genes. These include restriction fragment length polymorphisms (RFLP) associated with the IS100 insertion element [1] and variable number tandem repeats (VNTRs) [57]. Such repeats are composed of direct repeats of 7–25 nucleotides which change in length with high frequency. The usefulness of these loci is increased by the typing of several loci simultaneously. This method was originally developed to distinguish strains of *Bacillus anthracis*, the most genetically monomorphic pathogen described to date, and is now referred to as multiple locus VNTR analysis (MLVA) [37]. MLVA can be used to rapidly type large numbers of isolates at low cost. More importantly, the resulting strain profiles can be compared between laboratories. Along with MLVA, SNPs and insertion/deletion polymorphisms have also been used to distinguish nearly identical strains [59].

Understanding the evolutionary relationships between strains has many important applications, but is challenging given that there is tremendous genetic variation among bacteria and bacterial species are notoriously ill-defined entities [41]. It is well-known that there can be significant differences both in the total quantity and composition of DNA between even very closely related isolates. The surprising degree of diversity, revealed through genome sequencing, even between different strains of the same bacterial species, implies that single genome sequences can no longer be viewed as defining the genetic repertoire of named taxa, but rather as a sample of the genes potentially available to members of a given (often ill-defined) population. For example, the analysis by Welch and coworkers [76] on three genome sequences of *E. coli* revealed that only about 40% of all identified open reading frames were common to all three strains. This finding has motivated the genome sequencing of multiple strains for a number of different named species, often in the hope that this will facilitate the discovery of the genetic basis of variable phenotypes of specific ecological or clinical relevance (such as heightened virulence or antibiotic resistance).

In order to examine the detailed dynamics of genome divergence at this fine-scale phylogenetic level, it is necessary to compare these genomes as thoroughly as possible within a phylogenetic or population biology framework. Now that we have the genomes of many pathogens, it is becoming easier to apply MLST approaches, but MLST studies can also be undertaken without the benefit of a genome (as was the case with the early MLST schemes) if enough suitable housekeeping genes, with uniform levels of variability, can be selected.

The case of *S. aureus*, a “species” for which seven complete genome sequences are now available, clearly demonstrates the importance of detailed information on evolutionary relationships when dealing with a set of isolates. MLST data has revealed *S. aureus* to be a highly clonal species, and the seven sequenced strains correspond to three pairs (each pair being very closely related and belonging to the same clone) and a single more diverged strain [32]. In the absence of the MLST data and without a complete appreciation of the genetic diversity in this species, it might be reasonable to suppose that the more diverged strain is atypical in some way. The ability to place the sequenced strains in the context of the whole population reveals that they are not representative of the full diversity within the population.

Nevertheless, the genome data for *S. aureus* enable comparisons both at a very fine level (within a given clone) and at a relatively more diverged level, encompassing the variation of the named species. Comparisons of gene content between pairs of strains belonging to the same clone reveals that a significant fraction (about 2%) of the genome is lost or gained extremely rapidly. This results in marked clinical differences between strains which are essentially identical in terms of nucleotide sequence divergence. However, it appears that the rate of change in gene content decreases in proportion to sequence divergence when comparisons are made between strains clearly separated on the phylogenetic tree. This example illustrates how comparisons between genomes belonging to the same species are most powerful when used in conjunction with MLST and/or microarray data that can provide the "big picture" for the structure and diversity of a given population [32].

4 Mixing of Genetic Material among Bacteria

Bacteria were once thought to be clonal organisms that evolved without recourse to recombination of their genetic material with that of other individuals. In the case of truly clonal organisms, the reconstruction of evolutionary relationships using any molecule will, in theory, reconstruct the same evolutionary tree. This will hold true for all loci at which sufficient "phylogenetically informative" polymorphisms are detectable and in the absence of both selection and convergent evolution. Recombination, or the exchange of DNA between independent lineages, can obscure the phylogenetic signal of individual lineages and lead to the reconstruction of trees which do not reflect the true relationships between isolates, but rather the individual evolutionary history of the recombinant molecules being scrutinized.

The last decade has revolutionized our view of the stability and clonality of bacteria through many lines of evidence and it is now clear that bacteria can acquire new pieces of DNA from a variety of sources. Until the advent of complete genome sequencing, the extent of horizontal transfer and the resulting "mosaic" nature of bacterial genomes was largely unappreciated. DNA acquired from the environment, or from infection with phage and plasmids, can result in significant changes in genetic repertoires in a way that can have a significant impact on a bacterium's success in a particular niche or even allow it to change its niche completely [51]. Such changes can result in the emergence of new pathogens or in heightened pathogenicity of existing pathogens. The single most important result of horizontal gene transfer is the global spread of antibiotic resistance.

Genes obtained through horizontal gene transfer can often be recognized by their atypical base composition, sporadic distribution within a given phylogeny or landmark features. For example, horizontally acquired sequences containing *H. influenzae* uptake signal sequences (USSs) have been found in *Neisseria meningitidis* [39]. Rates of horizontal transfer largely depend on niche (i.e. access to foreign DNA) and the presence of internal sequences that promote exchange. The small genomes of intracellular pathogens have few molecular mechanisms that promote exchange and contain little foreign DNA, while species with larger genomes might have gained up to 20% of their total gene content from external sources [51].

In addition to new genes or gene islands being acquired by horizontal gene transfer, thus launching the bacteria into a new, potentially pathogenic lifestyle, homologous recombination can also result in metabolic genes from any given strain being replaced by orthologs of a "donor" strain. MLST data, being based on ubiquitous "core" genes and often used on large isolate collections, are ideal for examining the extent to which this process occurs. By examining the sequence changes between very closely related isolates, it is possible to estimate the relative contributions of point mutations and homologous recombination [69]. This approach has been used to estimate that alleles change up to 10-fold more frequently by recombination than by point mutation in some species (e.g. *S. pneumoniae* and *N. meningitidis*) whereas in other species, such as *S. aureus*, point mutation appears to play a more major role than recombination [27, 28]. The reasons for these differences are unclear but are probably related to both the biology (e.g. efficiency of transformation) and ecology of the organism (e.g. the probability of diverse lineages meeting in the wild).

The extent of recombination can also be assayed from MLST data sets by comparing phylogenetic trees from a small representative sample of isolates. The logic behind this approach is that a history of frequent recombination will result in discordant trees when different gene loci are compared. A statistical approach based on the maximum likelihood method of phylogenetic reconstruction has been used to demonstrate that trees built from different gene loci for *S. pneumoniae* and *N. meningitidis* are typically no more similar to each other than they are to random trees [27, 28]. Thus, this approach is consistent with the method based on comparing very closely related isolates outlined above and indicates that recombination has been so frequent in this species that there is no consistent phylogenetic signal. It therefore makes little sense in such extreme cases to attempt to reconstruct the evolutionary relatedness between diverged strains, as these will be reticulate (network-like) rather than tree-like.

4.1 The Importance of Phage and Plasmids

The importance of plasmids and phage in bacterial evolution and adaptation has long been recognized, but it is continuing to come to the fore as evidence for the ubiquity of horizontal transfer accumulates. While phage are viruses and therefore pathogens (or "predators") of bacteria, it is more difficult to explain the persistence of plasmids [6] although it is clear that both provide important mechanisms for genetic exchange within bacteria. The gene pool potentially harbored within phage and plasmid populations is significant [44]. For example, the sequencing of 27 phage genomes from a single host, *S. aureus*, revealed a minimal overlap in gene content [40]. The discovery of such a high percentage of novel genes suggests further that phage store a vast reservoir of genetic diversity [40].

It is well recognized that prophages contribute significantly to observed inter-strain differences by donating, among other things, genes related to pathogenicity [9]. In a comparison of two *Salmonella typhi* strains, 113 predicted proteins were found to be unique to one strain. Seventy-six of these were prophage genes [20], illustrating the impact prophages have on the genetic individuality of bacterial strains. Similarly, in the species *Streptococcus pyogenes* all major sequence gaps found in the alignments of "M" serotypes are traceable to phage integration events [67]. Further, the prophages found in *S. pyogenes* encode proven or suspected virulence factors, and therefore the diversity observed between strains is likely to be of clinical relevance [5]. In a global study of 115 bacterial genomes, including pathogens and nonpathogens, 190 prophages were identified [10]. These prophages were predominantly found in pathogens. Several of them encoded disease-modifying factors found in species such as *Vibrio cholerae*, *E. coli* 0157 and *Corynebacterium diptheriae*. In some cases, including *S. aureus*, *S. pyogenes* and *Salmonella* spp., the genome contains multiple prophages, each of which contributes incrementally to virulence [10].

It has recently been suggested that phage contribute large numbers of orphan genes to bacteria [18]. It has been found that orphan genes have certain characteristics that differentiate them from other genes. Orphans are significantly shorter than native genes and are A + T-rich when contrasted with the rest of the genome [18]. These characteristics have led to the belief that phage may be responsible for the generation of bacterial orphans. Phage encode short A + T-rich genes [54]. The dinucleotide frequencies of *E. coli* orphans and of phage known to infect *E. coli* were found to be similarly biased in contrast with native genes [18]. In addition the genetic diversity of phage has been poorly sampled. Hence, if orphan genes did originate from phage it should not come as a great surprise that, as yet, we have not found homologs [18].

A classic example of the pathogen-defining potential of phage-encoded virulence factors is found in *V. cholerae*. The genome sequence of *V. cholerae* Tor N16961 revealed a single copy of the cholera toxin (CT) genes, *ctxAB*. These genes are localized within the integrated genome of CTX$^{\phi}$, a temperate filamentous phage [75]. The receptor for entry of CTX$^{\phi}$ into the cell is the toxin-coregulated pilus (TCP). The TCP also represents the critical intestinal colonization factor of *V. cholerae* [45]. The genes involved in TCP assembly are part of a pathogenicity island that also includes a helicase-related protein

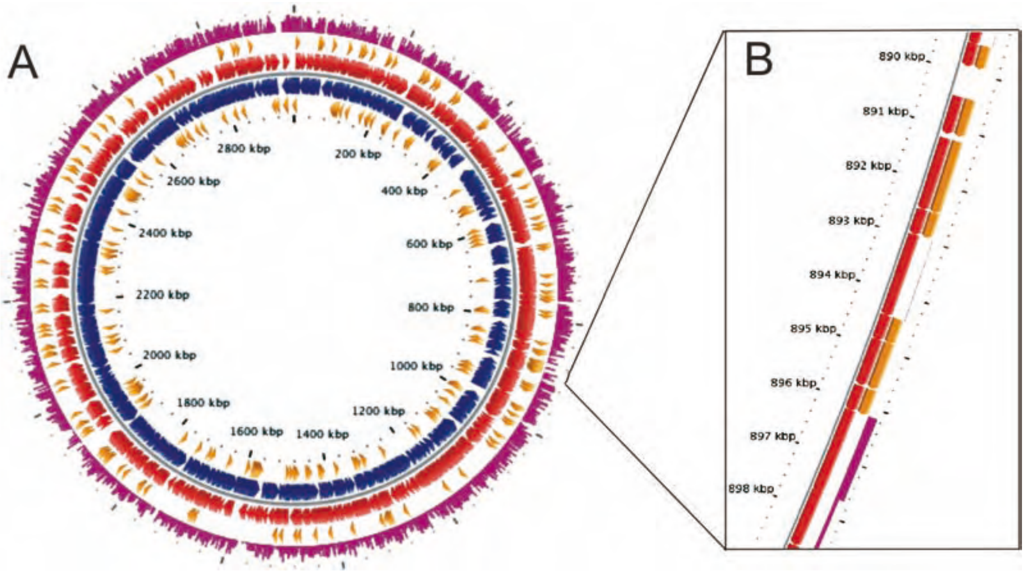

Figure 1 Circular representation of *V. cholerae* chromosome 1. This image was created using the program CGView [71] and data from the OrphanMine orphan gene database [78]. (A) Inner circle: predicted orphans on the negative strand. Second circle: predicted genes on the negative strand. Third circle: predicted genes on the positive strand. Fourth circle: predicted orphans on the positive strand. Fifth circle: representation of the number of bacterial species (from a total of 121 species) with hits to the associated gene. (B) The TCP Gene Cluster. Genes believed to be orphans prior to the sequencing of *V. fischeri* are shown in orange.

and a transcriptional activator that both share homology with bacteriophage proteins [31]. The TCP cluster of genes is shown in Figure 1. The majority of the genes located in the TCP cluster were long believed to be orphans until orthologs to many of these genes were found in the genome of the symbiotic bacterium of squid, *Vibrio fischeri* [63]. This surprising finding is made more intriguing by the suggestion that this region is native to *V. fischeri* but was acquired recently by *V. cholerae* from a low-GC genome such as *V. fischeri* [63].

This example illustrates how genes, annotated as orphans and derived from phage, can be responsible for important biological phenotypes that play a major role in the lifestyle of an organism. By sequencing more closely related genomes we will be able to "home" more of these taxonomically restricted put phenotypically relevant genes into gene families and in doing so, gain greater understanding of the evolution of these genomes. The discovery of genes associated with virulence in a commensal organism has more profound implications for the evolution of "virulence" factors and the role these genes play in nature. Although long-studied through the perspective of relevance to human health, it is possible that many of these genes carry out functions unrelated to pathogenicity in the environment. Perhaps this implies that virulence itself does not always evolve as a selected trait, but is an (unfortunate) byproduct which results from certain combinations of hitherto 'blameless' genes which occasionally arise in an ecological setting conducive to the onset of disease.

5 Coevolution of Infectious Bacteria with Their Hosts

The coevolution of infectious bacteria with their hosts is just beginning to inform medical science and yet is essential to understand when attempting to interpret levels of variation found between isolates [80]. For example, it is crucial to understand pathogen ecology and distribution with respect to its host(s) since shifts in either can lead to a jump between hosts, a phenomenon increasingly being seen in the case of emerging diseases. Here, we discuss two aspects of the coevolution of pathogens with their hosts that have a significant impact on the ability of pathogens to cause disease and which have been revolutionized through the sequencing of genomes. These are the coevolution (reduction) of metabolic capacity in pathogens associated with their hosts over long evolutionary time periods and the evolution of mechanisms for rapidly generating genetic variation that arise as a direct result of having to survive within the ever changing and hostile environment of a host.

5.1 Reconstructing Metabolic Pathways

As described above, while many bacterial strains become pathogens, or gain heightened pathogenicity, by acquiring new genes, the long-term evolution of many pathogens involves a loss of genes. The size of a bacterial genome can range from less than 0.5 to almost 10 million base pairs and this variation depends on the number of genes required to live in a specific niche. Larger genomes have more complex metabolic capacities as well as a high degree of redundancy in their pathways. Small genomes reflect a degree of specialization, with the smallest genomes belonging to obligate intracellular parasites.

The metabolic potential of any pathogen is largely a product of the amount of time it has coevolved with a particular host(s). The most interesting insights into this phenomenon are gained from the examination of the metabolic pathways lost in genomes undergoing reductive evolution (reduction of genome size). As pathogens become more dependent on their hosts over long evolutionary time periods, they lose the need to maintain a complete set of metabolic capabilities. If a given pathway is lost, it is likely that the corresponding metabolite is being acquired directly from the host.

Snapshots of this process in different species have been captured by the sequencing of genomes. We now have the complete genomes of several species that have experienced different degrees of reductive evolution. These include the insect symbionts Buchnera and the intracellular pathogens like Mycoplasmas, which are of special interest because they represent "minimal" genomes. The larger genomes of species of Rickettsia and Mycobacteria are still undergoing reductive evolution, as is evidenced by the relative sizes of the repertoire of pseudogenes (nonfunctional, or "dead" genes) that are currently present in these genomes. It is clear that the route to a reduced genome can vary significantly among different organisms and very different gene complements can be successfully adopted.

Detailed metabolic knowledge of an organism can have important practical applications, for example in the study of fastidious and unculturable pathogens in the laboratory. Computer modeling of metabolic networks in the *Tropheryma whipplei* genome led to the design of a medium that allowed *T. whipplei* strains, a species previously only culturable in the presence of human fibroblast cells, to grow in cell-free culture [61]. The success of this approach has led the authors to develop the MetaGrowth Knowledgebase, an online source of empirical and *in silico* evidence for the culture of species, which will hopefully lead to better culture conditions for species including *Coxiella burnetii*, *Mycobacterium leprae*, *Rickettsia prowazekii*, *Rickettsia conorii* and *Treponema pallidum* [52]. The biochemical network view of host–pathogen interaction is discussed in Chapter 23.

5.2 The Genetic Arms Race between Pathogen and Host

The host has a variety of mechanisms for defending itself against pathogens and as a result host–pathogen relationships are associated with some of the highest known selective pressures found in nature. The analysis of genomic sequences has provided new insights into the mechanisms by which bacteria invade and survive in host environments, and these often involve the rapid generation of genetic variability. In addition, genomic sequencing is providing detailed evidence to support one of the most fascinating observations to come from the study of bacterial mechanisms of generating genetic diversity, namely that bacteria (and other organisms) have evolved "the ability to evolve" [11].

Random genetic mutation is the "engine" of evolution producing variation that can be the source of new adaptive genotypes. Bacteria have two strategies for elevating the number of beneficial mutations generated within a given period of time. The first is to raise global mutation rates and the second is to evolve regions of localized hypermutation [48]. "Mutators" usually arise through a genetic mutation in a gene related to DNA replication or repair.

Damage to such genes can increase the number of errors made during chromosomal replication or decrease the rate at which errors are repaired leading to the fixation of higher than average numbers of mutations. “Mutators” have been associated with the emergence of hypervirulence and antibiotic resistance [14].

Raising global mutation rates above background rates increases the probability of a beneficial mutation in the short term (because there are overall more mutations occurring), but will have a damaging effect on an organism’s fitness over the longer term as the vast majority of mutations are deleterious [47]. To avoid this problem, many pathogenic bacteria have evolved a different strategy of increasing rates of evolution. This second strategy involves the ability to generate large numbers of mutations at specific locations within their genomes.

Phase variation, or phenotypic switching, is a widespread adaptive strategy among pathogens [30]. It is well known that DNA sequences of different compositions can have varying mutation rates. Bacteria have capitalized on this phenomenon to evolve a variety of “molecular switches” that generate rapid and reversible change. For example, as described above, candidate SSR contingency loci are straightforward to extract from DNA and with the sequencing of a variety of pathogen genomes we are beginning to appreciate the extent to which these phase-variable loci are distributed among different taxa. It is also becoming clear that contingency loci have evolved many times during the course of bacterial evolution (Figure 2). Of the first 220 sequenced isolates of bacteria, to the best of our knowledge, at least 30 isolates are reported to possess putative or known SSR contingency loci. These isolates belong to 30 species of 18 genera found in five divisions of bacteria.

6 Conclusions

The importance of an evolutionary perspective in the study of infectious bacteria is coming into the fore in the era of genomics. The analysis of genome sequences is elevating our general appreciation of the tremendous amount of genetic diversity harbored in the bacterial gene pool and is elucidating phenomena of specific importance to clinicians. These include the rise in antibiotic resistance and emerging diseases. The tremendous potential of bacteria to undergo adaptive evolutionary change can confound the development and application of widely efficacious therapies and make pathogens formidable foes of humans which can have devastating consequences for human health. Collaborations between evolutionists, bioinformaticians, clinicians and those generating complete genome sequences should be fostered as this approach will grow in importance as we continue to sequence more bacterial genomes

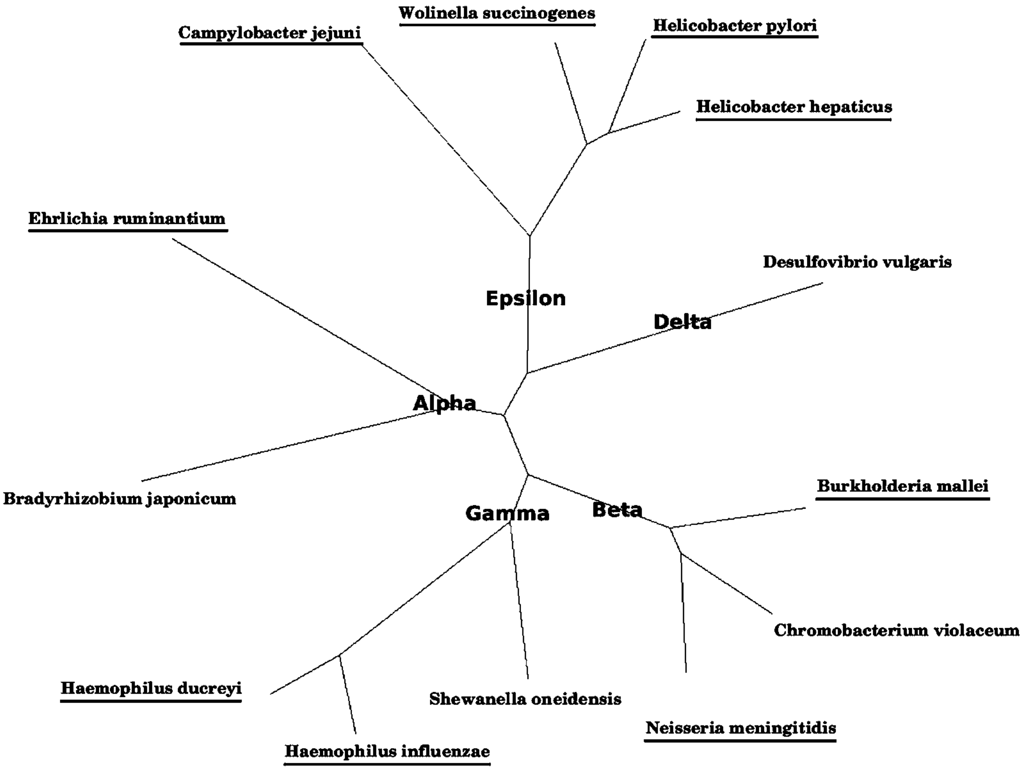

Figure 2 A phylogenetic tree of selected species of proteobacteria demonstrates the independent evolution of phase-variation among commensals and pathogens. Characterized and putative SSR contingency loci have been found in the underlined species. These species are interspersed among free-living environmental species (nonunderlined species). This unrooted neighbor-joining tree was constructed using the Jukes–Cantor method from pre-aligned 16S ribosomal sequences downloaded from the RDP [15].

and generate phylogenetic data sets for large sets of isolates. The study of pathogens using molecular evolutionary theory and bioinformatics is fuelling the emergence of the multidisciplinary field of evolutionary pathogenomics.

The wealth of genomic and phylogenetic data presents vast opportunities for the study of infectious bacteria. Along with these opportunities come challenges, including the need for better methods, databases and tools for mining data from collections of genomes in a phylogenetic context [29]. There is also a pressing need for additional information on the specific phenotypes associated with clinical isolates, improved sampling of natural isolates, and targeted sequencing of nonpathogens. Understanding the extent, fluidity and significance of the bacterial gene pool is one of the grand challenges for researchers working in this field. The most powerful data sets will be those with a phylogenetic tree describing the entire genetic diversity of a species (i.e. thousands of isolates), 10–30 complete genomes to allow detailed genomic analyses coupled with microarray-based typing studies of hundreds of strains. Such data sets are for the future, but at the present rate of advance are unlikely to be too far over the horizon.

Basic Bioinformatics Technologies

42
Integrating Biological Databases

Zoé Lacroix, Bertram Ludäscher and Robert Stevens

1 Biological Resources

Biological resources useful to the scientists include a variety of data sources and applications. These resources are made publicly available to the researcher on the web, or are privately accessed through subscriptions or within the scope of collaborations. The number of these resources is overwhelming and increases significantly each year. In 2005, the Molecular Biology Database Collection listed 719 public data sources [33] – a 31% increase since the previous year and 351% since the first compiled list in 1999 [15]. The thousands of data sources providing biological information overlap: multiple data sources may provide information about a scientific object, e.g. a nucleotide sequence, and thus share entries. When these data sources provide information about the same scientific objects, e.g. a gene, their data differ dramatically with respect to (i) organization ("How is the scientific object represented?"), (ii) format [ASCII, eXtensible Markup Language (XML), etc.], (iii) number of entries (the instances of the scientific object entered in the data source), (iv) characterization ("What information related to the scientific object is provided?") and (v) data quality ("What level of curation is achieved?"). As scientific objects are related by various scientifically meaningful relationships, e.g. a gene *codes for* a protein, the biological data sources providing information about those objects are often intertwined with links that capture those relationships, expressing them through hyperlinks, indices or generated by applications.

Scientific reasoning in bioinformatics relies on complex scientific protocols partially or completely involving digital data sets retrieved from public or

ISBN: 978-3-527-31278-8

private data sources. The digital parts of scientific protocols include data collection from various sources, data analysis – using a wide range of applications – and data transformation, including traditional database operations such as selections, projections, and joins. The execution – automated or not – of a single protocol may thus involve multiple resources including data sources and applications [77]. Integrating these resources and the data flows resulting from the execution of scientific protocols is critical to scientific discovery. Other areas in which scientific data integration is the core technology include the design of scientific knowledge repositories and the representation of systems biology and scientific pathways. Systems biology relates to different types of biological information, such as DNA, RNA, protein, protein interactions, cells, tissues, etc., together with their individual elements, e.g. specific genes or proteins, and the relationships of these with respect to one another and the elements of other types. The aim of systems biology is to integrate all of this information to obtain a view or model of the system as a whole. Similarly, molecular interaction networks, including metabolic pathways, regulatory pathways and molecular complexes, aim at modeling the complex interactions between various scientific objects and the systems that support them aim at providing access to information relevant to these entities and their relationships.

The problems pertaining to scientific data integration are inherently complex and challenging. Scientific data integration relies on the integration of various systems often developed on different platforms, with different operating systems. These primary differences already raise various operability problems of communications between the integrated resources and the integrating system. Then, scientific integration requires the integration of the data themselves – a task that requires the integrating system to access and "understand" the data. Accessing and understanding the data requires from the integration system the ability to express (retrieval or database) queries to the data source so that the integrated resource provides the expected data and to map the data to the integrated data representation. In addition, scientific integration requires from the integration system to provide all analysis, transformation and, sometimes, visualization tools that are available to the scientist. In fact, to the scientist, data access (via a database or a retrieval query) and data analysis (via a tool) often are alike. Applications and data both play primary roles in the scientific data integration scenario. Data without suitable technology to access and analyze them are as meaningless as the technology without the data. For these reasons, a data integration approach should allow flexibility of use of the integrated data with available scientific tools.

Many approaches have been developed in the past to address these problems. Although they all offer benefits to the life scientist, they fail to provide a complete solution to the scientific integration problem. The main reason may reside in the legacy with which they have to deal. There are several communities that have developed integration technology, although not always primarily motivated by scientific integration challenges: (i) the database community which develops database management systems and focuses on the design of data definition languages to represent the data and query languages to access and transform the data, (ii) the computing community which develops approaches to facilitate interoperability of applications with distributed computing architectures, Common Object Request Broker Architecture (CORBA), the Grid, peer-to-peer (P2P) and web services, (iii) the knowledge community which develops intelligent-based approaches where integration is driven by a meaning expressed with Semantic Web or ontologies and achieved by intelligent agents, and (iv) the process community which aims at modeling business processes with workflows. As biological data integration involves a combination of data, computing, process and knowledge, we believe that a solution suitable to scientific discovery should benefit from all approaches. For these reasons, we present the main contributions from those domains that may shape in some extent the next generations of biological integration systems.

The chapter is organized as follows. Various data models are presented in Section 2. Section 3 successively addresses the problems of the mapping of the conceptual model to underlying models and introduces three traditional approaches to data integration: data warehouse, linked-based federation and mediation. The problem of application integration is addressed in Section 4. Section 5 is devoted to semantic issues related to data integration. In Section 6, we discuss scientific workflows, which aim at combining data access, integration, analysis and visualization into an integrated whole.

2 Data Modeling

An issue critical to data integration is related to data models. As integrated data are typically extracted from multiple resources, each having its own data organization, data model and data structure, reconciling these different modes of data modeling into a integrated model requires adequate understanding of these three layers of data modeling. Although the terminology to distinguish those three layers may differ in the literature, to clarify the discussion, we define them as follows.

- *Data organization* (or conceptual model) pertains to the way data is understood by the data providers. For example, GenBank is sequence-centric (all information the data source provides is organized with respect to the scientific object sequence).

- *Data model* is one among various data management definition languages offered (mostly) by the database community. They include relational model, nested-relational model, object-oriented model, XML, etc. Each database management system provides such a data model that captures the internal representation of the data in the system.
- *Data structure* (or schema) is the chosen structure with respect to the organization and model. Once a data model is selected, it offers multiple ways to represent internally the data. The data structure in the relational model is defined with respect to the tables (relations) and columns (attributes) of the relational schema. The data structure of the XML data model is characterized by a document type definition (DTD) or a XML schema.

The selection of each of these layers of data representation may affect significantly all aspects of data management including: data storage (ease of entering the data and efficiency of storage), data access (expressive power of query language), maintenance, etc.

2.1 Conceptual Model

The data organization may be represented with models designed not to manage the data, but to organize the data and represent their meaning. Such models include the Entity–Relationship (ER) model and the Unified Modeling Language (UML), respectively developed by the database community and by the programming languages community. These models provide abstract data representations that are not used to actually format the data (entities). Conceptual models represent classes of scientific objects such as *gene* or *sequence*, and their relationships and processes, but they do not represent the instances of these scientific objects. Instances will be represented with respect to the data structure, the third layer of data modeling.

2.1.1 **ER**

Schema diagrams were formalized in the 1960s by Charles Bachman who used rectangles to denote record types and directed edges (arrows) from one record type to another to denote relationships between instances of the two types [2, 3]. Peter Chen later used a similar formalism called ER where rectangles formalize entity types (or entities) and edges labeled with a diamond formalize relationship types (or relationships) between entities [21]. Although relationships in the ER are not directed, their connectivity – the constraint on the number of instances of entities they may connect – is specified with a number, e.g. 1, or a letter, e.g. M, that, respectively, expresses that a single instance or multiple instances of the entity may be linked with the relationship. Both entities and relationships may have attributes to describe their characteristics.

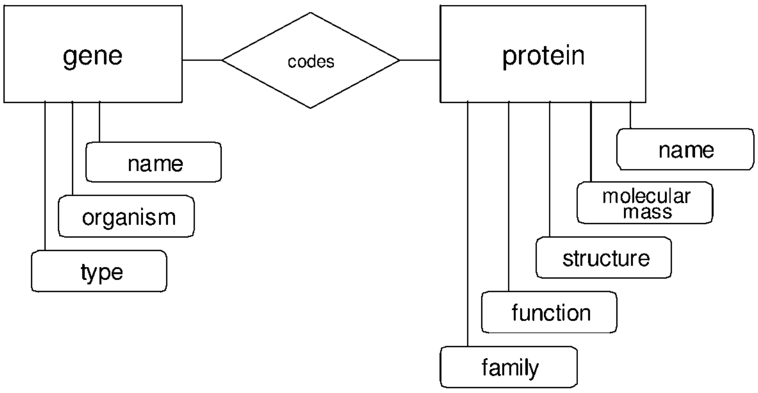

Figure 1 ER diagram.

The ER model is simple and intuitive and thus is easily understandable by database designers and users alike. The success of the ER model has lead to multiple extensions of the original model, e.g. to model generalization, specialization and aggregation, as published in numerous papers and books ([14,29,42] and references therein).

We illustrate how ER may model biological information in Figure 1. Gene and protein are defined as entities. Each entity is qualified by attributes represented in ovals linked to the entity they refer to. The relationship capturing the scientifically meaningful relationship a *gene codes for a protein* is represented with a connector between the two entities labeled codes. Although the model defines a *codes for* relationship between the entities *gene* and *protein*, an instance of the entity *gene* may encode no protein, one protein or many proteins.

Relationships may be characterized by one or several attributes in an ER diagram. For example, in a diagram aiming at representing literature references, two entities, i.e. author and journal, may be linked by a relationship "publish" with attributes date, volume, number, etc. These attributes characterize the relationship, not the entities. The ER model allows n-ary relationships that link n entities together, for any integer $n > 1$. For example, an alternative representation of the literature references would be to define a relationship "publish" between three entities: journal, date and author. In addition to these powerful basic representation mechanisms, the ER model has been extended to allow for the definition of a hierarchy of entity types (generalization hierarchy). Two entities, e.g. DNA and RNA, may be sub-entities (subtypes) of a common super-entity (supertype), e.g. sequence. When such a hierarchy is defined, all the attributes defined at the super-entity are propagated down the hierarchy to sub-entities. Like any modeling framework, there is no unique way to model the information. Often a representation is best suitable for a particular aim.

The ER model is a formidable tool for conceptual modeling. Not only it is easy to understand and use by both users and data providers, but it offers valuable advantages. First, it captures adequately the level of complexity of abstract objects that scientists need to represent. Then, unlike data models offered by data management systems, ER is not biased towards a particular data model and thus may be translated in the model of any computer system. This is especially important, as we will see that each data model typically twists the data with respect to its characteristics. Once an ER model is specified it is easy to translate it into available data models including relational, XML, etc. Many automatic and semiautomatic tools generate data structures from an ER diagram. Finally, as we will present in Section 5, the need for semantic integration raises the need for a formal conceptual model to represent the data organization. The ER model seems to be little used in the biological community. We find only 25 hits for "entity–relationship" retrieved from PubMed in September 2006. Still, its ease and the various technological support available make it a promising candidate for modeling conceptually biological data as needed for data representation and integration.

2.1.2 Unified Modeling Language

UML is a notation that helps documenting system specifications [10, 51, 72]. The language provides various diagrams that characterize the structure (class, composite, etc.), the behavior (use case, activity, state machine, etc.) and the interactions (sequence, communication, etc.) a computer system aims at achieving. The UML diagrams offer orthogonal abstractions or viewpoints of a soon-to-be designed computer system that overlap significantly. Although not all diagrams may be useful in every context, some of them appear to be beneficial to the scientists to represent the data organization of the data, but also to express the requirements of a system that will be designed to support bioinformatics tasks (see, in particular, the UML use case and activity diagrams).

The UML class diagram illustrates model elements such as classes and types, their content, and their relationships. In order to create and evolve a class diagram, the scientist needs to iteratively model the classes, responsibilities, associations, inheritance relationships and composition associations. We illustrate the expressive power of the UML class diagram with Figure 2 where seven classes are represented. It is worth noting that in Figure 2 all classes have the same weight and the diagram does not provide a data organization that is gene-centric or biased towards other characteristics. However, when translating this overall abstract data organization into the data structure related to a selected data model, the scientist may alter this uniform representation to adapt the data to the selected data model or to improve performance.

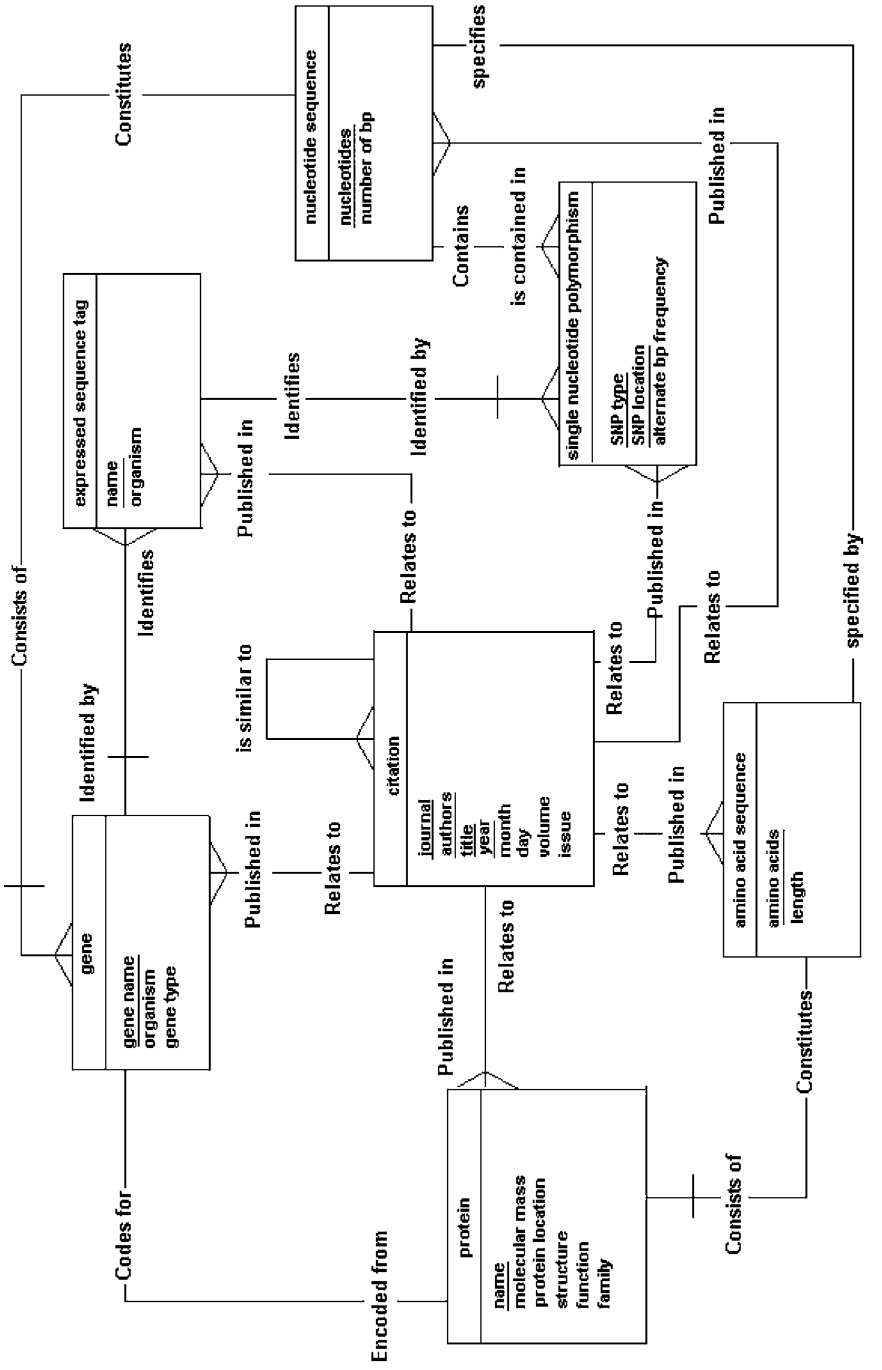

Figure 2 UML class diagram representing biological objects.

Although less critical for data integration, use cases are a powerful mechanism to characterize all interactions with the computer system which is being designed. Use cases are defined by the actors (system, users, other systems, organizations and groups) and the tasks (actions, interactions, and associations) that the system is expected to perform [47]. For example, a use case for searching the bibliographic references related to a particular genetic disorder could be characterized by an actor scientist and the following six tasks: (i) select the resource that provides information about genetic disorders, e.g. Online Mendelian Inheritance in Man (OMIM), (ii) enter the keyword in the form, (iii) click the search button, (iv) the search algorithm is executed, (v) the results are returned to the actor and (vi) the bibliographic references are extracted. In UML, a use case is characterized by a task linking two actors or systems. The UML use case diagram represents each use case by ovals labeled by the task it represents. In a use case, each system is represented by a rectangle that may, itself, contain internal use cases, i.e. the tasks performed by the system and the actors. The edges represent the interactions between the actors and the system, or between systems. Each edge links an actor (or a system) to a use case and a system. Tasks may exploit other tasks and labeled edges between tasks express these paths between actors (or systems) to systems.

The use of UML to model biological data and scientific activities is rather limited (127 entries in PubMed in September 2006), but it offers promising modeling for complex biological processes and systems [71] and efforts such as the development of BioUML to support systems biology are encouraging (http://www.biouml.org/model.shtml).

2.2 "Flat" Data Models

A flat data model uses a single mechanism (or container) to structure all information. For example, a textual document, as a string of characters, is a flat representation of information (*flat file*). The only level of structure provided by such a model is given by the named container (here the *document*). The relational model can be seen as a flat model as all information is contained in relations (*tables*). As complex as the conceptual representation of the information may be, the complete diagram can be represented as a single table (however, applying principles of database schema design and optimization [8] will generally lead to a multi-table organization). For example, the diagram shown in Figure 1 could be represented in a table with eight attributes – gene name, organism, gene type, protein name, molecular mass, structure, function and family. The relationship between two instances of, respectively, a gene and a protein will be implicitly expressed for the instances of a protein and gene on the same row. Such a row is also called a *tuple*. Alternative representations of information in the relational model rely on splitting the information among multiple tables, at the cost of maintenance (there exist various approaches to normalize schemata and minimize maintenance and problems with update anomalies due to redundancy). Resulting tables may be linked through foreign keys that express the relationship among scientific objects split over multiple tables, creating a complex graph of linked tables.

A relational database schema obtained from an ER diagram or from any other method, once used to structure data in a relational database system, may need some transformations to improve performance, integrity and maintainability. For example, an instance of a table Reference with attributes title, author, journal, date, and page number is likely to show a large amount of redundant data as a reference authored by five people will be stored with five rows each containing the same title, journal name, date, etc. In order to avoid these situations, relational schemata are normalized [8]. Normalized schemata gain in performance, but the resulting transformation often blurs the conceptual understanding of the data set. When integrating relational databases, approaches must extract (or reconstruct) from relational schema the logical organization of the data. Techniques such as database views, schema mapping (see Section 3.1) and semantic integration may facilitate the process.

2.3 Tree-structured Representations

Tree-like structures are often preferred by life scientists to represent scientific data. Maybe the legacy of classification combined with the overwhelming textual information stored in flat files (often nested) can explain this infatuation. Tree-like structures may be easily produced from an ER diagram by selecting an entity for root – all entities linked to the root entity via relationships become children of the root node, and so on. Illustrations of the process are given in [68].

The recent advent of XML and the development of nested relational data management system led to the development of the efficient management of data stored in tree-like structures. In XML, data are represented by elements and valued attributes in a tree. The XML data model was designed to accommodate the exchange of documents over the Internet. Markup languages such as the Standard Generalized Markup Language (SGML) and the HyperText Markup Language (HTML) were widely used to tag textual documents to facilitate their processing and web publishing, respectively. To overcome the limitations of HTML (where all tags are for display), XML was designed to extend HTML while being significantly simpler than SGML. Later, the XML data model was adapted for data management (see the XML schema and XML Query Language working groups at the World Wide Web Consortium, http://www.w3.org). Because of its legacy, the XML data model organizes data in a document (root of the XML tree), whose nodes are elements and attribute values, organized with respect to the order of their occurrence and depth of nesting in the document [1].

There are currently two categories of XML management systems: XML-enabled and native XML [17], although the borderline between them can sometimes be blurred. The first group includes traditional database systems extended to an XML interface for data collection and publication. However, the underlying representation is typically with tables. Examples of XML-enabled systems are Oracle10i (http://www.oracle.com) and SQL Server 2000 (http://www.microsoft.com). These systems were mostly designed to handle business tasks on the web. They have not yet been proven to be useful in scientific contexts. Native XML systems such as Tamino (a commercial XML management system from Software AG), ToX (an academic XML management system being developed at the University of Toronto, http://www.cs.toronto.edu/tox) and Galax (developed by Bell Laboratories of Lucent Technology, see http://www.db.bell-labs.com/galax) rely on data internally represented with XML trees, and should provide a flexibility interesting in the context of scientific data management. The implicit order of elements in a document, although very useful when handling textual data, affects significantly data storage and processing of XML enabled relational data management systems [61]. As biological data are for a large amount textual and deeply nested, XML native systems may be favored to access and store biological XML data.

The nested relational data model is an extension of the relational data model that allows attribute domains to be either atomic (as in the relational model) or valued (the value of the attribute is then a set of values, thus a relation). It can be a more efficient storage model than flat relational databases, as the nesting mechanism allows for implicit representation of relationships, and avoids redundancy of data over multiple tuples and tables. While being an extension of the relational data model, the nested relational data model possesses a query language as mathematically sound as the relational calculus [70]. The biological data management system BioKleisli [20, 26] uses the nested relational data model and calculus to manipulate internally scientific objects. Not only does the data model offer significant benefits, but the nested relational calculus appears to be a suitable language for expressing scientific protocols [34]. (See Ref. [49] for more information about those data models and their used in scientific data management.)

2.4 Graph Representations

There is a large variety of scientific data which are naturally represented as graphs. These data include all kinds of biological pathways and networks.

Metabolic pathways represent chemical reactions used for energy production, synthesis of proteins, carbohydrates, etc. Metabolic pathways can be represented by directed graphs, with nodes for reactions, inputs, outputs and catalysts. Genes, gene regulatory sequences and signaling proteins, which control the activation or suppression of gene expression, are structured in gene regulatory networks whose graph structure is similar to metabolic pathways. Note that these graphs are usually directed and cyclic. Cyclic directed graphs are typically difficult to query efficiently and also more difficult to process with functional programming methods, which have traditionally been developed for lists and trees. In contrast, protein interaction networks are undirected graphs. Graph operations such as *find a path between two nodes*, *find the shortest path between two nodes*, *transitive closure* (browsing through edges until all connected nodes are met) or *subgraph homomorphism* (exact match of graph structure – edges) express meaningful scientific queries.

Translating ER diagrams into graph-based data management systems is rather straightforward. However, there are not many systems supporting rich graph structure and graph query language such as needed in the life sciences. Research projects such as the Biopathways Graph Data Manager (BGDM) at Lawrence Berkeley National Laboratory (http://pueblo.lbl.gov/∼olken/graphdm/graphdm.htm#graphDataModel) are devoted to the design and development of a general purpose graph data management system to support biochemical pathways and protein interaction network databases for microbial organisms. A similar focus is the core of the MetaCyc effort at Stanford Research Institute (http://metacyc.org).

The primary purpose of Object-Oriented Databases (OODB) is to design a database that could easily model the world as classes of similar objects while being compatible with declarations of an object-oriented programming language such as Smalltalk or C++. In an OODB, the world is modeled in terms of a hierarchy of object classes, valued and abstract attributes, and collections [16]. A valued attribute assigns a value to an object, whereas an abstract attribute links two objects. The object-oriented data model seems similar to the ER conceptual model, but the differences between the two models are significant. The translations from an ER diagram to an OODB schema are straightforward as long as the ER diagram has been transformed so that all *n*-ary relationships, all attributes characterizing a relationship and all many-to-many relationships have been removed. Once the ER diagram is defined with only one-to-one or one-to-many binary relationships with no attribute, an OODB schema may be obtained by creating an object class for each entity, an abstract attribute for each relationship and a class hierarchy for each entity hierarchy. Unlike in the ER conceptual model, an object class can inherit from multiple classes.

The Object Protocol Model (OPM) is an object-oriented data model specifically designed to handle scientific data [19]. It allows for the definition of two different types of classes: object and protocol classes. As in traditional object-oriented data models, object classes in OPM are populated with identifiers of objects of the same kind. In contrast, protocols classes are designed to represent scientific experiments. An atomic protocol represents a process instance, with its input and output. Expanded protocols are composed of a complex network of connected atomic protocols. This expressive data model is used to develop the OPM multi-database system [45] and Web mediator [48]. The need to store scientific protocols together with the data they collect is still critical and is currently addressed with solutions based on workflows, as presented in Section 6.

2.5 Multi-dimensional Data Model

Scientific applications often generate large multi-dimensional arrays. These large data sets are often stored in files or spreadsheets that provide little or no meaningful structure. The multi-dimensional data model evolved from the processing of data contained in spreadsheets and used by business analysts in specialized multi-dimensional databases such as Express. The multi-dimensional data model consists of *facts* and *dimensions*. A fact can be regarded as an entity of an ER diagram and is represented graphically in the multi-dimensional data model as a data cube. Each dimension corresponds to a perspective under which facts can be analyzed, characterizing various measurement data related to the fact. Dimensions can be structured in hierarchies of levels for characterizing the modalities in which data can be grouped along dimensions. In a dimension, there may be more than one path along which to aggregate the data [82, 83]. Relational database systems often offer a multi-dimensional data representation by way of the star schema that structures the data in a cube. The star schema aims at structuring a set of mostly numeric measures and a set of dimensions that provide the context for those measures. A collection of dimensions uniquely defines each measure, while each dimension is specified by a set of attributes or a hierarchy of attributes. The star schema consists of a single fact table that contains the numeric or non-numeric measures and several dimension tables. The fact table is usually very large – the number of columns equals the number of dimensions it represents. In contrast, the dimension tables are usually significantly smaller, as they contain the non-numeric data associated with the attributes of the dimensions. While the star schema offers great performance and is intuitive for users to visualize, its limited multi-dimensional structure does not capture explicitly the hierarchy between different levels of aggregations [82].

Obviously, in the context of data integration it is critical to exploit the fact that data are organized in a data cube or in a star schema so that the multidimensional structure is understood when not made available to the user.

3 Data Integration

Once the data sources are selected, the first two challenges in data integration are to understand the data structures of the sources to be integrated and design a structure for the integrated data. When the analysis of the data structure has generated a framework for structuring the data and suitable mapping mechanisms for translating data from the remote sources to this integrated structure, data integration approaches may be chosen. Data integration approaches may be used to query heterogeneous resources or access data to populate a local data repository. Here, we present three traditional integration approaches: data warehouses, federations and mediations.

3.1 Scientific View of Data

There are multiple ways to represent data as presented in Section 2. Each data source has its own data organization, data model and data structure. When integrating these different data representation modes, integration methods often assume a *global schema*, thus a selected data organization and data model for representing integrated data. To provide the users with an integrated view of the data, any approach needs some formalism. This integrated view may be conceptual, if only the data organization is shown to the users, or structural, if the data are organized and structured with respect to a data model. Conceptual integration (illustrated in Figure 3a) maps integrated concepts to those of the integrated resources. The approaches presented in Section 5 typically use an ontology as a conceptual model and user interface for accessing data. Successful integration systems such as Transparent Access to Multiple Bioinformatics Information (TAMBIS) [76] and Knowledge-based Integration of Neuroscience Data (KIND) [57] were developed combining conceptual integration and mediation. Recent approaches aim at mapping not only scientific concepts, but also scientifically meaningful relationships [50].

In this section, we will focus on approaches based on structural integration (illustrated in Figure 3b). Although structural integration does not address conceptual integration, it does not mean that the organizations of data within the data sources to be integrated will correspond semantically, such that structural integration will be facilitated. Indeed, some data organizations maybe quite incompatible and require significant transformation in order to

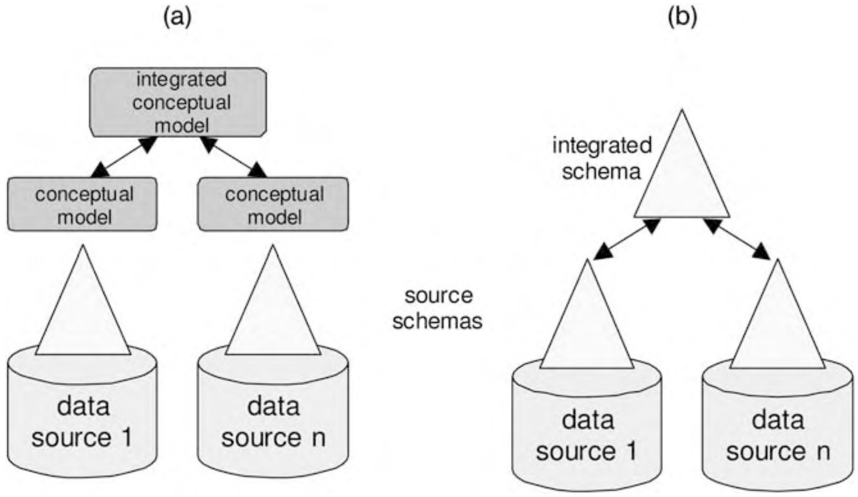

Figure 3 Conceptual integration (a) and structural integration (b). The triangles represent the data structure (or schema), while the ovals represent the conceptual diagram.

enable data integration. We list below some of the problems that the scientist may meet while integrating heterogeneous data sets.

- What is the integration problem?
  - Does the user already have an integrated data organization in mind? (Thus the customization of the integrated data set will be achieved with respect to users' requirements.)
  - Does the user wish to produce an integrated data organization that best meets the existing data organizations of the data sources to be integrated?
- What is the integrated data model?
  - Is the data model specified for the integrated data set?
  - Does it correspond to the underlying data sources to be integrated?
  - Does the user wish to select the data model that best meets the existing data models of the data sources to be integrated?
- What is the integrated data structure?
  - Is the schema specified for the integrated data set?
  - Does the user wish to produce an integrated schema that best map to the schemata of the integrated data sources?

Existing data integration approaches such as the ones presented in this section offer limited support to the problems listed above. Most of them assume that both the integrated schema and the mappings between the integrated schema and the source schemata are provided. They also offer limited support for maintaining the overall integrated architecture, e.g. with respect to changes at the source schema affecting the integrated schema or changes at the integrated schema affecting the mapping with source schemata. The development of *schema mapping* tools, that semi-automate the mapping between schemata, will improve this necessary support. Schema mapping tools typically assume that the integrated schema is known and map each of the source schemata to it by exploiting syntactic information (metadata) and semantic information (instance) in order to generate correspondences between structural components [28, 32, 84]. A general approach, applicable also in the context of data integration is *model management* [7]. In this approach, general schemata or "models" and mappings between them are considered as "first-class citizens" that can be stored, discovered, reused, transformed, etc., thus providing a useful data integration and transformation infrastructure. Recently, Clio, a schema mapping tool developed at the University of Toronto in collaboration with IBM, has been evaluated in the biological context of mapping the relational schema of GeneX (http://sourceforge.net/projects/genex) to the XML schema developed to exchange gene expression data GeneXML, formerly known as GEML [39].

Once the integrated schema and the mapping to (and from) all source schemata are specified, a *view* of the integrated data sources is defined. The notion of view was first introduced for relational database management systems to capture the customized transformation of an instance. A view is obtained by changing the data structure such that a certain category of users would only access the information they needed. Tables and attributes were often hidden to some users for security reasons. In the context of data integration, the data set shown to the user is an integrated view of data sources. The integrated schema is the structure of the view. A view may be *materialized* or *non materialized*. A view is materialized when an instance is created, accessing each integrated data source and loading the retrieved data into the new structure to create a new data source (thus materialized). When users query the view, they no longer access the integrated resources, but query the materialized instance. A view is non materialized when the view is used only as a querying interface and each time users query the view, queries are propagated to the integrated resources, retrieved data are integrated before being returned to the user.

3.2 Data Warehouse

A data warehouse is a collection of data integrated from multiple sources (databases, flat files, etc.) within a single system, usually a database. A data warehouse is a materialized approach as integrated data are downloaded – thus materialized – into the warehouse. Data from various sources usually need to be cleansed and reconciled before being integrated into the data warehouse. Maintenance is achieved at specified dates and within two updates the data accessed by the user in the data warehouse may be out of date.

The development of a data warehouse typically requires the selection of a data management system for storing the warehoused data and various resources from which data are collected. A warehouse schema is designed in order to structure the data in the system's format with respect to their chosen organization. The warehouse schema is a global schema as it structures data retrieved from various data sources and integrated in the warehouse. Once the warehouse schema is designed, queries or scripts are used to download data from the data sources, and various mechanisms are applied to curate and reconcile retrieved data that are reorganized with respect to the warehouse data organization and translated into the warehouse format. The resulting data source is independent from the resources from which it is generated. Therefore mechanisms are needed for its maintenance. In addition, the developers of the warehouse are also responsible for adding computational and analysis capabilities to the warehouse, capabilities that may be available at the integrated resource, but no longer usable.

The effort needed to develop and maintain a data warehouse often motivates the use of virtual integration frameworks such as a mediation approach (see Section 3.4) or partially virtual ones such as link-driven federations. Despite the additional workload, data warehouses are preferable in multiple settings occurring when data require significant curation or when users need privacy as well as for *data mining*. As data mining aims at discovering non-obvious relationships or trends in the data, data mining algorithms typically perform on data sets significantly less structured than in a traditionally data management system. The development of GeneExpress [58] illustrates the need for developing a data warehouse rather than using a virtual data integration system such as the OPM multi-database system.

When the data set includes statistics, a data warehouse exploiting the *data cube* may be a suitable solution for enhancing the ability to analyze large measurement data with respect to various orthogonal directions. On-line analytical processing (OLAP) relies on a data structure in terms of data cubes composed of data aggregated with respect to some parameters. In a nutshell, a data cube is a multi-dimensional table (see Section 2.5). This data model was introduced such as to overcome the limitations of the relational model which spreads the data over multiple two-dimensional tables and its query language [structured query language (SQL)] which does not support the expression of queries such as histograms, cross-tabulations, and roll-up and drill-down features [18].

3.3 Link-driven Federations

Although the terminology of database integration is not commonly agreed upon, we distinguish *federations* introduced in this section from *mediations* treated in the next section. Here, a federation is a partially virtual integration approach. It has a non-materialized feature as the data are not downloaded into any system and remain in the various systems that host them. A federation of databases is obtained by *linking* semi-autonomous, distributed databases. Each database has significant autonomy in the distribution while offering an interface to provide the user the capability to access integrated resources in a unified manner. In a federation, databases do not have total autonomy as they must maintain the links to the other members of the federation. These links constitute a materialized component of the integration and can be seen as a data set (typically a set of indices) that characterize the way data are integrated and need to be stored and maintained. Data providers may develop a federation to link the data source they develop. An example of such a federation for biological resources is Entrez developed at the National Center for Biotechnology Information (NCBI). For the user, the federation allows to query each of the integrated resources and conveniently navigate from one to the other. There is no global view provided to the user. A system such as the Sequence Retrieval System (SRS) was developed for maintaining a federation of multiple flat file data sources [30]. The system has since evolved to integrating flat files as well as structured databases and applications [31], providing an object-oriented integration schema.

3.4 Mediations

The concept of mediation was first introduced by Wiederhold to provide flexible modular solutions for the integration of large information systems with multiple knowledge domains [89, 90]. A mediation system (or *mediator*) integrates fully autonomous distributed heterogeneous data sources. In contrast to federations, mediations do not materialize any information. Instead they rely on *wrappers* to translate queries expressed with respect to the integration schema into queries to an integrated data source and translate the query results expressed in the source schema into data expressed with respect to the integrated schema. In contrast to the multi-database approach, mediators do not assume that all integrated sources will be relational databases.

Instead integrated resources can be various database systems (relation, object-relational, object, XML, etc.), flat files, etc. The major benefit of mediation systems is to always provide access to up-to-date data. An example of mediator is DiscoveryLink (also known as the DB2 Information Integrator and WebSphere) [38].

Although the approaches developed by the database community provide a powerful and efficient interface for accessing and transforming integrated biological data, they are often limited by the applications made available in order to analyze, simulate, visualize, etc., biological data. This limitation is due to the focus on data that ignores the integration of all resources, including applications. In the next section, we investigate how integration approaches developed for providing users access to all the useful applications they need (see Chapter 44) address the issues specific to data integration.

All integration approaches require expertise in order to comprehend the data organization, model and structure of each integrated resource. This expertise can be made available through valuable metadata (information about the data) for automatic processing and semantic integration as presented in Section 5.

4 Integrating Applications and Data

There are many technical solutions for integrating distributed resources into one application. These can be seen as the "plumbing" that joins resources together such that data can "flow" into one application. These technologies are explored in detail in Chapter 44, but a brief overview is provided here. These technologies for plumbing really address the lower levels heterogeneity: system and syntactic heterogeneity. At the system level, resources or applications run on different platforms, use different protocols and languages, and use a variety of call interfaces. At the syntactic level, the data are offered in a variety of formats. To overcome these hurdles it is necessary to "include" external resources into the local environment such that they appear to be present within the local application. Further, these external resources need to be "transformed" such that all resources appear to have the same syntax and a common behavior within the host application.

Most programming languages now have the necessary libraries, etc., to enable some sort of integration in an application setting. Java, for instance, has Java Database Connectivity (JDBC) by which an application can connect to a remote database and perform SQL queries upon that database. To overcome the syntactic heterogeneity between the "Standards" in SQL, there are layers such as Hibernate (http://www.hibernate.org) that will translate an incoming SQL query to that hosted by the target database. Programming languages also usually have facilities for importing web pages and consequently running services available via the Common Gateway Interface (CGI). All these facilities give partial access to distributed data resources, but they do not provide a complete or robust solution to the basic levels of heterogeneity that arise through distribution.

In this section we will briefly review the idea of middleware and some technical approaches to integration. By introducing some case studies from bioinformatics, we will soon see that "plumbing is not enough" [35a]. These technical approaches go as far as to bring all the data into one application, but those data themselves are still heterogeneous at the level of their structure and the values within this structure. This more difficult level of reconciliation will be dealt with in Section 5.

4.1 Middleware

To a programmer attempting to integrate bioinformatics resources within a single application, the fact that all the resources present different interfaces implies that a considerable amount of effort has to be expended. For example, consider the case when a Java program needs to access a remote database written in C++ and feeds some of the results to another program written in Perl. In order to do this the programmer must cope explicitly with the different languages in question – the C++ will be invoked in one way, Perl in another – and also deal with the distribution. The C++ program would likely be invoked differently if it were available on the local machine. As well as taking a large amount of effort, the resultant program is fragile. If it is decided to mirror the database locally, the Java program will need rewriting. If the Perl program is ported to C++, again the Java needs rewriting.

One solution to this problem is to use some *middleware* technology. As the name suggests, this adds a middle architectural layer that abstracts away from the different languages, systems and locations. It does what its name suggests – it sits in the middle between the application layer and the underlying resource layer. Following the example above, instead of writing code in Java to invoke the C++ database directly, both will be *wrapped* with the middleware technology. This technology then has the task of managing the communication between these wrappers. While this seems overly complex, it actually simplifies many issues. The Java programmer no longer has to worry whether the C++ database is local or remote nor does it matter that interaction is needed with both C++ and Perl. Therefore, middleware technologies offer an attractive solution to overcoming system and syntactic heterogeneity in a distributed setting.

4.2 CORBA

CORBA is one middleware solution to the problems of integration. It arose in the 1990s, and is now a mature industry standard and was widely proposed as a solution to the problem of integration [85], especially in bioinformatics [78, 85].

CORBA attempts to present a common view of the world by presenting it from an object modeling perspective. To continue the example introduced earlier, to the Java program both the C++ database and the Perl program would appear to be Java objects. Interaction with these objects would be identical to interaction with any other Java object. Similarly, on the C++ side, queries to the database would appear to be coming from a local C++ object rather than from remote Java.

In order to enable this technology, the target resources can be described in a common language. This common language can then be compiled automatically into the programming language of choice, which then enables these target resources to appear as if they were part of the local host application. A core feature of the CORBA specification is this language – the Interface Definition Language (IDL) [78]. This language is used to describe what operations, including return types and arguments taken, target resources perform, and it can be used by CORBA compliant tools to generate code for both providing access to the services and the means for the services to be accessed. One low-level task performed by CORBA is to define how much memory is used for primitive types such as real and integer numbers. Typically on a PC an integer uses 2 bytes of memory and UNIX machine 4 bytes of memory. This system-level heterogeneity needs to be smoothed away, otherwise numbers too big for a platform will cause errors at the application level.

Once described in IDL, a platform-specific compiler takes this code, and generates skeleton and stub code for each class, attributes and operations upon that class. The skeleton code includes all the code needed to support a server-side application for hosting the remote resource. There is code generated for the client side; it includes all code necessary for calling the remote object and simply makes the remote objects appear as if they were located "in" the host application. These requests from the application are all processed via an Object Request Broker (ORB) which, as its name suggests, brokers requests between objects. By this seemingly heavy and complex set of procedures, it is possible to build robust, integrated applications including distributed resources running on different platforms, using different languages.

The European Bioinformatics Institute (EBI), in particular, invested a great effort in providing CORBA solutions for many services, including EMBL (http://corba.industry.ebi.ac.uk) [40, 67, 69]. The Object Management Group (OMG) formed the Life sciences Research Group (LSR) that has developed several standards for services including bibliography and sequence resources (http://www.omg.org/lsr). However, the uptake of CORBA by the community has not been widespread. The main reasons for this have been the perception that CORBA is too heavyweight a mechanism – the large effort required to develop the standards seen as necessary by the Object Management Group (OMG) and the implementations themselves obstructed development. Many of the early ORBs were expensive and focused on enterprise-level computing, which did not fit well with the bioinformatics cottage industry. In addition, many ORBs themselves did not actually inter-operate. Finally, CORBA seemed to be plagued by continual problems with tunneling through firewalls, defeating the promise of location independence.

4.3 Web Services

Web services [25] take the same basic approach to distribution as CORBA, but with several significant differences. At heart, both take a description of a service being offered, and produce code for developing clients and servers. Web services takes the view that distributed tools and data are offered as "services" to applications that wish to use them. Any such service-orientated architecture has the following components:

- A standard communication protocol between services and host applications.
- A uniform data representation and exchange mechanism.
- A standard language for describing the service's attributes and operations.
- A mechanism for registering and discovering web services.

All these have their counterparts in CORBA, but web services take advantage of developments in web technology not apparent during CORBA's earlier development. These are the standard Internet protocol HyperText Transfer Protocol (HTTP) and XML. The approach also tries to make delivering a Web Service as lightweight as possible.

The Simple Object Access Protocol (SOAP) is the channel used for communication between a web services provider application and a client application [25] (http://www.w3.org/TR/soap). SOAP re-uses HTTP for transporting messages. Messages are passed between services using XML documents. The structure for SOAP message includes an *envelope* and a *body*. The body itself describes a message to a service, for instance, a call to a particular operation or communicates failure. The envelope gives the metadata necessary for this invocation.

As CORBA's IDL is used to describe services, web services use another XML document type to describe services – Web Services Description Language

(WSDL). Just as with CORBA, these descriptions are compiled to generate client and server code. These can be for a variety of programming languages on a variety of platforms. Client and server, once deployed, are ready to pass SOAP messages between one another. Finally, just like CORBA's naming and trading services, web services need to be discovered for use. WSDL documents can be placed in a registry based on the UDDI framework and these registries can be searched to retrieve WSDL descriptions of interest. A user would then compile to generate a client and use information from the WSDL description to locate and use the service.

Web services take a different technology approach to that of CORBA. While the latter uses a remote object approach which provides the ability for passing around data and subsequent fine grained client–server interaction with that data, web services use a "document-based" paradigm. Here, potentially complex structured data is passed between services in bulk. The hope is that instead of a series of fine-grained interactions between client and server, fewer coarser, but richer, interactions will happen – something of clear benefit when faced with any serious problems of network latency or failure.

Web services have already seen a much higher uptake than did CORBA. Taverna, a bioinformatics workflow editor [63], can currently access over 1000 web services, with many of these being third-party services. Stein [75] sees web services as the technology that has the possibility of uniting the fragmentary bioinformatics world. Where CORBA took the resources of a large institution to deploy, web services can easily be provided by a single user. This is why we already see many services provided by many institutions.

4.4 P2P

P2P architecture models a network of autonomous systems as a graph of nodes called peers (Figure 4b). Unlike the client/server architecture (Figure 4a) used in distributed computing models where some computers are dedicated to serving others, in the P2P architecture all participants can be alternatively clients or servers in the network. In a P2P architecture participants rely on one another for service as each peer is expected to offer a service, typically sharing its CPU with other peers.

Many P2P networks have been developed and the evaluation of such architectures has been published in multiple papers (a useful bibliography maintained until 2003 is available at http://www.cs.toronto.edu/db/hyperion/bibliography.html). Often P2P systems have been developed for sharing data over the web. For instance, Napster is a P2P network devoted to sharing music. Still, such systems can also be used in domain-specific contexts such as bioinformatics where scientists cannot only share their CPUs, but also

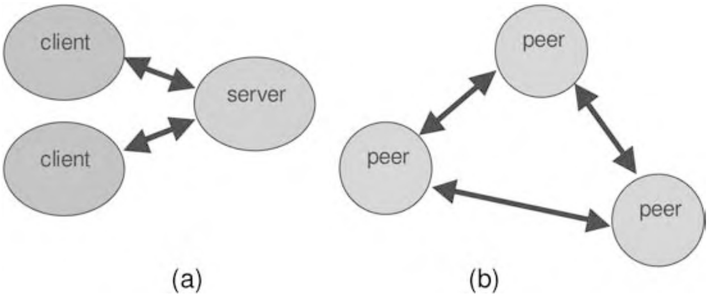

Figure 4 (a) Client–server. (b) P2P

share integrated resources, access to databases or applications alike. Such communities are implemented as *grids*.

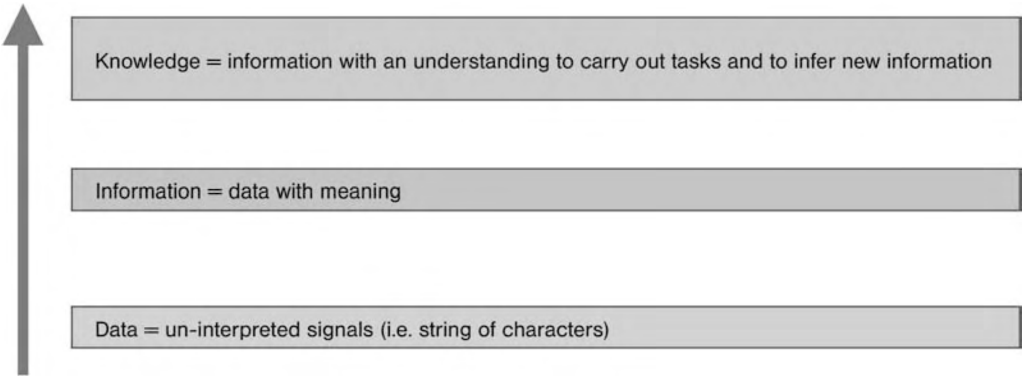
4.5 Grid

It is easy to see how the Grid paradigm (see Chapter 44) of sharing resources fits into the world of bioinformatics: a sophisticated, complex bioinformatics *in silico* experiment may involve people, many forms of data, instruments, etc., and all of these could share resources in a Grid [36].

High-throughput biology is forcing bioinformaticians to adopt distributed computing solutions, such as Grid, within bioinformatics – it simply has to happen. In addition, many bioinformatics resources have realized the need to overcome the problems of semantic integration (see Section 5). From the technical side, web services and Grid computing are coming together to form a potentially lightweight, transparent access to the problems of system heterogeneity and distribution. On a more prosaic level, funding bodies see the Grid as a potentially high-impact area and funds have been available for large scale projects using these technologies. Finally, much of the Grid and web world follows an open-source agenda, suggesting a larger uptake of the technology. Despite the continuing problems described below, the cases described in Chapter 44 suggest that some aspects of integration will become much easier.

5 Semantic Integration

A challenge in data integration is to properly understand the data provided by a resource such that they are meaningfully integrated. To address this challenge, there is a need to integrate or at least make use of information and knowledge rather than data only, and exploit all the information related to the way the resource makes these data available. As illustrated in Figure 5, we



Knowledge = information with an understanding to carry out tasks and to infer new information
Information = data with meaning
Data = un-interpreted signals (i.e. string of characters)

Figure 5 From data to knowledge.

refer to *data instance* as a string of characters carrying no meaning, because no context or metadata are given. In contrast, we speak of *information* and *knowledge* when additional metadata and context information provide some level of meaning or "understanding" of the data. For example, *tp53* without further context is only a data string of four characters, while *gene TP53* can be considered information, with "gene" providing a minimal context to help a human or a system "interpret" the subsequent data string.

Metadata are data about data and thus are used to describe the content, context, and "meaning" of a resource. Metadata add value to the data so that together they define information. For example, a data source using a relational table called "gene" with an attribute "symbol" provides the structural terms gene and symbol as metadata. When extracting the value TP53 from the resource, this is only a string of characters, but with the knowledge that TP53 is the value of attribute symbol of table gene, we obtain information: *gene symbol TP53*. (In a data integration context, the context/metadata string "gene" might help the system determine which tables to access to find related information. Moreover, "gene" might be a term from a controlled vocabulary or a concept from an ontology, thus providing additional context information about "TP53".)

A complementary challenge in data integration is to provide users with a meaningful view of the integrated data set. While data may be internally represented and stored in a complex data structure poorly reflecting the users' understanding of the data, it is critical that the users are provided a meaningful view of the data set. Such a view is closer to the conceptual view as expressed with ER. In this section we present some approaches that exploit semantics to either provide useful metadata to facilitate data integration or to specify the overall organization of integrated data to users.

5.1 Identifying Objects

Each time a scientific object is stored in a data repository (e.g. a database) it is typically assigned an identifier. The problem is that as the number of resources providing information about each scientific concept (e.g. protein) increases, the number of identifiers for each instance of the concept multiplies. Although two data sources may provide information about the same concept, the challenge for integrating the data from the two resources relies on the mapping of two different identifiers. Sometimes, a scientific entity has not only as many identifiers as the number of data sources that contain information about it, but it does not possess a name upon which the entire community agrees. These combined discrepancies make it very difficult for humans and systems alike to refer to entities without ambiguity. To overcome the lack of naming process, the scientific community has adopted identifiers to name, or to refer to in an unambiguous way, the scientific objects. Examples of this adoption mechanism can be found with literature references typically identified for PubMed identifiers and sequence accession numbers from GenBank. Once these identifiers are adopted by the community, they become new attributes for most of the resources providing information about the scientific concept to which they refer. (In general, while referring to the commonly accepted identifier, the data provider still keeps its redundant internal identification process.) This avalanche of different ways of identifying an instance may be overcome by various resources that aim at providing for each entry the mapping between many existing identifiers in various data sources. GeneCards [66] and Genew [86], both databases of human genes, can be seen as playing this role. The effort to resolve conflicts in identification in life sciences led the Object Management Group (OMG) together with the Interoperable Informatics Infrastructure Consortium (I3C) in conjunction with vendor members including Sun Microsystems and IBM to design an identifying framework called Life Science Identifier (LSID) that locates scientific entries within the resource that hosts them (http://www.omg.org/technology/documents/formal/life_sciences.htm). These identifiers play a role similar to URLs to locate web pages. LSID uses a uniform resource name (URN) that contains five parameters that uniquely identify the data of interest [73]. An example of an LSID is: urn:lsid:ncbi.nlm.nig.gov:GenBank:T48601:2. The five parameters are: a mandatory preface for LSID data (urn:lsid), the Internet domain of the organization that assigned the LSID to the data (ncbi.nlm.nig.gov), the name of the data source (GenBank), and the last two parameters are the name or identifier as defined by the data source authority (T48601) and version number (2) of the scientific entry. The use of identification frameworks such as LSID offers numerous benefits. It clarifies the identification of scientific objects with respect to each data provider. Instead of refereeing to an often meaningless string (e.g. T48601) whose interpretation may be ambiguous, identifiers such as LSIDs carry enough context information to avoid misinterpretations and ambiguity. Obviously, such identifiers will be valuable to express the multiple links between entries among heterogeneous distributed resources. Another advantage of LSID is that when automatically processed, systems cannot only access the data source (the URL is included in the URN), but also may link that resource with a known data entry format (e.g. a XML DTD) in order to process automatically the entry once retrieved [73]. The involvement of database management systems vendors in the design of this identification format illustrates the need for meaningful identification in the life science. However, using such a common format to identify scientific objects does not resolve the problem of unique identification. For example, the two distinct LSIDs urn:lsid:au.expasy.org:SwissProt:U64442:1 and urn:lsid:www.gene.ucl.ac.uk:HUGO:APC both refer to the same scientific object hosted in two different data sources, respectively UniProtKB and Genew. Resources aiming at maintaining identification mappings between resources combined with a specific and meaningful identifier such as offered by LSID may be the solution to the current challenge of identification and location of scientific data. Although LSID will not solve the problem of redundant identification of scientific objects, it will facilitate the unambiguous mapping of equivalent identifiers for better data integration. Various viewpoints or contexts may affect the meaning of scientific object identity and, thus, life science identifiers should have the ability to match the different senses of "sameness" that pervade the life sciences [68].

5.2 Representing Metadata

Data are only as useful as the metadata that accompany them. Metadata, the data about data, inform the user, whether computer or human, about how to interpret those data. We use metadata at every stage of any bioinformatics representation or analysis. Take, for instance, a UniProt/Swiss-Prot record. The real data, the sequence itself, is only a small proportion of the record. Most of the record is taken up with management information (accession numbers, identifiers, change dates, etc.), descriptive metadata (gene names, species, organelles, keywords, meaningful names, etc.) and then broader and more detailed knowledge about the sequence (individual features, comments on disease and function, etc., cross-links to other databases, bibliographic references, etc.). All this is metadata about the sequence. Of course, what is viewed as metadata depends on where the user is standing – we are well acquainted to using metadata as data. There is data about data about data, etc.

How should all these metadata be represented so that they are most useful? Data without metadata are almost useless, but the usefulness of those metadata very much depends on their representation. Metadata can be captured in a whole spectrum of presentations: natural language (glossaries), structured vocabularies, frame-based representations, formal systems, through to logic representations. This spectrum covers the range from that only really interpretable by humans to that interpretable by computers and, with some help, by humans.

Bioinformatics metadata fall into two categories – the schema that structures the data and the values that describe the data. For most of its history, the bioinformatics community has used natural language or stylized natural language to describe its data. In the early days, with little data, this was easy, as only humans used those metadata. With the growth of volumes of data and creeping heterogeneity at the semantic level, this simple approach became untenable.

Controlled vocabularies were the next step. Simple keywords were used to describe database entries, such as Swiss-Prot keywords, and eventually these keywords were defined. We now see the growing use of vocabularies generated from ontologies to provide semantically rich, consistent metadata. Similarly, structures for data have moved from proprietary ASCII encodings to increased used of relational schemata, XML and also ontologies to provide the structure in which values are placed. Various efforts to integrate data demonstrated the role of generic schema and structured vocabularies, which will be described below.

The Resource Description Framework (http://www.w3.org/TR/rdf-concepts) is one of a range of technologies that aims to support the Semantic Web. This is the vision for the next stage of the development of the web, where it will move from an artifact only really interpretable by humans to one interpretable by both humans and computers [6]. This move is predicated upon the use of metadata that will describe both the content and services available on the web. The Resource Description Framework (RDF) is the means by which this metadata will be provided.

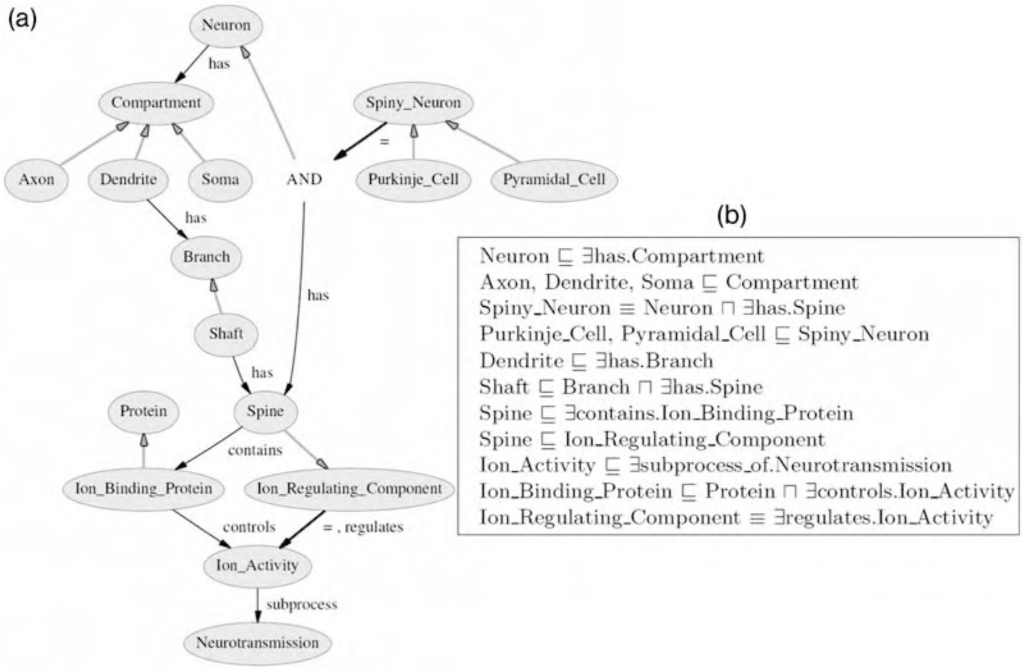
RDF uses a system of triples – a subject, a predicate and, finally, an object – to describe resources. For example, a resource or subject might be a UniProt/Swiss-Prot record, a predicate would be "has accession number" and the object would be "P21598". The object can be another resource, rather than only a value, so we could describe that sequence A is similar to sequence B. Each of these elements has its own URN (see above) to identify it. The mass of triples forms a graph describing resources. What is important is that the RDF triples have a simple, but formal semantics. This means that they are easily exported from data sources into this simple format and then interpretable by computers.

Graphs can be aggregated, stored in RDF stores [13, 91] and queried with SPRQL – an RDF query language (see http://www.w3.org/TR/2005/WD-rdf-sparql-query-20050721). We are beginning to see more data in bioinformatics described using RDF – UniProt/Swiss-Prot (http://www.isb-sib.ch/∼ejain/ rdf) and Affimetrix (http://www.affymetrix.com/community/publications/affymetrix/tmsplice/index.affx) provide a great deal of genomic data described using RDF. YeastHub [22] is an example of integration using RDF technology. Here, a series of third-party yeast resources are simply transformed into RDF and automatically integrated by virtue of RDF's simple data model.

Whatever the representation for these metadata is, they have to represent a shared understanding for their domain. As already described, one of the main barriers to integration is the heterogeneity in the semantics of the data being integrated. Integration becomes much easier if the semantics of those data are described in a form that captures the understanding of their community [79]. The most conspicuous example of this is the Gene Ontology (GO)'s use for describing the major attributes of molecular functionality across bioinformatics [81]. Similarly, we see generic representation of schema for certain domains, such as pathways in BioCyc [46], protein families [92] and in XML schema for many domains [44,88]. One technique for describing both the structure and values for a domain are ontologies and these will be described in the following section.

5.3 Ontologies and Data Integration

In the following, we briefly introduce ontologies and describe the role they play in the context of data integration; for a detailed exposition of ontologies in molecular biology see Chapter 29. In computer science, *ontologies* are artifacts used to (partially) formalize a domain of interest by identifying and uniquely naming relevant concepts and the relationships between them. In the broadest sense of the word, controlled vocabularies, thesauri and taxonomies (classification hierarchies), even database schemata are sometimes called ontologies. In the narrower sense, ontologies are often defined to be "explicit and formal specifications of a conceptualization" [37]. Description logics (DLs) are decidable fragments of First Order (FO) logic that are often used to define ontologies. [This means that there are algorithms for answering certain questions, e.g. is concept C subsumed by concept D (an implication problem), is a concept definition satisfiable or consistent with another concept, etc.] The vocabulary of a DL ontology consists of a set of *concept* (or *class*) names and a set of *roles* or *relationships* which are used to interrelate concepts. Specifically, an ontology consists of a set of *axioms* interrelating concept names



$\text{Neuron} \sqsubseteq \exists\text{has.Compartment}$
$\text{Axon, Dendrite, Soma} \sqsubseteq \text{Compartment}$
$\text{Spiny\_Neuron} \equiv \text{Neuron} \sqcap \exists\text{has.Spine}$
$\text{Purkinje\_Cell, Pyramidal\_Cell} \sqsubseteq \text{Spiny\_Neuron}$
$\text{Dendrite} \sqsubseteq \exists\text{has.Branch}$
$\text{Shaft} \sqsubseteq \text{Branch} \sqcap \exists\text{has.Spine}$
$\text{Spine} \sqsubseteq \exists\text{contains.Ion\_Binding\_Protein}$
$\text{Spine} \sqsubseteq \text{Ion\_Regulating\_Component}$
$\text{Ion\_Activity} \sqsubseteq \exists\text{subprocess\_of.Neurotransmission}$
$\text{Ion\_Binding\_Protein} \sqsubseteq \text{Protein} \sqcap \exists\text{controls.Ion\_Activity}$
$\text{Ion\_Regulating\_Component} \equiv \exists\text{regulates.Ion\_Activity}$

Figure 6 Ontology in graph form (a) and formalized in DL (b).

and relationships, thereby constraining the set of possible interpretations for these symbols.

In the context of databases, ontologies may be used to describe the information pertaining to a particular scientific object, thus providing the foundation for data characterization and schema definition. Such usage is presented in detail in Chapter 29. Another use of ontologies consists of the description of how various scientific objects interact. With an ontology, one may define an integrated conceptual model (see Figure 3 in Section 3.1). This second usage mentioned in Chapter 29 is described in detail in this section.

5.3.1 **Example**

Figure 6 depicts an ontology in graph form (left) with oval *nodes* representing concepts of interest (here from a neuroscience domain: Neuron, Axon, Dendrite, etc.) and *labeled directed edges* expressing binary relationships between concepts. For example, has(Neuron, Compartment) means that every Neuron has some Compartment(s); the upward unlabeled arrow means "is a", e.g. isa(Soma, Compartment), i.e. soma is a compartment. In the center-right of Figure 6 the ontology axioms are given as formulas in DL (logical constraints). For example, the first line in the DL ontology is syntactic sugar for the FO logic formula:

$$\forall x\ [\text{Neuron}(x) \rightarrow \exists\, y\ \text{has}(x, y) \wedge\ \text{Compartment}(y)],$$

which states that if x is a neuron, then there exists some y which is part of x (i.e. "x has y") and which is a compartment.

5.3.2 **From Information to Reasoning**

Domain knowledge expressed in DL can be seen as a kind of "formal metadata", potentially capturing more semantics than their informal cousins, i.e. controlled vocabularies, simple taxonomies and thesauri:

- As mentioned earlier, *controlled vocabularies* already provide a simple mechanism for uniquely and consistently naming object classes of interest. However, there is little additional functionality – beyond consistent naming, which already is a significant achievement in practice – that is offered by controlled vocabularies.

- A *taxonomy* provides a classification mechanism, typically expressed as a subclass–superclass relationship. In biology, a taxonomical unit (*taxon*) is a named group of organisms. Taxa are organized into a hierarchical scheme. Traditionally, scientific names have been directly used as taxa, but this leads to ambiguities due to changes in the naming schemes and the meaning of a name over time [43].

- A *thesaurus*, creates relationships between terms of interest using special relationships such as "broader_than(x,y)" and "synonym(u,v)", stating that the term/concept x is broader than y, and that u and v can be used interchangeably. It is easy to see that an information retrieval system or a database system can exploit such information when answering user queries. In particular, when a user asks for information on x, then synonyms and subconcepts of x (and sometimes even superconcepts) can be listed. (The same is true for taxonomies.)

Ontologies can further refine the domain knowledge capture by providing additional constraints that the other formalisms cannot provide. A basic idea of ontologies, especially when formalized as DL axioms, is to define (new) concepts in terms of other (given) concepts. For example, in Figure 6, we define the constraint expressing that for something to be a *Spiny_Neuron*, it is necessary and sufficient to be a neuron and to have spines; in DL:

$$\mathit{Spiny\_Neuron} \equiv \mathit{Neuron} \cap \exists \mathit{has.Spine}.$$

Translated into FO logic this statement becomes:

$$\forall x\ [\mathit{Spiny\_Neuron}\ (x) \leftrightarrow [\mathit{Neuron}(x) \wedge \exists y\ \mathit{has}(x, y) \wedge \mathit{Spine}(y)]].$$

From this logic axiom it follows the following statement (among others): spiny neurons are a subclass of neurons.

In order to compare the modeling capabilities of the different formalisms, consider, for example, a controlled vocabulary that includes the terms *Monocyte*, *Leukocyte* and *Macrophage*. The use of such a vocabulary limits (in a positive sense) the number of "allowed terms", e.g. when annotating a microscopic image. A thesaurus or taxonomy based on this vocabulary can add more information, e.g. by saying "isa(*Monocyte*, *Leukocyte*)" or "synonym(*Monocyte*, *Macrophage*)". In this way, when running a database search for "*Leukocyte*" or "*Macrophage*" related information, a system can take the information captured by the thesaurus or taxonomy to expand the search in a way that guarantees that all relevant data is returned. Using an ontology, even more information can be specified. For example, we might want to define that macrophages are those monocytes that occur in tissue:

$$Macrophage \equiv Monocyte \cap \exists occurs\_in.Tissue.$$

Additional information could be captured in an ontology, e.g. on the process that has a monocyte move into the tissue.

5.3.3 Biological Ontologies

Over the years, life science has generated multiple vocabularies and more complex conceptual models to organize, represent, and share scientific knowledge. The Medical Subject Heading (MeSH) published by the National Library of Medicine is a controlled vocabulary used for indexing articles of Medline/PubMed (the complete description of MeSH is available at http://www.nlm.nih.gov/mesh/meshhome.html). The 22 568 MeSH descriptors include broad headings (e.g. anatomy) and specific ones (e.g. ankle) arranged in both an alphabetic and a hierarchical structure, and linked with thousands of cross-references that assist in finding the most appropriate MeSH Heading. An example of a large meta-thesaurus (i.e. combing information from multiple thesauri) is the Unified Medical Language System (UMLS) from the National Library of Medicine (http://www.nlm.nih.gov/research/umls/umlsmain.html). A prominent biological ontology is GO. The GO project is a collaborative effort to address the need for consistent descriptions of gene products in different databases (http://www.geneontology.org). It aims at capturing information about molecular functions, biological processes and cellular components. Additional biological ontologies include RiboWeb which structures the ribosome as well as supplementary functional data (http://smi-web.stanford.edu/projects/helix/riboweb.html) and the Fungal Anatomy Ontology (FAO) (http://www.yeastgenome.org/fungi/fungal _anatomy_ ontology/index.html) which is a controlled vocabulary that describes the anatomy of fungi and other microbes.

Conceptual models in all their forms, from the simpler vocabularies to the most complex and expressive logics, are increasingly used for biological data integration. They are used to provide meaningful annotations to biological data to improve data access or data sharing and integration through textual search engines. Examples of such uses include the interface provided by NCBI to search PubMed visa MeSH terms (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db =mesh) and the annotations of EBI. UniProt UniProtKB/Swiss-Prot has joined the GO Consortium and has adopted its standard vocabulary to characterize the activities of proteins (http://www.ebi.ac.uk/GOA). Ontologies may be used to provide users with a meaningful data representation of integrated data as explained in Section 3.1 and illustrated in Figure 3(a). A precursor was TAMBIS developed at the University of Manchester (see http://imgproj.cs.man.ac.uk/tambis) [79]. More recently, KIND, like TAMBIS, has combined mediation and ontology approaches to integrate heterogeneous autonomous data sources [55]. KIND was developed at the Super Computer Center of San Diego (http://www.npaci.edu/DICE/Neuro). Current approaches aim at mapping not only scientific concepts, but also scientifically meaningful relationships [50]. Conceptual models may also be used to provide scientists valuable support when exploring the wide scope of available resources to express their scientific protocols. Path-based guiding systems use conceptual models to annotate the graph of existing biological resources (databases and applications) and return paths on physical resources to evaluate scientific protocols expressed against the conceptual model. BioGuide [24] (http://www.lri.fr/∼cohen/bioguide/bioguide.html) and BioNavigation [50] (http://bioinformatics.eas.asu.edu/BioNavigation.html) are examples of such systems.

5.3.4 **Ontologies and Data Integration**

Figure 7 illustrates a number of uses of ontologies and articulations (mappings between ontologies) in a data integration setting [11, 55]. Figure 7(a) shows an architecture which includes, in addition to standard data access services (e.g. to run SQL queries on a database), also "registration services" to register schemata of data sources with one or more ontologies. Based on these source-to-ontology mappings, a semantic mediation service can support interlinking and grouping of data based on conceptual level information (Figure 7b). Sometimes more than one ontology needs to be considered. In this case, *articulations*, i.e., mapping between ontologies, can be employed, essentially creating a "merged ontology".

When resources already provide a description of their data with ontologies, these ontologies need to be integrated to integrate the underlying data sets. When several ontology editors such as Protégé [60] (a free, open-source ontology editor and knowledge-base framework developed at Stanford and

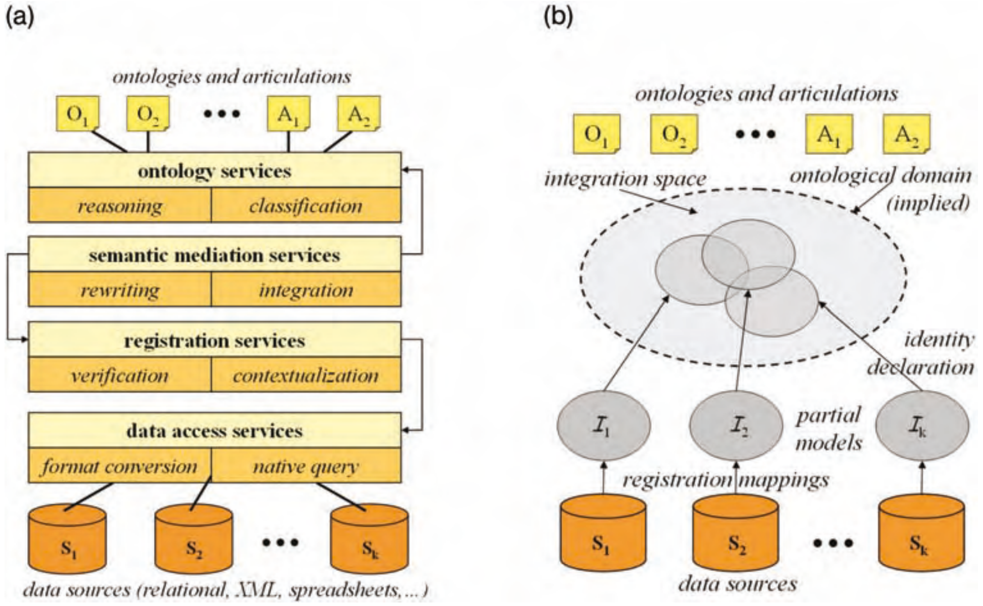


Figure 7 Semantics-enhanced data integration architecture (a) and integration mappings from the data domain to the ontological domain (b) (see Ref. [11]).

available at http://protege.stanford.edu), Chimaera [59] (developed at Stanford and is available at http://www.ksl.stanford.edu/software/chimaera) or OilEd [4] (an ontology editor developed at the University of Manchester and available at http://oiled.man.ac.uk) allow scientists to define and manage their ontologies, systems such as PROMPT [62] and ONIONS [23, 35, 65] (http://www.loa-cnr.it/Ontologies.html) allow the integration (merging) of ontologies, thus facilitating the data integration process.

5.4 Semantic Web

The Semantic Web [6] is a project for developing technologies and standards that capture some of the semantics of documents, particularly web documents. The vision is that Semantic Web technologies will enhance conventional searching, browsing and integration techniques by taking advantage of machine-processable annotations of documents and data. The Semantic Web can be viewed as a set of standards including XML, RDF and OWL (Web Ontology Language). A description of the features of the language OWL is available at http://www.w3.org/TR/owl-features. In general, the most up-to-date and complete information about the Semantic Web activity, including documents and announcements regarding related implementation, is available at the working group web site hosted at the World Wide Web Consortium (http://www.w3.org/2001/sw). XML, introduced in Section 2.3, is a format developed to exchange data over the web. RDF introduced in Section 5.2 is the framework developed to describe resources on the Web. OWL is a family of web ontology languages, i.e. OWL-Lite, OWL-DL and OWL-Full. OWL-Lite supports classification hierarchies and simple constraints and is easy to process, whereas OWL-DL corresponds to a DL, i.e. a decidable fragment of FO logic. OWL-DL is more expressive than OWL-Lite, while retaining computational completeness, i.e. questions about whether an OWL-DL formula is implied by a set of OWL-DL axioms (an ontology) are still decidable. In contrast, OWL-Full offers maximum expressiveness, but is no longer decidable. A logic is decidable if there exists an algorithm such that for every formula the algorithm is capable of deciding in finitely many steps whether the formula is valid or not. A decidable logic allows a mechanism to answer questions expressed in the logic, thus validating or not any given statement. As biological ontologies aim at allowing reasoning about scientific objects, it is critical to provide a validation process, therefore to use a decidable language to express statements. OWL constructs include mechanisms for identifying resources (RDF schema features), property restrictions (e.g. quantifications such as allValuesFrom), class interaction (e.g. intersection Of), comparison operations (e.g. equivalentClass), restricted cardinality (e.g. minCardinality), versioning (e.g. priorVersion), property characteristics (e.g. SymmetricProperty) and annotations. All terms cited are OWL constructs as specified in the OWL Guide (http://www.w3.org/TR/owl-guide). This set of constructs allows the reasoning about resources and thus can be exploited to achieve meaningful data integration.

Many technical issues underlying the Semantic Web, e.g. automated deduction and graph-based knowledge representations, have been studied extensively. The importance of the Semantic Web lies in the adoption of standards for metadata, knowledge representation and reasoning, and thus the potential leverage for joint tools and services. For more information on the Semantic Web, see http://www.w3.org/2001/sw and http://en.wikipedia.org/wiki/Semantic_Web.

6 Scientific Workflows

Scientific workflows are becoming recognized as an important unifying mechanism for combining scientific data management, analysis, simulation and visualization tasks, as witnessed by the following recent examples:

Meetings

- Scientific Data Management Framework Workshop, Argonne National Labs, August 2003, http://sdm.lbl.gov/∼arie/sdm/SDM.Framework.wshp.htm
- Sixth Biennial Ptolemy Miniconference, Featuring the Kepler Project, May 2005, UC Berkeley;
- LINK-Up Workshop on Scientific Workflows, San Diego Supercomputer Center, October 2004, http://kbis.sdsc.edu/events/link-up-11-04

Workshops

- Workflow in Grid Systems Workshop, GGF10, Berlin, March 2004, http://www.extreme.indiana.edu/groc/Worflow-call.htm
- e-Science Grid Environments Workshop, e-Science Institute, Edinburgh, May 2004, http://www.nesc.ac.uk/esi/events

Special issues devoted to the topic [27, 54].

Roughly speaking, the goal of scientific workflows is to capture scientific data handling, processing, and visualization steps in a way that facilitates repeated execution (often with different parameter settings or varying input files), possibly "steered" and guided by runtime user interactions. Other goals include reuse of workflows and workflow components (tasks, modules, steps, or actors), documentation and sharing of workflows, and capturing data provenance of the products created through a workflow. The various aspects of data integration, as discussed above, can often be considered as specific (often upstream) tasks of a larger workflow or data analysis pipeline, with downstream analysis and visualization components. In a sense, scientific workflows complement the more "static" *data integration* obtained by wrapping scientific data sources at the schema or conceptual level (e.g. via ontologies) and resulting in integrated or mediated data sources, by providing a dynamic *process integration* which includes elements of data integration at various stages or steps, but which also encompasses the overall scientific data management and analysis workflows that scientists need to consider as part of their scientific investigations.

6.1 Example: Promoter Identification Workflow (PIW)

Figure 8 shows a high-level, conceptual view of a typical scientific "knowledge discovery" workflow that links genomic biology techniques such as microarrays with bioinformatics tools such as BLAST to identify and characterize eukaryotic promoters – we call this the PIW (see also Refs. [53, 64,

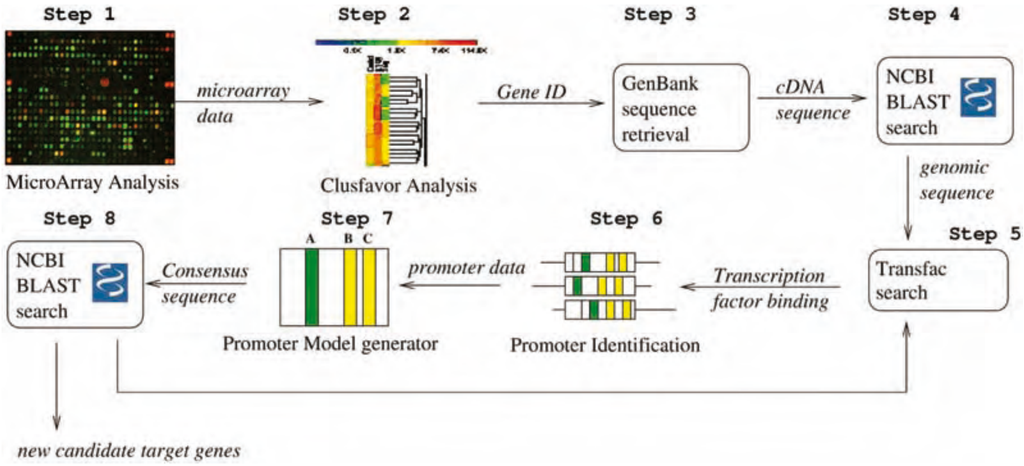

Figure 8 Conceptual ("napkin drawing") view of a PIW.

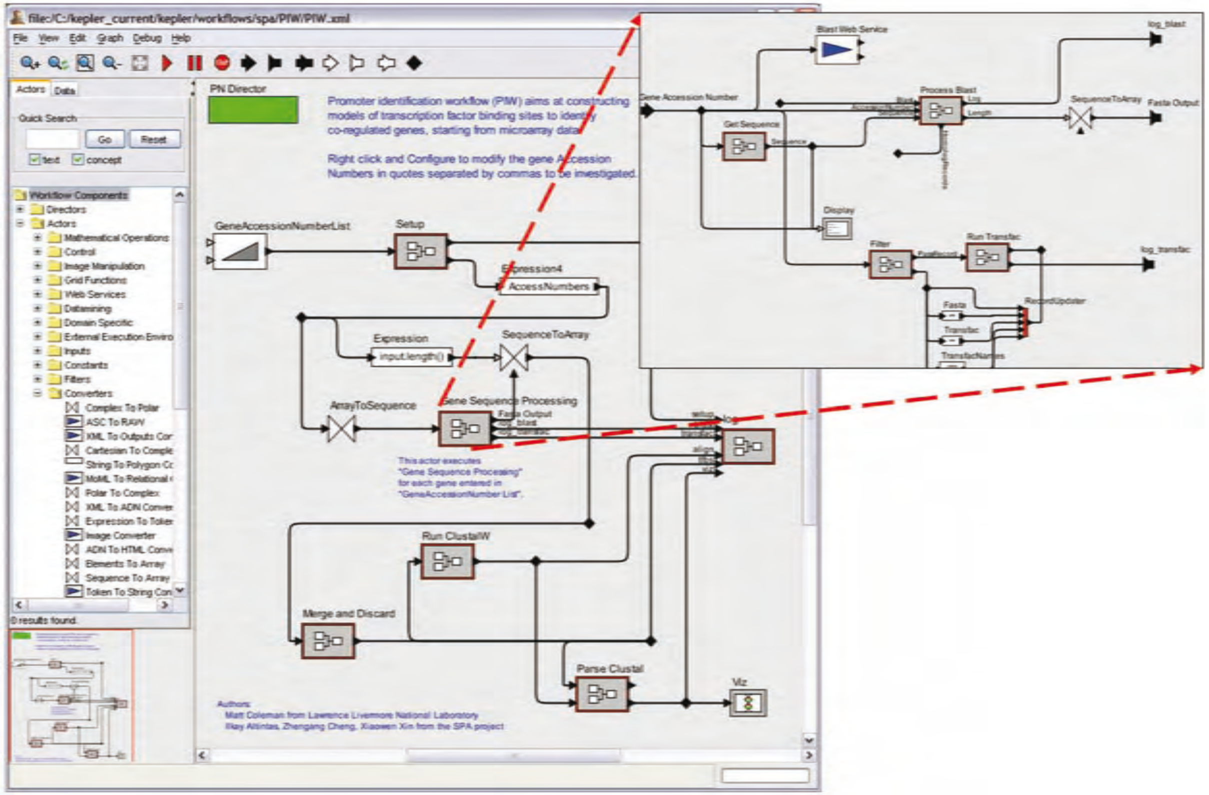
87]). Starting from microarray data, cluster analysis algorithms are used to identify genes that share similar patterns of gene expression profiles that are then predicted to be coregulated as part of an interactive biochemical pathway. Given the gene identifiers, gene sequences are retrieved from a remote database (e.g. GenBank) and fed to a tool (e.g. BLAST) that finds similar sequences. In subsequent steps, transcription factor-binding sites and promoters are identified using specialized tools to create a promoter model that can be iteratively refined. While Figure 8 leaves many details open, some features of scientific workflows can already be identified: there are a number of existing databases (such as GenBank) and computational tools (such as Clusfavor and BLAST) that need to be combined in certain ways to create the desired workflow. Even at this "napkin-drawing" level, scientific workflows are often data-centric, with edges corresponding to the dataflow between different computational components or databases. Unlike conventional (e.g. Unix) pipelines, scientific workflows may involve loops (such as the one from Step 8 to Step 5 in Figure 8) and often include explicit user interaction, e.g. to determine revised parameter settings, threshold values, etc., or the selection of data objects to be passed on to downstream steps.

In the past, accessing remote resources often meant implementing a wrapper that mimics a human entering the input of interest, submitting an HTML form, and "screen-scraping" the result from the returned page [52]. Today, more and more tools and databases become accessible via web services, avoiding low-level screen-scraping steps. Another trend is the development of web portals such as NCBI (http://www.ncbi.nlm.nih.gov). Nevertheless, chaining together workflow components, whether they are web services or other applications that are invoked, e.g. through shell commands or scripts, creates a number of problems that are similar to those found in data integration and thus can be similarly addressed, e.g. the various components are typically developed by independent parties and thus often do not use the same exchange format. Even if a common exchange (meta-)language such as XML is used, the different concrete XML schemata or DTDs being used require additional data transformation and schema mappings steps, such that the output of component $n - 1$ fits the structure of the input required for component n. Special intermediate components that can reconcile structural and/or semantic heterogeneities are sometimes called *shims* [41] or *adapters* [12] and can be seen as the workflow equivalents of wrappers or mediators in "conventional" data integration.

Figure 9 depicts a snapshot of an implementation of (part of) PIW in Kepler (http://kepler-project.org) [53]. Kepler is an extension of the Ptolemy II system specifically designed for scientific workflows. The Ptolemy project studies modeling, simulation and design of concurrent, real-time, embedded systems with a focus on assembly of concurrent components (http://ptolemy.eecs.berkeley.edu/ptolemyII). Using Ptolemy II terminology, we call the individual workflow steps *actors*, since they act as completely independent components which communicate with each other only through the dataflow channels indicated in Figure 9. A mechanism for collapsing details of a sub-workflow into an abstract component (called *composite actor* in Kepler) is essential to tame complexity. The upper-right window in Figure 9 has well-defined input and output ports, and thus corresponds to a (sub)-workflow that can be collapsed into a more abstract, composite actor (called "Gene-Sequence-Processing") as shown. Also, backward loops as the one in Figure 8 can often be avoided by incorporating higher-order collection programming constructs (known from functional programming, e.g. "map" or "fold") in the visual workflow language, resulting in a more comprehensible overall workflow model.

6.2 Scientific Workflow Requirements and Desiderata

Many scientific workflows exhibit a number of common "stages" or steps such as the following: (i) discovery of data sets, often by browsing and searching based on metadata of the data sets, (ii) querying and retrieval of the relevant data sets or parts of them, (iii) application of an "analysis pipeline" – in one or more analytical steps, e.g. cluster analysis – to the data sets, (iv) visualization and comparison of the results by the user, (v) repetition of some or all of the above, possibly with changed parameters and/or data sets until the user achieves a satisfactory result, and (vi) registration and storage of the analysis results along with workflow execution metadata (e.g. to facilitate repeatability of a workflow run).



Promoter identification workflow (PIW) aims at constructing models of transcription factor binding sites to identify co-regulated genes, starting from microarray data.

Right click and Configure to modify the gene Accession Numbers in quotes separated by commas to be investigated.

This actor executes "Gene Sequence Processing" for each gene entered in "GeneAccessionNumber List".

Figure 9 Executable PIW in Kepler [53]. The composite actor (center) contains a nested sub-workflow (upper right). Workflow steps include remote service invocation and data transformation and analysis steps. An overall model of execution is enforced by a Process Network (PN) director (green box, upper left).

Scientific workflows often exhibit particular “traits”, e.g. they can be data intensive, computer intensive, analysis intensive and visualization intensive [53]. Depending on the intended user group, one might want to hide or emphasize particular aspects and technical capabilities of scientific workflows. For example, a computational biologist with extreme computational requirements and producing very large volumes of data might be interested in low-level workflow aspects such as data movement and remote job control. Thus, having workflow components (or actors) that operate at this level will be beneficial to the computational scientist. Conversely, a scientific workflow system should hide such aspects from analytical scientists who do not need specialized data and cycle management.

From a technical viewpoint, the following requirements and desiderata are often found in connection with scientific workflows:

R1 Seamless access to resources and services. This is a very common requirement, and web services provide a first, simple mechanism for remote service execution and remote database access via service calls. However, web services are a simple solution to a simple problem. Harder problems, e.g. web service orchestration and third-party transfer, are not solved by “vanilla” web services alone.

R2 Service composition and reuse, and workflow design. Since web services emerge as the basic building blocks for distributed Grid applications and scientific workflows, the problem of service composition, i.e. how to compose simple services to perform complex tasks, has become an attractive research topic [80]. Among the different approaches are those that view service composition as an artificial intelligence planning problem [9], a query planning problem [55, 56] or a general design and programming problem. A related issue is how to design components such that they are easily reusable and not geared to only the specific applications that may have driven their original development. By employing an actor-oriented approach at the design level [12], but also flexible means for data transformations and data integration at the “plumbing” level, the reusability of workflows and workflow components can be improved.

R3 Scalability. Some workflows involve large volumes of data and/or require high-end computational resources, e.g. running a large number of parallel jobs on a cluster computer. To support such data-intensive and computer-intensive workflows, suitable interfaces to Grid middleware components (sometimes called Compute-Grid and Data-Grid, respectively) are necessary. For example, the Kepler system includes actors to launch and monitor Globus jobs and to issue Storage Resource Broker (SRB; http://www.sdsc.edu/srb) commands for that purpose.

R4 Detached execution. Long-running workflows require an execution mode that allows the workflow control engine to run in the background on a remote server, without necessarily staying connected to a user's client application that has started and is controlling workflow execution.

R5 Reliability and fault-tolerance. Some computational environments are less reliable than others. For example, a workflow that incorporates a new web service can easily "break", as the latter can often fail, change its interface or just become unacceptably slow. To make a workflow more resilient in an inherently unreliable environment, contingency actions must be specifiable, e.g. fail-over strategies with alternate web services.

R6 User interaction. Many scientific workflows require user decisions and interactions at various steps. For example, an improved version of PIW allows the user to inspect intermediate results and select and re-rank them before feeding them to subsequent steps. An interesting challenge is the need for user interaction in a detached execution. Using a notification mechanism the user might be asked to reconnect to the running instance and make a decision before the paused (sub-)workflow can resume.

R7 "Smart" reruns. A special kind of user interaction is the change of a parameter of a workflow or actor. For example, in a visualization pipeline or a long running workflow, the user might decide to change some parameters after inspecting intermediate or even final results. A "smart" rerun does not execute the workflow from scratch, but only those parts that are affected by the parameter change. In dataflow-oriented systems (e.g. visualization pipeline systems such as AVS, OpenDX, SCIRun or Kepler) this is easier to realize than in more control-oriented systems (e.g. business workflow systems), since data and actor dependencies are already explicit in the system. Another useful technique in this context is *checkpointing*, which allows for backtracking to a previously saved state, e.g. in the case of a parameter change or even a system failure, without starting over from scratch.

R8 "Smart" (semantic) links. A scientific workflow system should assist workflow design and data binding phases by suggesting which actor components might possibly fit together (this is also an aspect of *R*2) or by indicating which data sets might be fed to which actors or workflows. To do so, some of the semantics of data and actors has to be captured. However, capturing data semantics is a hard problem in many scientific disciplines, e.g. measurement contexts, experimental protocols and assumptions made are often not adequately represented. Even if corresponding metadata are available, it is often not clear how to best make it useable by the system. It seems clear though that ontologies provide a very useful semantic type system for scientific workflows, in addition to the current (structural) type systems [5, 11, 12].

R9 Data provenance. Just as the results of a conventional wet lab experiment should be reproducible, computational experiments and runs of scientific workflows should be reproducible, and indicate which specific data products and tools have been used to create a derived data product. Beyond the conventional capture of metadata, a scientific workflow system should be able to automatically log the sequence of applied steps, parameter settings and (persistent identifiers of) intermediate data products. A related desiderata is automatic report generation: The system should allow the user to generate reports with all relevant provenance and runtime information, e.g. in XML format for archival and exchange purposes, and in HTML (generated from the former, e.g. via an XSLT script) for human consumption.

6.3 Semantic Extensions and Scientific Workflow Design

One problem in designing scientific workflows lies in the increasing amount of components (and possibly sub-workflows) made available, e.g. as web services, SOAP-lab services [74], statistics packages (e.g. R packages) or as other custom applications. While web services provide a minimalistic interface definition of the various operations via the accompanying WSDL files, there are no standard means of helping the scientist or a scientific workflow system to determine whether two components/web service operations can be chained together. One promising approach is to separate the concerns of structural data typing and semantic data typing [5,12], i.e. to use conventional structural typing mechanisms (such as XML DTDs or schemata) to describe structural aspects of the data flowing between workflow components, but to use a *semantic typing* mechanism, such as an OWL concept expression, to describe what kind of data (at the conceptual level) is being exchanged.

Consider, for example, the Kepler workflow shown in Figure 10. A connection has been identified to be structurally safe – an array of integers is produced and consumed by the two connected actors – but semantically unsafe – the type checking window of the highlighted connection indicates this with a green, respectively red type status, next to the display of the structural and semantic port types. Note that to guarantee semantic type safety, (i) semantic types (concept expressions) have to be declared for actor ports and (ii) a reasoning engine has to establish that the desired concept subsumption relation holds. For structural type safety any of the common type systems can be used, e.g. XML DTD, XML Schema, or even object-oriented or relational schemata. For semantic types, concept expressions, e.g. from a DL ontology, encoded in OWL can be used. The simple workflow in Figure 10, for example, uses concepts from a biodiversity ontology Science Environment for Ecological Knowledge (SEEK) project web site (http://seek.ecoinformatics.org).

Many other workflow systems have been developed by academic institutions and industry to address (often partially) the challenges presented above. Among those designed to support scientific protocols, academic systems include Triana an open-source problem-solving environment de-

Figure 10 A Kepler data set actor (yellow "folder") is connected with an R statistics actor. The Kepler type checker determines that the connection is safe with respect to the *structural* type (array of integers), but is *semantically* not well-typed since the output semantic type "Population" is not compatible with (subsumed by) the input semantic type "Cover Area" of the instantiated R actor.

veloped at Cardiff University that combines an intuitive visual interface with powerful data analysis tools (http://www.trianacode.org/index.html), Kepler (based on the Ptolemy II system for heterogeneous, concurrent modeling and design, http://kepler-project.org) criteria and Taverna (developed in the UK by a European team; http://taverna.sourceforge.net and http://homepages.cs.ncl.ac.uk/peter.li/home.formal/tutorial).

7 Conclusion

Data integration is a critical issue for life science. Although many traditional approaches such as data warehouses, federations and mediations provide efficient integrated platform to query the data, there is a need for a broader view on biological data integration. Although scientists need to integrate data from multiple heterogeneous and autonomous sources, they also need to integrate the various applications made available to them. Traditional database integration approaches do not offer solutions to the complex problem of application integration. Today, the community seems to agree on one fundamental fact: to enable efficient and meaningful integration, biological resources – databases and applications alike – need to provide semantic information. Many solutions are being developed to define, support and exploit this semantic layer for data integration. Orthogonally, traditional database approaches do not provide an access to data suitable to scientific protocols. To allow scientists to express and execute scientific queries, systems based on workflows are developed. This work in progress should result in a new generation of data integration systems.

Visualization of Biological Data

Harry Hochheiser, Kevin W. Eliceiri, and Ilya G. Goldberg

1 Introduction

Despite their considerable power, the computational techniques described throughout this book are unlikely to replace direct visual examination of biological data. High-resolution, interactive displays leverage the considerable processing power of the human visual system to help biologists identify patterns, locate outliers and build hypotheses that would escape detection by less-sensitive algorithmic approaches.

This chapter will examine two classes of visualizations of biological data, and discuss some of the issues related to their use and interpretation. The first class of data is generated by direct light-based microscopy imaging techniques, which provide pictures and movies of biological phenomena. Although traditional two-dimensional (2-D) images may be relatively straightforward to examine visually, 5-D (x,y,z, time and wavelength) data present substantial visualization challenges. These advanced multidimensional microscopy techniques have proven to be powerful biological research techniques, allowing scientists to record such phenomena as the dynamic process of embryogenesis. Increasingly, these methods are beginning to show great promise for medical imaging. While histopathology-based techniques are still the mainstay microscopy techniques in medicine, light microscopy methods such as fluorescence and multiphoton (MP) microscopy are being explored to track key medical processes such as cancer metastasis. There is promise that some light-microscopy modalities might be developed into diagnostic methods to complement the more traditional medical imaging techniques such as positron emission tomography (PET) and magnetic resonance imaging (MRI).

The second class of visualization discussed in this chapter includes data that are not amenable to the direct visual display used for microscopy data. Despite the possibility of graphical depictions of DNA helices, genomic sequences are most easily interpreted as strings in the familiar four-letter alphabet. Derived data such as sequence alignments, high-dimensional repre-

Bioinformatics – From Genomes to Therapies Vol. 3. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

sentations of microarray gene expression data, pathways and other computationally derived data sets can also benefit from displays designed to highlight trends and patterns. Drawing from recent work in the young field of *information visualization*, systems for analyses of these data types use techniques like interactive filtering and multiple coordinated displays to assist users. This chapter surveys tools that apply these techniques to bioinformatics data, including descriptions of systems for examination of genomic sequences, microarray data, proteomics, interaction networks and pathways, phylogenies and taxonomies, and phenotypes and lineages.

Recent advances in the collection and storage of large collections of microscopy images have led to the advent of high-content screening (HCS), in which collections of cells can be systematically examined for responses to genetic and chemical stimuli. Management and interpretation of the resulting large volumes of data requires visualization of image data, metadata describing both images and experimentally meaningful collections of those images, and results of automated analyses. An examination of the image informatics requirements of HCS illustrates some of the challenges involved in building complete solutions.

Visualization of molecular structures is not discussed in this chapter. For recent work in this area, see Ref. [127].

2 Microscopy Image Visualization

Current cell-based screening methods have evolved from simple nonimaged light scattering or fluorescence measurements to cell imaging systems where cells in individual wells of a multi-well plate are imaged using wide-field fluorescence microscopy techniques. The challenge with these cell imaging systems is to develop robust algorithms that can automatically extract meaningful morphometric or spectral parameters from populations of cells. Due to the vastly increased amount of data available from imaging, these screening techniques are collectively called HCS. Several live cell imaging methods are discussed below. While all are not standard HCS techniques – often because of technical challenges – they are all proven methods to extract additional information on dynamic *in vivo* processes.

2.1 Fluorescence Microscopy Techniques Applicable to HCS Screening

The availability of extensive sequence data from many organisms, including humans, affords probes, such as fluorescent protein chimeras, to be made to identify any protein; these chimeras can identify the location and distribution of that protein within an organism. Furthermore, advanced optical techniques can yield information on the physiological state of a cell or the molecular environment of a particular reporter probe. The challenge for the HCS researcher is to harness all of these techniques in a manner that allows for the effective identification of specific changes in cell architecture or physiology. These techniques include the following.

2.1.1 Spectral Imaging

Fluorescence signals may be derived from probes such as fluorescent protein reporters or endogenous fluorophores such as collagen or reduced nicotinamide adenine dinucleotide [143] (Figure 1). Fluorescence spectroscopy studies using specimens in cuvettes have yielded a wealth of information about how subtle fluorescence spectral shifts may be used to report on molecular environments of fluorophores [110]. The availability of spectral analysis on a pixel-by-pixel basis in an image could extend these analyses to molecules in identified cellular or subcellular environments. Current cell-based HCS screening systems have very limited spectral discrimination, having only three or four spectral channels. Although this is adequate for identifying fluorophores with well-separated emission spectra, difficulties arise when spectra overlap or when it is necessary to measure the spectral shifts of certain indicator probes. Double or triple fluorescence-labeling approaches have great power to investigate complicated processes, as individual gene products of interest can be tagged with different colors. This approach is often complicated by overlapping emission spectra of many of the most popular fluorophores such as cyan, yellow and green fluorescent protein (CFP, YFP and GFP). Spectral imaging techniques can simplify multiple fluorescence label experiments by allowing for fast, flexible probe separation unavailable with traditional techniques of optical filter separation.

2.1.2 Lifetime Imaging

A fluorescence signal contains more information than just intensity and color. The lifetime of the excited state, which gives rise to the fluorescence signal, is diagnostic of the fluorophore and also of its microenvironment [11] (Figure 2). Factors such as ionic strength, hydrophobicity, oxygen concentration, binding to macromolecules and the proximity of molecules that can deplete the excited state by resonance energy transfer can all modify the lifetime of a fluorophore. Measurements of lifetimes can therefore be used as indicators of these parameters. Fluorescence lifetime measurements are generally absolute, being independent of the concentration of the fluorophore. Furthermore, lifetime properties may be particularly useful in identifying fluorophores with significantly overlapping spectral properties. Fluorescence lifetime imaging microscopy (FLIM) has been recently described and the potential of this

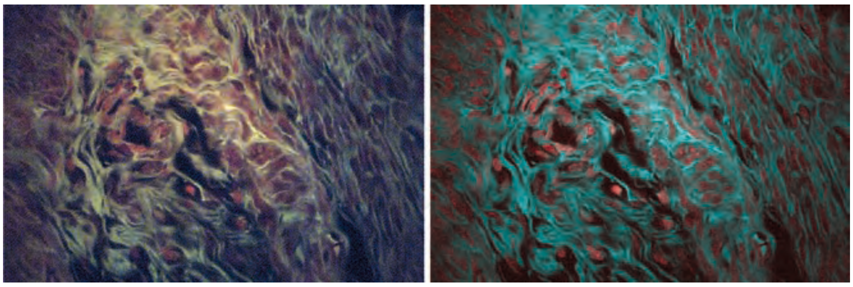

Figure 1 Spectral imaging. Seventeen-channel spectral image of a methyl green-stained section of uterus imaged with MP excitation. Displayed is image chrominance as a weighted function of wavelength values in each channel. The left-hand image is colored according to "best-guess" mapping, with the first third of the channels equally weighted toward red, the second third toward green, and the last third toward blue. The right-hand image illustrates the discrimination of nuclei by overweighting the contribution of channel 1 (660 nm) and negatively weighting channel 5 (600 nm) with respect to the red color component. This scheme reveals nuclei as red and surrounding tissue as turquoise. (Uterus section prepared by Al Kutchera, Midwest Microtech; reproduced from Eliceiri *et al.* 2005. Photochem. Photobiol. **81**: 1116 with permission of the American Society for Photobiology.)

technique demonstrated [66, 112, 190]. Practical applications include *in vivo* mapping of the metabolic states of a cell by using FLIM to distinguish the two forms (bound and free) of the intrinsic fluorophore NADH [16]. FLIM is not currently available in a commercial HCS instrument due to technical challenges such as the long photon counting times needed by FLIM. As the electronics and detectors for FLIM continue to improve, the speed of this technique should as well, making it more practical for HCS studies.

2.1.3 Fluorescence Resonant Energy Transfer (FRET)

FRET is a technique that can detect the close proximity of two fluorescently labeled molecules [116, 172]. Furthermore, this technique may be readily used *in vivo*. If one of the fluorophores (the donor) has a fluorescence emission spectrum that overlaps the excitation spectrum of the second fluorophore (the acceptor), then fluorescence from the donor can be partially quenched if the acceptor molecule is closer than the so-called Förster distance (around 10 nm). Energy is transferred to the acceptor molecule, which increases in fluorescence; the effect varying as the sixth power of the distance separating the two molecules. The technique is capable of detecting when a ligand binds to a receptor and so can be a potent way of visualizing the activation of a signal transduction pathway. However, often it is difficult to obtain reliable FRET estimations from measurements of fluorescence intensity changes, particularly within intracellular domains. Selective bleaching or compartmentalization of the two fluorophores can give rise to changes in relative fluorescence that are

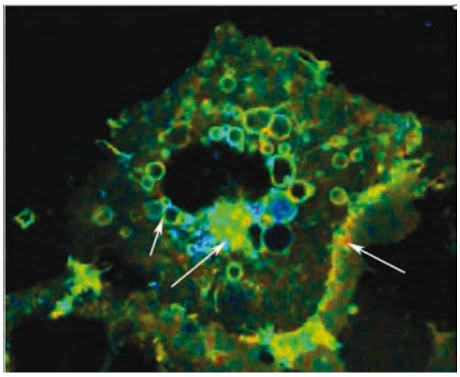

Figure 2 Lifetime imaging. GFP-R-Ras(38V), a constitutively active mutant of R-Ras, imaged at 900 nm using a Ti:sapphire laser and lifetime detector. Color mapping indicates changes in fluorescence lifetime Note more blue/green (shorter) lifetime values on vesicles (arrows near nucleus) and orange/green (longer) lifetime values at a membrane ruffle. Lifetime imaging can be used to reveal information about the dynamic interaction of labeled proteins or endogenous fluorescence in the context of its *in vivo* microenvironment. (Image courtesy of Dr Patricia Keely, University of Wisconsin–Madison.)

indistinguishable from those resulting from a FRET interaction. However, lifetime imaging can potentially circumvent these problems. When a FRET interaction occurs, the donor excited state lifetime increases. This is an absolute change that is independent of intensity. Using lifetime measurements to estimate FRET can potentially yield the percentage of the donor species that is involved in the FRET interaction (ratio of the shorter to the longer lifetime components) and the proximity if the two interacting molecules (degree of lifetime shortening). Practical applications of FRET include the investigation of protein–membrane interactions [118,119,197] and Ca^{2+} dynamics [187].

2.1.4 **Optical Sectioning**

Optical sectioning fluorescence microscopy has become the method of choice for imaging living specimens as it offers high signal-to-background ratios and the ability to spectrally discriminate between multiple fluorophores. Recently developed techniques such as confocal [137,193] or MP [51,194] imaging allow optical sections to be made of intact live specimens. These may be collected as stacks of images at different focal depths to obtain 3-D structural data. Stacks of images may be collected at regular time intervals in order to reveal the dynamics of 3-D structures in living tissue [182]. Optical sectioning could allow for cells in an HCS screen to be grown in a collagen gel, possibly a more natural environment for some cells. Three-dimensional imaging could be used to measure morphometric parameters of a cell. The association of cells with an extracellular matrix could be also characterized. HCS systems that use optical sectioning such as differential interference (DIC) are being widely used [94, 195]. These systems allow scientists to do high-content tracking of phenomena in 4-D. There is also active development to utilize laser-scanning methods such as confocal and MP laser-scanning microscopy that would allow for better viability and deeper sectioning [78, 111].

2.1.5 MP Imaging

MP laser-scanning microscopy (MPLSM) uses laser raster scanning to assemble an image (Figure 3). At a very high photon density, two or more photons may be simultaneously absorbed by an excitable molecule in order to generate fluorescence emission. The sum of the individual photon energies is equivalent to the energy transition of a single photon absorption event [51]. In the case of two-photon imaging, the excitation wavelength is set to about twice that of the absorption peak of the fluorophore being observed. Normally, this wavelength would not produce any appreciable fluorophore excitation. However, if a high-power, ultra-short pulse laser is used, it is possible to achieve instantaneous photon densities that will give rise to a significant yield of two-photon events at the focal volume of an objective lens, while maintaining a mean power level that will not damage the specimen. In this manner, fluorophore excitation is confined to the focal volume because the photon density is insufficient to generate appreciable MP events outside of this region. Optical sectioning is achieved because there is no appreciable fluorophore excitation above or below the focal volume (i.e. the plane of focus), thereby elegantly avoiding the problem of out-of-focus interference by not generating it in the first place.

Since scattering is lower at the longer wavelengths of excitation used in MP imaging, and also because there is no fluorescence excitation above the plane of focus, there is significantly reduced extinction (relative to confocal microscopy) of the excitation light from regions above the plane of sectioning. In addition, the emission signal does not have to be imaged and is therefore relatively insensitive to scatter. These characteristics provide the deep sectioning capabilities of MP imaging [33]. An additional advantage of MP imaging for *in vivo* studies is that photo-toxic effects are minimized [167]. The benefits of deeper sectioning and improved viability have made MPLSM the tool of choice for developmental biologists who can track fluorescently labeled proteins in both space and time. MPLSM can be used effectively with other techniques such as FLIM and spectral imaging, allowing the scientist to peer deep into the cell and track complicated spatial and temporal processes involving intrinsic (such as NADH) and extrinsic fluorophores (such as GFP-labeled cells). This type of multi-modal experiment presents complex analysis challenges, as multiple dimensions (space, time, lifetime and spectra) can be simultaneously collected [15].

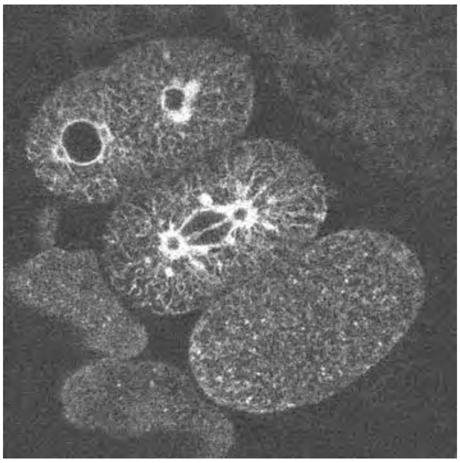

Figure 3 Dynamics of the endoplasmic reticulum in the early nematode embryo. This MP image is of three living *C. elegans* embryos expressing a fusion protein of SP12 (an endoplasmic reticulum protein) and GFP. In these embryos, the endoplasmic reticulum cycles between a highly organized reticulate state during mitosis and a more dispersed state during interphase. The top embryo is a two-cell embryo in which one cell (left) is in interphase and the other cell (right) is entering mitosis. The middle one cell embryo is in the first mitosis, with the endoplasmic reticulum lining the mitotic spindle clearly evident. The bottom one-cell embryo is just post-meiotic and exhibits the more dispersed endoplasmic reticulum organization. (Image courtesy of Dr. Jayne Squirrell, University of Wisconsin–Madison.)

2.1.6 Second Harmonic Imaging

Nonlinear optical effects other than MP fluorescence excitation can occur at the very high photon densities attained at the focus of the scanning excitation beam in a MP microscope (Figure 4). Molecular assemblies with high-order structure, such as collagen matrices, can generate a second harmonic generation (SHG) signal at half the wavelength of the excitation [29]. Unlike MP imaging, the SHG signal has a narrow spectral line-width (determined by the excitation source) and a zero lifetime. These characteristics allow SHG signals to be distinguished from MP signals in a laser scanning microscope with high peak intensity, ultrafast pulse excitation, even if there are fluorescence signals which overlap the SHG signal. These characteristics make SHG imaging a very useful adjunct to MP imaging when observing cells that are embedded in an extracellular matrix. SHG has proven to be effective in investigating processes where collagen plays a critical role such as muscle development [22, 23, 125, 142] and breast cancer progression [26, 148].

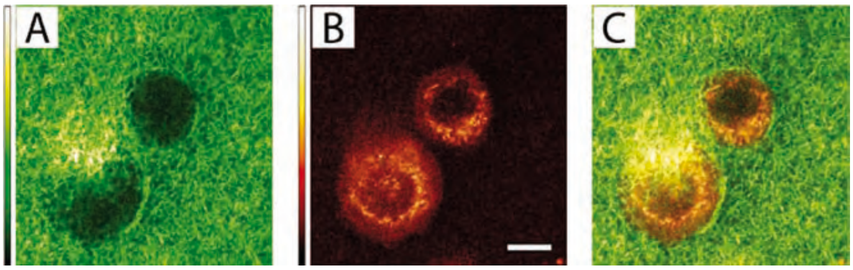

Figure 4 Harmonic imaging. DsRed2-expressing SCC13y cells embedded within a collagen matrix. Collagen second harmonic generation signal (SHG) (A) was collected using a narrow bandpass filter centered at 445 nm and fluorescence from DsRed2 (B) was collected using a 460-nm longpass filter. A 580-nm longpass filter (excluding cellular auto-fluorescence) confirmed that the origin of the fluorescence was exogenous. Panels (A) and (B) are merged in panel (C). This demonstrates the power in live cell imaging of combining endogenous signals such as SHG with fluorescent labels such DsRed. (Image courtesy of Erin Gill, University of Wisconsin–Madison.)

2.2 Functional Genomics

HCS experiments are generally performed to screen through genomic libraries in order to ascertain the function of genes or to screen through compound libraries in order to identify biologically active compounds. Cells can be systematically manipulated either by using RNA interference (RNAi) to interfere with their genes or by exposing them to chemical compounds [124, 153].

2.2.1 RNAi

RNAi is a genetic technique first demonstrated in the nematode *Caenorhabditis elegans* [61, 74] that can be used to block the expression of a target gene by introducing small fragments of double-stranded RNA (dsRNA) with a coding sequence that blocks the gene of interest by binding to its mRNA transcript. This method of DNA silencing has proven to be an extremely powerful tool in *C. elegans* research and has recently been successfully extended to mammalian systems. Four methods have been reported for dsRNA delivery in *C. elegans* [189]: (i) dsRNA injection [61], (ii) feeding with bacteria producing dsRNA [183], (iii) soaking in dsRNA [176] and (iv) *in vivo* production of dsRNA from transgenic promoters [179].

Similarly to *C. elegans*, *Drosophila melanogaster* can also be readily used to study the effects of silencing specific genes using RNAi. The advantage of *D. melanogaster* is that there is a well-developed, cell-based system that can absorb dsRNA directly from solution or when printed on microscope slides using a microarray printer [192]. The combination of microarray technology with this cell-based system allows for an extremely high-density form factor where an entire genome can be assayed on five to 10 standard microscope

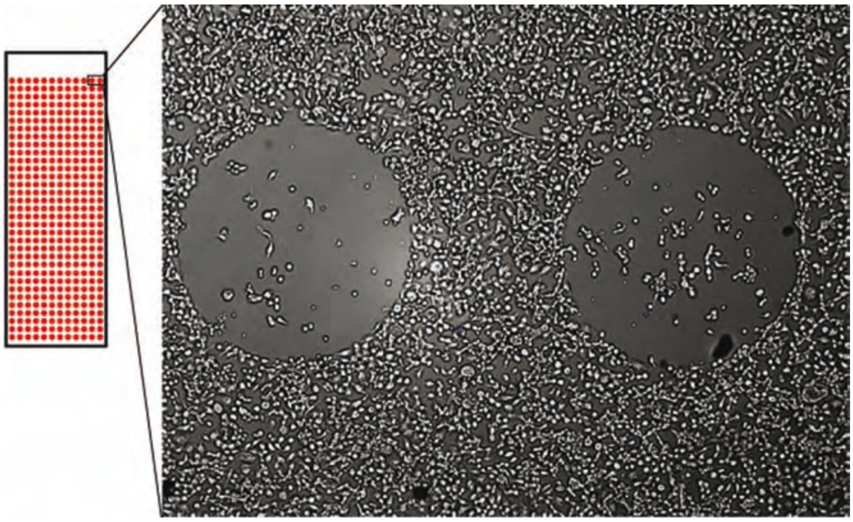

Figure 5 A living cell microarray. On the left is a schematic representation of a standard microscope slide printed with dsRNA "spots" using a standard microarray printer. The spot density can be 2000–5000 per slide depending on the spot size. On the right is a phase-contrast image (×10) of cells growing on top of and around two printed spots of dsRNA that code for a required gene. The phenotype displayed by the cells as a result of "knock-down" of these required genes is lack of growth. Much more subtle phenotypes can be assayed by imaging the cells at higher resolution (×100 is routinely possible), in 3-D, time-lapse, multiple fluorescence channels or a combination of these. As the platform for the assay is a standard microscope slide, 2000–5000 genes can be assayed for one or more phenotypes using a standard fluorescence or confocal microscope with a motorized stage. An organism's entire genome can be represented on 5–10 slides (Figure by Mark Eckley, NIH.)

slides. This platform, called "living cell microarrays", also benefits from using standard microscopes with computer-controlled stages and standard optical equipment instead of the specialized robotics, liquid handling and imaging equipment needed for optical high-density microtiter plates (Figure 5).

High-throughput techniques for RNAi in mammalian cells lag behind those developed for worms and flies. However, several options are under development that share the theme of introducing small interfering RNAs (siRNAs) to cells directly rather than using large dsRNA and allowing the cells to process it. These include digesting a dsRNA library with a nuclease prior to transfection, synthesizing the siRNAs or producing constructs that express siRNA *in vivo* [27,57,75,134,196].

2.2.2 **Chemical Compound Libraries**

Traditionally, chemical compound libraries have been used by the pharmaceutical industry and some academic laboratories to screen compounds for a targeted biological function. With the advent of HCS, the same approaches can now be used for screening a morphological response of the cell to these compounds. The most important aspect of HCS in this application is that knowledge of a molecular target is no longer necessary in order to develop an assay for the compound screen. In HCS, the target of the screen is a morphology that can be reached via potentially many molecular pathways and targets. In this way using HCS to screen chemicals potentially casts a much wider net while simultaneously requiring that compounds are active in cellular context [122, 124].

2.3 Tools for Scientist-driven Analysis Development and Deployment

By necessity, advances in imaging instrumentation have frequently been accompanied by the development of corresponding visualization tools. Although often the visualization needs for these instruments can be met in part by commercial image analysis tools, new instrumentation development can rapidly generate new data types and analysis problems. As the driving image technology is generally not commercially viable, these data types and problems are often beyond the scope of current commercial development, and more flexible, customizable visualization solutions are often needed.

In response to this need there has been a long tradition in the academic microscopy community of the development of freely available image analysis tools that can be harnessed by the microscopist and adapted for their needs. Examples of these imaging tools include tools for 4-D visualization [60, 182], measurement [36] and 3-D reconstruction [42, 109]. Of particular note are tools that are designed to not serve just a specific analysis need, but serve as a general imaging analysis frameworks. Below we discuss two such tools, VisBio and ImageJ, that not only offer a defined set of features, but also a flexible framework to allow additional image analysis techniques to be developed and deployed. Rather than focusing on the development of novel algorithms, these tools are designed to provide flexible environments that can be used to harness existing algorithms.

2.3.1 ImageJ

ImageJ [1] is a public domain image analysis program written in Java, principally by Wayne Rasband of the National Institutes of Health (NIH). Originally designed as a 2-D analysis tool, ImageJ provides image visualization facilities that can be extended via a plugin architecture and by scripting tools accessible to scientists without extensive programming experience. These facilities have encouraged programming contributions from throughout user/developers in the imaging community. Notable user-contributed plugins include the hypervolume browser (http://rsb.info.nih.gov/ij/plugins/hypervolume-browser.html), which can be used to explore 3-D and 4-D data sets, and VolumeJ (http://bij.isi.uu.nl/vr.htm), a plugin for volume rendering. Developers in the ImageJ community have also linked it to other visualization efforts including open-source efforts such as VisAD and the Open Microscopy Environment, and commercial packages such as VTK and MatLab. While ImageJ was not intended as algorithm development project, it has become a highly effective way for scientists to customize their analysis approaches in a way that would often be outside the scope of commercial interests. Like many of the visualization programs discussed below, ImageJ's greatest strength is its user developer group and perhaps more so than any it is designed to be used by the nonprogrammer/developer as well as the experienced scientific programmer.

2.3.2 **VisBio**

The Java-based VisBio (http://www.loci.wisc.edu/visbio) – principally developed by Curtis Rueden at the University of Wisconsin–Madison – is an application for the interactive graphical display and quantitative analysis of biological image data of arbitrary dimensionality [146]. The development of a tool that has support for data of *n*-dimensionality was driven by the emergence of a new class of microscopy data that goes beyond space and time to include new dimensions such as spectra [15, 44, 52, 113] and lifetime [11, 15, 45, 66, 112, 190].

VisBio allows its users to interactively explore and measure the data within 4-D recordings of specimens. In addition to being specially tailored to the demands of handling and animating massive data sets fluidly, VisBio enables the interactive representation of recordings in which each spatiotemporal pixel element contains multiple dimensions, e.g. emission intensity, color spectrum and fluorescence excited state lifetime.

VisBio has been built with the VisAD scientific toolkit [80, 81] – a programming suite that provides capabilities for the analysis and visualization of numerical data (http://www.ssec.wisc.edu/∼billh/visad.html). VisAD's flexible data and display models provide an ideal base from which to design complex applications for visualization and analysis. The data model can be used to express virtually any numerical data, including multispectral images. VisAD's display model enables applications to define arbitrary mappings from numerical variables to various display quantities, such as spatial coordinates, color components, transparency, animation indices, range selectors, contouring, etc. Furthermore, VisAD's support for interaction with displays enables users, for example, to interactively select a pixel in a spatial display and see the corresponding spectrum in another display, and to select a spectral band in the spectral display and see the corresponding image in a spatial display. Other displays map image spatial coordinates to the *x*- and *y*-axes and map spectral band to the *z*-axis, visualized as images stacked up along

the z-axis. In some applications, user can interactively draw the outline of a spatial image region, triggering computation of statistics involving only pixels inside the selected region.

VisBio takes advantage of many VisAD features, with the current release providing a general mechanism for handling image data in n dimensions (in fact, it is the only biological imaging software of which we are aware that does so). For example, the software can efficiently browse through a data set consisting of multiple images across time, focal plane and spectral channels, visualizing the images in both 2- and 3-D (Figure 6). The software can understand data of any dimensional organization, including spectral and lifetime dimensions. See Section 4 for further discussion of image analysis software and data management issues.

3 Biological Information Visualization

Familiar types of nonimage biological data share fundamental characteristics that make interpretation and analysis inherently challenging. Annotated sequences, gene expression profiles, pathways, protein interaction maps, phylogenies and other data sets have many data points with complex interactions that are potentially of interest. As these data sets are essentially abstractions that describe underlying physical phenomena, visual representations are not given or necessarily obvious. Strings of nucleotides for sequence data, trees for phylogeny and node–link graphs for pathways are starting points that leave visualization designers with a number of challenges, including scaling up to very large data sets and the appropriate use of available visual cues.

Recent research in the field of information visualization has focused on the development of interactive tools to support the exploration and interpretation of abstract data [164]. This work has involved the application of innovative displays and interaction techniques to data sets from a wide variety of domains [14, 31, 191]. Much of the recent work in bioinformatics visualization builds upon these efforts, particularly with respect to visual encoding of data, multi-scale displays and interaction techniques.

Visual encodings of data define the appearance of individual data items and the relationships between them. Often, the location of items in 2- or 3-D embeddings is of primary importance, encoding either some specific measurements in two or three dimensions (as in a scatter plot) or an indication of relatedness to other items in the data set (as in a graph or network diagram). Size, color coding and shape of representation of data points and connections between them (in graphs) can be used to display values of one or more continuous or categorical attributes. In some cases, redundant coding might be used to provide greater clarity. For data sets involving hierarchical data, appropriate encodings can be used to display containment relationships. Other possibilities include the use of orientation, texture, and animation [31].

Multi-scale displays are a class of strategies designed to address the challenges of interpreting data sets at vastly differing granularities. The classic example of this problem in bioinformatics would be moving from overviews of an entire genome to detailed examination of individual nucleotides. Ideally, visualization systems provide overviews that are compact and usable, detail views that present low-level information in context, and interaction techniques for moving from one extreme to another (or to points in between). Three classes of techniques are commonly used for managing multi-scale displays. Semantic zooming involves modification of the amount of detail displayed to fit the space available: at low magnifications, high-level overviews of large numbers of items can be provided, with detailed information about fewer items at higher magnification [13]. Overview + detail displays provide multiple, linked windows with displays at different scales [163]. Navigation windows in page layout programs are a commonly used overview + detail technique. For data sets involving larger ranges in magnification levels, multiple overviews may be useful. Distortion, or focus + context, techniques warp spatial embeddings to provide proportionately greater space to items of interest, with contextual information displayed around the periphery, forming a "fisheye" view of data [65].

Interaction techniques support browsing, searching and retrieval of details-on-demand. Mouse-over tooltips, hyperlinks, search fields and other fairly common approaches are used in many bioinformatics visualizations. Coordinated multiple views clarify the relationship between differing perspectives on a data set by linking selection across views: when an item is selected in one view, its representation is highlighted in all other views [132]. This coordination can be particularly useful for managing overview + detail displays. Dynamic query tools combine interactive widgets for filtering data sets with fast (below 100 ms) query results and display updates, providing essentially instantaneous feedback [2].

Most tools support some sort of navigation, browsing and searching. Facilities for viewing detail at varying scales of resolution/magnification and retrieving records of interest from related data sets are also common. Other tasks that might be supported include integration of new data sets, statistical analysis, data annotation and construction of scientific arguments. Some tools also provide for the coordination of visualizations of multiple data types and visualization of complex analysis protocols.

A 2001 discussion at the IEEE Information Visualization Conference identified three classes of challenges for bio- and cheminformatics visualization: visual integration of analyses of diverse data sets, high-dimensional analytic visualization and new visualization designs [114]. Although these challenges have been addressed by many of the systems that have appeared in the literature – including those described in this chapter – they are still active problems in need of further research.

3.1 Genome and Sequence Data

With data granularities ranging anywhere from single nucleotides to billions in a sequenced genome, sequence data demonstrates the difficulties of visualization of large data sets. Although tools for examination of synteny at the genome level may not need to provide the nucleotide-level displays needed for analysis of single nucleotide polymorphisms, the ability to move between multiple scales is clearly a useful feature in examining sequence data. Annotations, alignments (local and global) and other task-specific types of data often provide necessary context.

The constant evolution of complete genomes and their annotations makes web interfaces particularly appropriate for genome visualization. Leading web-based sequence visualizations include the University of California at Santa Cruz (UCSC) genome browser (http://www.genome.ucsc.edu) [97] and the Ensembl genome browser (http://www.ensembl.org) [17, 41, 89]. These tools are based on a "track" metaphor: portions of one or more genomes are shown in a horizontal line, with any number of annotations displayed in parallel lines above or below the sequence itself. Information is presented in a dynamically generated image. Users can click on the image to drill-down for more details on any given feature. A desired location in the genome can be accessed via search facilities, by navigating up- or downstream from a given starting point, or by adjusting the magnification. Specific details are given as magnification is increased – a form of semantic zooming. Both tools support integration of tracks from multiple external databases including synteny views for comparative genomics.

Given the wide variety of annotation data sets that might be viewed, configurability is a major concern. Both the Ensembl and UCSC browsers support manual selection of tracks of interest, along with either control over either the decorations used on the tracks (Ensembl) or the density of information on a track (UCSC). Text, graphic and other output formats are provided directly from the browser or via a companion tool [98].

The Ensembl browser's main sequence viewer (ContigView) provides an example of a coordinated, multi-scale view of genomes. A series of views, i.e. entire chromosome, overview, detailed view and base pair view (in the most recent version), are linked together on the same page (Figure 7). Ensembl also provides support for clickable browsing by chromosome location and a per-chromosome synteny view.

Many other web-based track visualization tools have been built. GBrowse, The Generic Genome Browser [169], is a web-based track visualization system designed to generically support multiple model organism databases (MODs).

The track metaphor is also used extensively in sequence applets and stand-alone tools. BioViews [79] was an early effort that used multiscale displays and semantic zooming in an applet environment designed with a specific focus on building reusable widgets. BioViews also provided hyperlinks to external resources, and analysis tools for restriction site mapping and polymerase chain reaction primer design. The Neomorphic GeneViewer annotation tool and ProtAnnot [120] tools are based on several proposed principles for track-based presentations of genome information in stand-along browsers,

including continuous, interactive 1-D semantic zooming (as opposed to discrete quantized zooms in response to button clicks), collapsible tracks that can be manually reordered, and the use of color coding and icons to represent alternative transcripts and genome annotations.

Track-based visualizations have also been used for sequence curation. Apollo [117] combines multi-scale track-based views of sequences with drag-and-drop facilities for creating and sequencing editing annotations. Dragging a feature from Apollo's sequence view into an annotation view creates a new gene model, which leads to an annotation for the longest associated open reading frame (ORF). A controlled vocabulary for annotation comments is also provided.

Several tools have adapted the track metaphor to circular displays. The microbial genome viewer is a web-based viewer that displays circular genomes and sequence annotations in concentric circles [101]. GenoMap displays sequence and array expression data on multiple concentric rings, with feature details available on mouse click [152]. CGView [171] produces circular maps that can be zoomed to show individual features (Figure 8). Circular views for noncircular genomes have also been proposed as being useful for identification of relationships between chromosomes [56].

Visualizations based on the embedding of sequences in 3-D space can be useful for comparison and analysis of sequence composition properties. Z-Curves [199] map sequences into curves in 3-D space, with coordinates of the n-th position in the curve determined by the cumulative occurrence counts of the four nucleotides in the first n bases in the sequence. Plotting of multiple curves in a common space supports comparison between sequences.

Sequence alignments present additional visualization opportunities, either as annotation tracks in track-based viewers like the UCSC and Ensembl Genome browsers, or in special-purpose displays. The AlignmentViewer [39] embeds alignment results in a 4-D (3-D and time) space. Any of 12 possible dimensions of alignment data can be mapped to any of the three spatial dimensions or time. When the position of the starting point is included, the alignment is displayed as a 2-D graph. The position of the graph is determined by the values of the remaining spatial axes. The graph extends for the length of the alignment, with values at each position indicating the strength of the alignment. Animation is used to display the time dimension. Two-dimensional range filters can be used to restrict the range of values under consideration for any dimension. Biological Arc Diagrams (BARD [165]) draws arc above (and below, for reverse-strand matches) sequences to link regions with similarities that exceed a given threshold score (Figure 9). Similar figures can also be found in Chapter 8.

A straightforward approach to comparing locations of similar genes or regions in different genes or genomes is to render a single track for each item

being compared, along with lines or other glyphs going between the tracks to connect similar regions. This approach is used in the GenomePixelizer [106] and Apollo [41].

The PIP (percent identity plot) displays homology by showing the position in one sequence and the similarity (percentage) for each aligning segment from the second sequence [155]. The MultiPip extends this idea to alignments of multiple sequences [154]. A MultiPip contains individual pips comparing sequences against a common reference sequence. Features including genes, exons, and repeats can be displayed within each Pip (Figure 10).

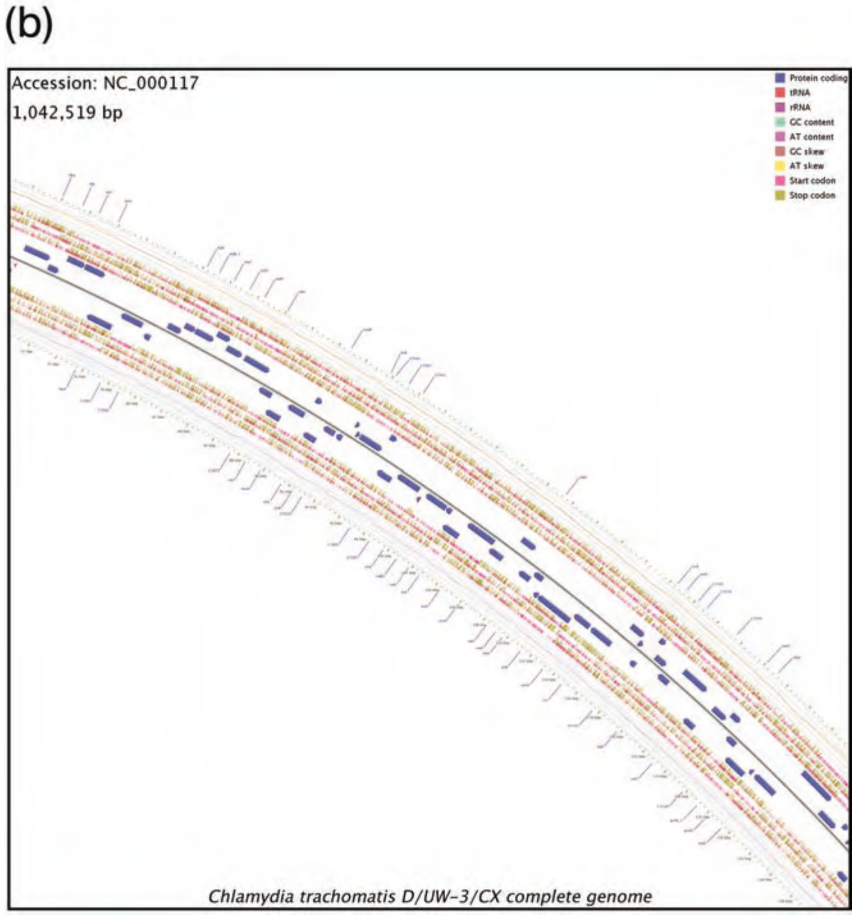

Figure 8b CGView output: Zoomed views of *Chlamydia trachomatis* genome [171]. (From http://wishart.biology.ualberta.ca/cgview/gallery.html, used by permission.)

VISTA and related tools use similar identity plots to display global alignment results. VISTA Browser [64] is a web browser that displays percentage similarities for two genomes. Similar regions are highlighted and color coded for coding and noncoding, with zooming, drill-down and search facilities. Given a multiple alignment and an associated phylogenetic tree Phylo-VISTA [159] generates similarity ratings for each internal node in the tree. Thus, similarities are defined relative to consensus sequences, as opposed to defining one of the input sequences as a reference point. An interactive display of the phylogenetic tree can be used to select the internal nodes that are displayed.

For each genome, the percentage identity of each gap-free alignment segment is plotted. Annotations above the plots indicate features in the human genomes. Color coding in the plots indicates introns, exons, noncoding regions and deletions. (From Ref. [154], by permission of Oxford University Press.)

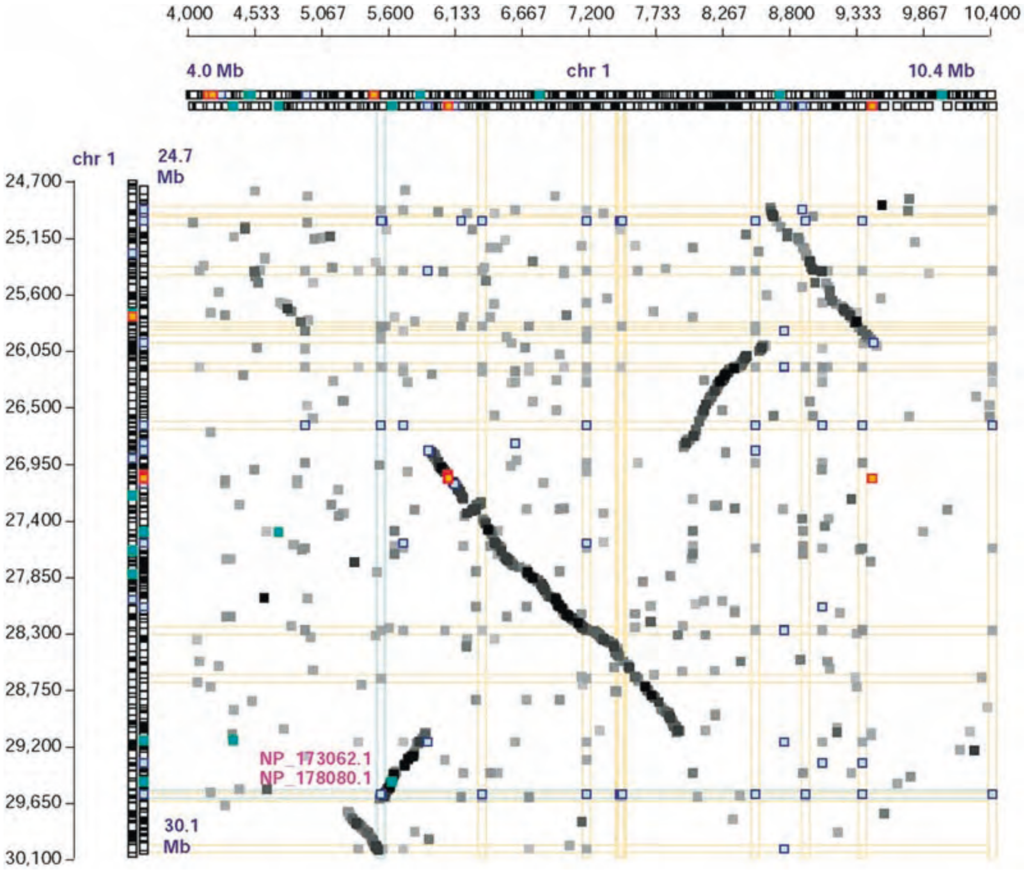

Figure 11 A GenoPix2D dot plot of *Arabadopsis* chromosome 1. Three gene families are color coded in the axes. Vertical and horizontal lines highlight homologs to the genes corresponding to the selected dot. (From Ref. [30], used by permission).

Other approaches to displaying large-scale homologies have used different perspectives include GenoPix2D [30], an interactive dot plot, which supports querying, filtering, zooming and coloring of genes by family membership (Figure 11), and DisplayMUMS, which shows alignments of individual shotgun sequences to a global alignment [108].

Noting the possibilities of a 3-D view, the Sockeye browser displays multiple genomes as parallel tracks in a projected 3-D space, using the height of annotations to display values such as alignment scores and alignment site confidence predictions [126]. As these scores are also color- coded, the height coding is redundant.

A variety of tools have been created for visualizing more specific types and applications of sequence data. viewGene [100] and GeneWindow [168] are track-based web browsers for SNP data. Gbuilder is a Java tool for visualization of EST clusters [128], while ESTminer provides similar functionality in a web interface [88]. ESTviewer displays ESTs that are conserved in the human genome and alternatively-spliced variants [35]. The Maize Mapping Project's iMap Viewer [58] provides side-by-side displays of genetic and physical maps of the maize genome, complete with links to external data. See Table 1 for selected genome visualizations.

Table 1 Selected genome visualizations

System type	Examples
Web-based browser	UCSC Genome Browser [97], Ensembl [89]
Stand-alone browsing and annotation	Neomorphic GeneViewer/ProtAnnot [120], Apollo [117]
Circular display	Microbial Genome Viewer [101], GenoMap [152], CGView [171], ChromoWheel [56]
Local alignments	Alignment Viewer [39], Biological Arc Diagram [165]
Large-scale homology	GenomePixelizer [106], GenoPix2D [30], PipMaker [155], MultiPipMaker [154], VISTA [64], Phylo-VISTA [159], DisplayMUMS [108], Sockeye [126]

3.2 Gene Expression Data

Gene expression data sets from microarray experiments can involve measurements for thousands of genes in dozens of cell conditions or cell states (called treatments from now on). The interpretation challenge generally involves identifying sets of genes with similar profiles, individual genes with distinctive profiles and, possibly, samples with profiles that might indicate the presence of a regulatory relationship (see also Chapters 24–27).

Classic approaches to visualizing microarray data are based on similarity clustering of profiles.

Red–green expression maps involve a combination of hierarchical clustering represented by a dendrogram and a dense, color-coded display called a heat map. Genes are clustered by calculating pairwise measures, replacing the two most similar samples with a cluster represented by their average and continuing until only one cluster remains. The genes are then ordered and displayed in a table, with one row for each gene and one column for each treatment. Each cell in the table contains a color-coded expression value, with red indicating increased expression and green indicating decreased expression [55] (Figure 12).

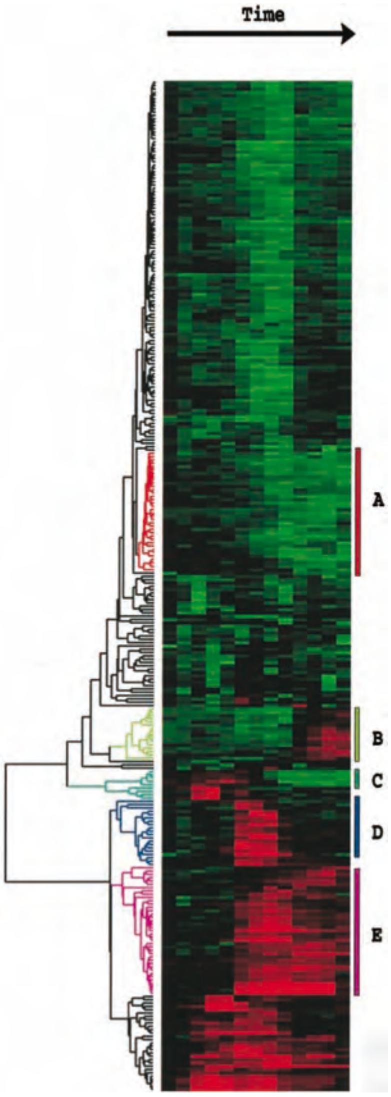

Figure 12 Gene expression values for a microarray time-course experiment. Each row is a gene, and each column is a time point. Cells are color coded to indicate expression levels relative to time 0: green readings are repressed, and red enhanced, with saturation level indicating the magnitude of the change. The dendrogram on the left groups the genes into clusters, with the lengths of the branches indicating levels of similarity. Five clusters of interest are marked on the right. (From Ref. [55], © 1998, National Academy of Sciences USA, used by permission.)

A wide variety of other clustering and dimensionality reduction techniques have been applied to microarray data sets. Techniques including self-organizing maps (SOMs) [105,177,184], multidimensional scaling [6,200], self-adaptive networks [188] and graph-theoretic methods [161] have been used to generate graphical maps indicating relationships between individual genes and clusters of genes. The MultiExperimentViewer (http://www.tm4.org/mev.html) supports comparative visualization of clusters generated by many of these algorithms.

Interactive array visualization tools provide user controls built upon the (generally) static maps created by clustering algorithms. Examples include animated SOMs to illustrate gene expression changes over multiple time points [54], and navigable interactive plots of clustered results [162]. GeneXplorer [144] provides linked dendrograms at multiple resolutions in a web-based application. Java Treeview [149] extends Eisen's original work with a multiscale view of a dendrogram, scatterplots, karyoscopes and links to external web resources. VistaClara [102] takes a different approach to extending basic heat maps, providing facilities for adding annotations, the ability to reorder rows (and columns, for comparisons of multiple experiments) based on similarity measures and an alternative rendering scheme that uses differentially sized ink blots to indicate differences in expression values. Genesis [173] is a Java tool that supports multiple clustering approaches and multiple views – including dendrograms and 3-D projection plots. The Hierarchical Clustering Explorer (HCE) [158] adds interactivity to dendrograms, including dynamic query controls for selecting an appropriate number of clusters, coordinated displays linking dendrogram views to 2-D scatter plots of arbitrary dimensions and linked views for comparison of alternative clustering algorithms (Figure 13). A version of the HCE for use in microarray probe design has also been developed [157].

Many of these techniques for generating and displaying clusters suffer from potentially misleading artifacts associated with the choices of color saturation levels and display reference points. GeneVAnD supports coordinated views of rank-based grayscale coloring of genes, views that indicate differences between genes and cluster averages, and interactive principal components analysis (PCA) projections [82].

Commercial products for visualizing microarray data include Spotfire Decision Site (http://www.sptofire.com), Agilent's GeneSpring (http://www.agilent.com), and OmniViz (http://www.omniviz.com). These products include support for data analysis and clustering along with customizable 2- and 3-D scatter plots and color-coded expression plots. Spotfire and GeneSpring also provide support for workgroups and relational database storage of expression data.

Clustering-based approaches are useful for large-scale analysis of microarray data sets. An alternative approach is the use of queries to search for patterns of interest in subsets of the data. For time-course arrays, these searches might involve, for example, the search for transcriptional targets via

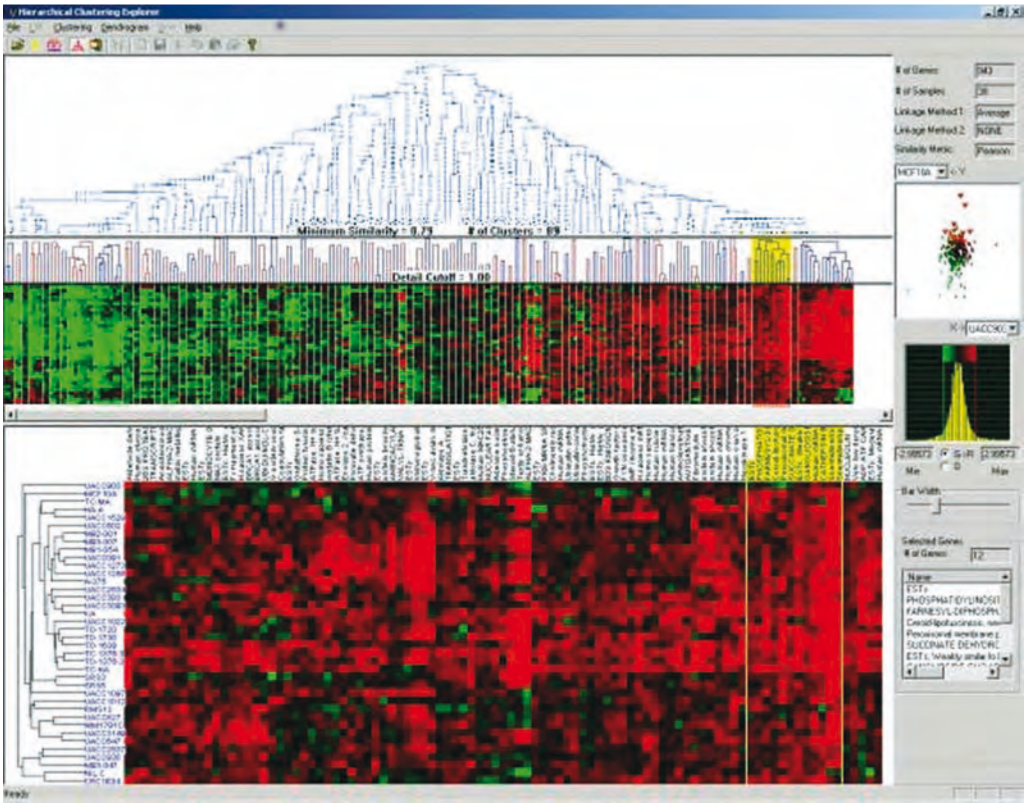

Figure 13 The HCE. An overview of a microarray data set is shown in the top pane. The "minimum similarity bar" has been dragged to split the dendrogram into multiple clusters. Details for the selected cluster (highlighted in yellow) are shown in the bottom pane. A scatter plot of items in that cluster is shown on the right. (From Ref. [158], © 2003 IEEE, used by permission).

the identification of genes with expression patterns that change significantly after changes in a known transcription factor. TimeSearcher is a general time series analysis tool that uses rectangular regions drawn on time series plots as queries, restricting results to items in a data set that have values in a given value range during specified times. This approach has been used to find regulatory targets for known transcription factors [83, 84] (Figure 14). The Time-series Explorer presents an alternative view, using a scatter plot to compare the change from normal expression over a selected interval (y-axis) to the change in values from the beginning of the interval to its end (x-axis), with animation conveying the changes in the interval [47].

Visual tools that place gene expression data in the context of annotations from the Gene Ontology (GO) [4] (see also Chapter 29) can be useful for identi-

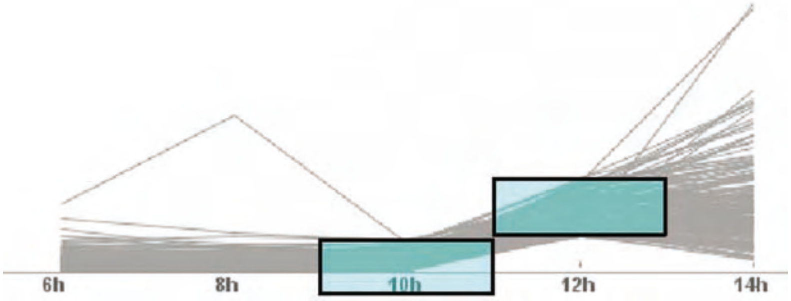

Figure 14 TimeSearcher queries specifying genes with low expression levels at the 10-h time point and higher levels at 12 h. (From Ref. [84], reproduced with permission of Palgrave Macmillan.).

fying groups of genes with similar roles that have similar expression patterns. GoSurfer is a Windows-based program that displays any one of the three GO hierarchies in a traditional tree view, with branch color coding based on relative expression levels [201]. Similar functionality is provided by GoMiner, which displays scalar vector graphics (http://www.w3.org/Graphics/SVG) trees with expression-level color coding alongside traditional tree-based browsers of the GO tree, annotated with expression levels [198]. Treemap is a space-filling hierarchy visualization. Given a hierarchy and a rectangular space, Treemap recursively divides the space based on the size of the contained nodes. Given an array data set, a Treemap display can use the relative change in expression level to size each gene, and the significance value for that gene as a color code, thus providing a concise view of GO categories with highly expressed genes of differing significance [8] (Figure 15). GenePlace and TreeMapClusterView [123] provide alternative uses of treemaps for GO and microarray data.

Another class of visualization tools addresses the challenges of interpreting comparative genomic hybridization (CGH) results. CGH uses microarray analysis of complementary DNA of multiple genomes to identify regions with sequence deletions or duplications [138]. These deletions and duplications lead to changes "copy number": deviations from expected DNA levels for specific regions. As interpretation of these results often involves examinations of copy numbers in a genomic context, visualization of CGH data often involves displays of results alongside genomic maps. SeeGH [38] and CGHPRO [37] combine displays of ratio information with individual chromosome maps with an individual chromosome view and a variety of parameterized filters.

VistaChrom [103] extends this approach with additional views at the level of individual genes and probes, with coordinated highlighting in the four

views (Figure 16). VistaChrom also provides additional statistical views, a summary "aberration view" and support for analysis of multi-array experiments. Caryoscope [5] provides genomic overviews without actual chromosome maps, with novel zooming techniques supporting the visualization of individual features in context. CGHAnalyzer [72] provides views at the chromosome level, with a focus on analysis of multiple experiments, with companion tools CircleViewer and CGHBrowser, respectively, providing a circular overview of a single experiment and high-resolution graphs of raw array data. ChARMView [130] combines visualization of Array CGH and gene expression array data from multiple experiments with a novel analysis algorithm.

Figure 16 VistaChrom visualization of array CGH data. In the genome view, copy number variations are shown alongside cytogenetic maps of each chromosome. Progressively greater levels of detail are provided in the chromosome view and gene view, with full details in the probe view. Linked interactions in all windows provide contextual information. (Figure courtesy of Robert Kincaid [103].)

A variety of more specific microarray visualization tools have been developed for other data types. Examples include tools for data sets involving circular genomes [101, 152] and SNPs [180]. ExpressionView combines microarray data with quantitative trait loci (QTL) information, showing loci from different samples alongside chromosome maps [62]. Other tools overlay gene expression level indicators on top of genetic maps [9] or microscopy images [67]. See Table 2 for selected visualizations of gene expression data.

3.3 Proteomics

Proteomics tools provides visualizations of proteomic information and protein interaction data in a genomic context. The UCSC Proteome Browser [86] displays protein information in a series of tracks, similar to those used in genome browsers. Amino acid sequences are displayed along with tracks for genomic sequences, exons, polarity, and other details. A variety of genome-wide histograms are also available, along with external links to related resources. PQuad [76] provides a varying perspective on the use of tracks for protein data, using a "wrapped line" metaphor to display long sequences on multiple lines that wrap like text on a page. PQuad provides linked views at three scales (overviews, individual ORFs and peptide sequences), along with filters, displays of predicted protein functions and difference visualizations for comparing the output of multiple experiments.

Visualization of protein families can provide perspective on relationships between proteins. TreeWiz [145] provides a tree visualization of more than 70 000 clustered proteins. Zooming and filters for subtrees are supported.

3.4 Interaction Networks and Pathways

Understanding the relationships between biological entities is clearly a core challenge of bioinformatics. Visual depictions of interaction networks and biological pathways are widely used to interpret this data. These visualizations are generally drawn as graphs, with proteins, genes or biological states as nodes and edges connecting interacting nodes. The use of color coding to indicate interaction confidence and GO annotations (e.g. Ref. [68]) can aid interpretation, but these large, dense graphs with thousands of interactions between thousands of proteins present significant challenges for visualization and interpretation. Interactive tools (both standalones and applets) for network visualization generally combine graph layouts with search facilities, zoom and pan, and filters based on confidence levels [46], GO annotations [34], and other criteria.

Large interaction networks generated from protein–protein interaction investigations (e.g. Refs. [63,68]) and similar experiments can contain thousands of nodes and a dense interaction structure. This complexity can be tamed somewhat via techniques that identify potentially promising subgraphs. Possibilities include graph-theoretic analysis of network structure [28], and integration of interaction results from differing sources along with genetic and gene expression data [7].

VisANT [87] is a web-based, database-driven interaction visualization system that integrates data from a wide variety of sources, including pathway and homology data. Osprey [25] combines color coding of interaction edges based on the experimental system with the use of GO categories to color-code nodes in interaction diagrams. Both types can indicate multiple values: interactions from multiple systems are segmented into multiple colors, while multi-colored pie charts are used for nodes with multiple GO categories. ProViz [93] adds support for managing views of multiple subgraphs of a network.

Cytoscape [160] is an extensible platform for integrating interaction networks with additional data sources, including expression profiles, phenotypes, and databases of functional annotations (Figure 17). Cytoscape also provides a plugin architecture that has been used to build bridges to the Systems Biology Workbench [90] and the Biomolecular Interaction Network Database [3].

Biological pathway diagrams are powerful tools for synthesizing experimental results into models that describe complex cellular behaviors. Often pathways are created by hand, and are therefore generally smaller than interaction diagrams. Interactions in these diagrams often have associated annotations, which are often visualized as edge decorations. Web-accessible pathways databases, such as EcoCyc [99] and KEGG [96], combine searching or browsing for pathways of interest with clickable pathway diagrams that provide drill-down access to specific detail (see also Chapter 20). Interactive pathway tools typically support both pathway creation and visualization. For example, the Genomic Object Net (GON) provides tools that can be used to both edit KEGG and other pathways and to create customized visualizations of simulations [131].

Despite efforts to define a visual language for pathway representation [115], pathway tools use differing techniques to encode information. Often the appearance of nodes in links is customizable [85,160], although some tools use customized glyphs [50]. Frequently, search facilities are provided for limiting the display to items of interest. GSCope [185] augments search facilities with

a fisheye display, which preferentially allocates space to a selected pathway element and its immediate neighbors, pushing other nodes to the periphery.

The challenges of managing and interpreting increasingly complex interaction diagrams have led some researchers to develop formal languages for pathway languages. PATIKA [50] defines a formal ontology for pathways, with each state and transition as a separate node in the graph. This ontology includes support of nested pathways and provisions for representation of incomplete information. CellDesigner is a network editing tool based on a formal process diagram language that uses visual notations to differentiate between specific types of states, molecules, and reactions [104]. CellDesigner can export model descriptions written in the Systems Biology Markup Language [91] and integrate with the Systems Biology Workbench [90] for simulation of models.

Integration of gene expression data can increase the utility of pathway visualizations. GenMAPP [49] is a tool for creating pathways with nodes that can be color-coded with gene expression values. An associated web site (http://www.genmapp.org) provides a public pathway repository. The companion program MAPPFinder [53] can be used to incorporate gene ontology annotations with GenMAPP pathways visualization. VitaPad [85] supports the creation and visualization of pathways that include edge decorations for catalyzing enzymes or genes and microarray data, along with a relational model for storage of pathway information. DRAGON View [24] is a web-based tool that provides several displays of microarray data, including the use of expression data to color-code nodes in KEGG pathways. ArrayXPath [40] uses diverse databases to produce a generalizable scheme for pathway visualization of microarray data. Given a microarray data set, ArrayXPath uses public databases to resolve probe identifiers, finds appropriate pathways, maps between the microarray data and the pathways, and produces a navigable annotated pathway.

GeneVis [10] uses a 3-D approach to display the hierarchical nature of some regulatory networks. Individual levels in a hierarchical network are drawn as rings, with links between rings indicating regulatory relationships. Distortion can be used to allocate more screen space to levels of interest within the hierarchy.

Several commercial products provide pathway and network visualizations. PimRider and PimWalker (http://pim.hybrigenics.com) are interactive tools for the exploration of protein–protein interaction networks. Pathway Enterprise from OmniViz (http://www.omniviz.com) is a pathway visualization and editing tool that supports a wide variety of pathway content. Ariadne Genomics (http://www.ariadnegenomics.com) provides a suite of tools – PathwayExpert, PathwayStudio Central and PathwayAssist – to support the visualization of pathways, including integration of experimental results and literature analyses.

A comparative evaluation of pathway visualization systems identified several requirements that would increase the utility of these tools for biologists. Automated pathway construction and maintenance based on analysis of scientific literature, linked overview and analysis of multiple pathways, and support for higher-level of abstraction were seen as desirable features [151]. See Table 3.

3.5 Phylogenies and Taxonomies

The examination of trees resulting from taxonomic classification and phylogenetic reconstruction is a long-standing challenge. Like protein–protein interaction networks, these trees are often quite large, involving thousands of nodes. Common user tasks generally involve browsing, searching for a known item and examining it in context, filtering to specific subtrees, and comparison of multiple trees [71, 129, 135, 145]. Although most of these tools are based on variants of traditional 2-D tree layouts, alternatives such as hyperbolic displays [92] and immersive virtual reality environments [147] have also been proposed.

TaxonTree [135] combines integrated navigation and visualization of these trees with smoothly animated transitions that illustrate how the tree changes when subtrees are expanded and collapsed. TaxonTree also provides visual context in the form of a highlighted path from the selected node back to the root. Edges can optionally be annotated with markers for shared characteristics used to diagnose phylogenetic relationships. A companion program, DoubleTree, extends TaxonTree to support tree comparison in two adjacent panes with linked coordination.

TreeJuxtaposer [129] takes a different approach to comparisons between these large trees, through the use of a similarity measure between nodes that allows for identification of a node that is most similar to another node. Constant-time lookup of these nodes during interaction provides the basis for linked highlighting of subtrees of other trees that are similar to a highlighted tree (Figure 18). TreeJuxtaposer also provides a distorted display that emphasizes marked areas, guaranteeing that they are always displayed. Progressive rendering features provide rendering times of less than 2 s for trees of 500 000 nodes. TreeJuxtaposer can be used to compare up to four trees at once.

Graham and Kennedy [71] propose an alternative approach to comparative visualization of multiple taxonomies. Taking advantage of the *n*-ary nature of taxonomies (as opposed to generally binary phylogenetic trees), their system

uses horizontal labels to display internal nodes in taxonomies. Each label spans the width of its enclosed subtrees, with leaf nodes displayed in grids. Several taxonomies can be stacked vertically, with linked selection and mouse-over brushing showing the position of nodes from a selected subtree in other subtrees. Internal nodes are also annotated with bar charts indicating the portion of a subtree that is currently selected and textures indicating changes in a subtree.

3.6 Phenotypes and Lineages

Phenotypic and cell relationship information provide an ideal opportunity for combining information visualization and microscopic visualization to provide a unified visualization. The RNAi database [73] is a searchable, web-based data repository which displays detailed information on RNAi experiments, including clickable maps of genetic regions and movies of appropriate phenotypes. The associated PhenoBlast tool compares RNAi experiments based on similarity and provides a color-coded result grid that is similar to a heatmap.

The Open Microscopy Environment (OME, discussed below) [70] is a database-driven system for imaging informatics, including tools for manually or automatically classifying images by phenotype. Images can be viewed in graphical browsers that use phenotypes to group images. BioSig [136] provides similar functionality for displaying phenotypic characterizations, using data-driven web interfaces, a navigable data model display, and a query manager that supports "query by feature", in which average values of computed features are used as query values.

Other tools focus more specifically on visualizing the structure of phenotypic or development graphs. PGViewer [178] and CRAVE [69] provide tree-based interfaces for accessing phenotype data from user-defined queries on a data store and ontology, respectively. The Edinburgh Mouse Atlas Projects' prototype visualization of mouse embryo development stages [48] displays developmental stages as acyclic directed graphs, with search filters, region-of-interest selection and zooming facilities. A 3-D version of the tool displays multiple data sets in parallel planes, with links between the planes indicating relationships between data sets.

Figure 18 TreeJuxtaposer. Subtrees in the left-hand tree are marked in corresponding colors in the right-hand tree. Guaranteed visibility ensures that these marked areas are visible in both trees. (From Ref. [129], used by permission.)

3.7 Visualization of the Scientific Process

Most of the visualizations described in this chapter focus on experimental results. Tools for visualizing both the processes involved in scientific analyses, and the conclusions that can be drawn from those analyses, can help bioinformaticians bridge the gap between analysis and synthesis.

Data analysis often involves the repeated application of a series of processes to new instances of a type of data. For example, genomics analyses might involve searching for data in one or more databases, followed by one or more transformation of results or subsequent searches [170]. Like raw experimental data, these workflows are valuable artifacts of the scientific process. Graphical tools for creating these workflows provide users with the ability to place computational modules on a canvas and to connect them with links that specify data flow. Examples include the Open Microscopy Environment's "Chain Builder" [70] (Figure 19) and the Taverna [133] tool for genomic analysis workflows.

Once collected and analyzed, data must be interpreted to evaluate hypotheses and develop new models. "Scientific notebook" tools attempt to augment data storage and management with interpretive data and model construction. Biological Storytelling [107] integrates a data display with a story editor that can be used to collect evidence for and against various interpretations, and a diagram editor for management of a network representation of the data interpretation.

Other visualizations examine use the content of research publications to inform further investigation. Cocitation analyses and related strategies have been used to generate models and visualizations of relationships between terms and concepts in published research in bioinformatics (and many other fields). Examples include networks of gene relationships based on co-occurrences in Medline records and color coded based on gene expression values [95], and networks that analyze publications trends over many years [121].

4 Image Informatics

The microscopy image techniques described at the start of this chapter are primarily concerned with data collection, whereas information visualization tools support interpretation and analysis of data. Image informatics bridges the gap between microscopy data collection and image interpretation by providing a framework for associating images with structured meta-data describing acquisition parameters. This information provides context that is necessary for both manual and computational interpretation of the images.

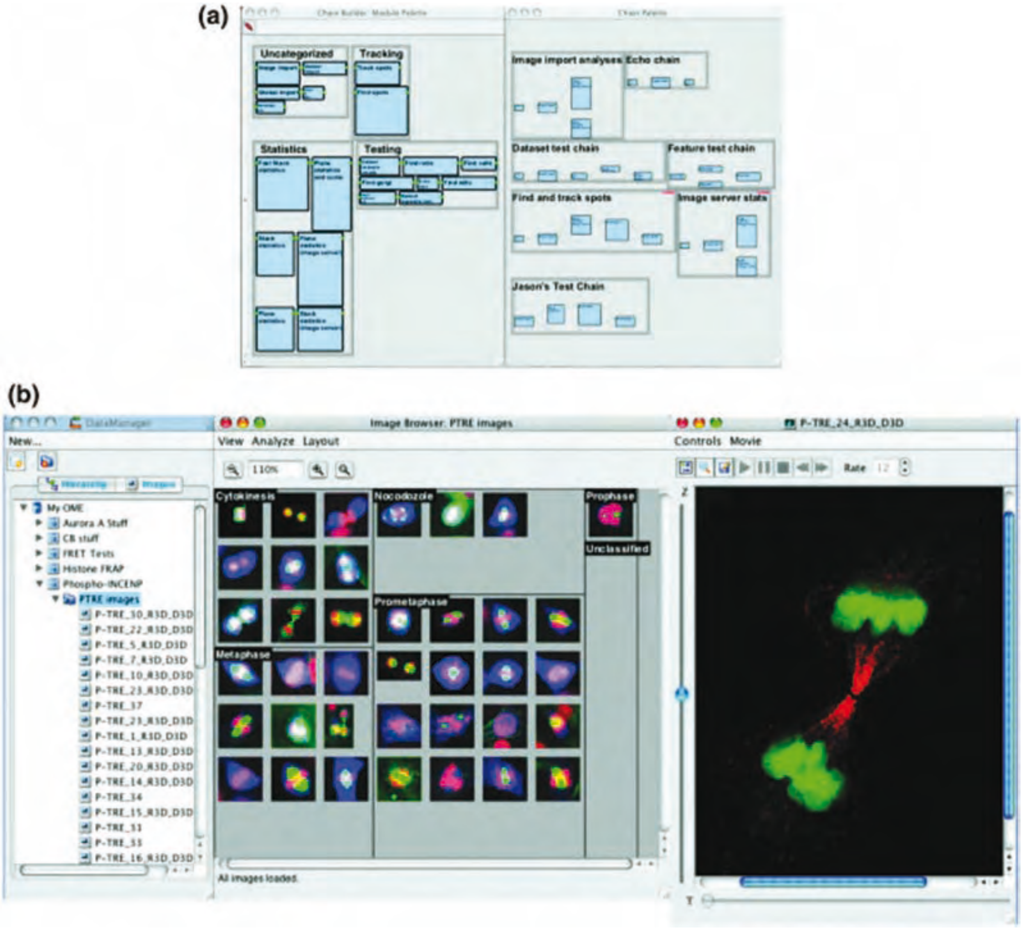

Figure 19 Visualization of microscopy data and analytic components in the OME. (a) The Chain Builder: computational modules (left) can be combined into analysis chains or workflows (right). (b) A data manager for hierarchical navigation of projects and images sets, a view of an individual image set, laid out according to manual categorization and an image viewer. (From Ref. [70], used by permission.)

This requires tools such as VisBio for displaying the image content, analytic tools for computational analysis of both images and meta-data, and information visualization tools for examining meta-data associated with the images.

An image without meta-data is of little scientific value because it cannot be meaningfully interpreted. Even a small collection of images requires attached meta-data in order to provide context and allow the image contents to be informative. What is this an image of? How was it acquired? By whom? What was the experiment? With large collections of images from high-throughput or genomic studies, the scientific conclusions that an image represents must also be recorded and associated with the relevant images due to the sheer number of them involved. If a conclusion was arrived at by image analysis, the steps taken to perform the analysis including any parameters and intermediate results must similarly be associated with the images analyzed. If the conclusion was arrived at by manual inspection, then the identity of the person making the conclusion must be recorded, including the option of maintaining multiple, possibly contradictory conclusions by different individuals. The management of this information about images, which is necessary for their scientific interpretation, is referred to as Image Informatics.

The need to store, analyze, retrieve and interpret this information presents significant challenges. The resulting systems have complex data models that may in themselves require visualization – in addition to visualizing data, users may need visual tools to inspect and explore data models, in order to find data of interest and draw comparison between different data sets. An examination of the specific issues associated with image informatics tools illustrates some of the challenges presented by these systems

An image informatics infrastructure for HCS should use an extensible data model to manage images and image meta-data. Extraction of scientifically meaningful results from large image collections will require an image analysis framework that allows for easy customization by the end-user biologist. The infrastructure must maintain an audit trail of any results it maintains such that everything can be traced back to an acquisition system or another entry point into the system. Open access to raw data, meta-data and analysis results will be needed to incorporate data from different acquisition systems and technologies, to compare results from differing analytic techniques, and to integrate image data with information in relevant external data sources. User tools – including both microscopy and information visualization – will be needed to allow scientists to easily manage, retrieve, manipulate, annotate, and interpret this data.

In traditional software for microscopy many of these requirements are met on an ad hoc basis. However, the high-throughput nature of HCS precludes ad hoc solutions and demands that these issues be treated systematically. The only known system to integrate all of these requirements in one place is the OME (http://openmicroscopy.org [70, 175]). See Chapter 44 for additional perspectives on workflow, provenance and other challenges addressed in this section.

4.1 Data and Information Management

All information for HCS must be stored in a relational database management system (RDBMS). The structure of the RDMS (the DB schema) must be specifically designed for HCS, which poses several challenges in DB design.

The first challenge is that image data comes in two highly distinct forms. The pixel data is very large and relatively unstructured while the meta-data and any extracted information is relatively smaller, but highly structured. These two forms are sufficiently different that storing them in common is impractical. Specifically, RBDMS binary data storage and retrieval facilities do not provide the performance and accessibility needed to rapidly retrieve arbitrary slices or time points from 5-D microscopy data. This shortcoming can be addressed by storing meta-data in the RDBMS, along with appropriate pointers to an image store on a private file system not accessible to normal users (a pixel repository). A specialized image server can support flexible retrieval of image data from the repository.

The second challenge is much harder to overcome and it is related to a general problem of databases used in scientific research – it is not possible to completely define the database structure when the database is being designed. The database is used in the discovery process, which leads to new information that must be stored in the same database. Although relational databases are extensible, this flexibility is at too low a level to be useful to most users. Augmenting the database with metadata that describes the structure of the raw scientific data provides application software with information needed to determine how to interpret and present that data. Interactive tools for creating new data types can help biologists extend the database structure, without having to learn the details of RDBMS query and data definition languages.

4.2 Image Analysis

Although image analysis has been around decades, the advent of HCS places new demands on this traditional field. Image analysis for microscopy is extremely difficult because of the bewildering variety of morphologies that biology can produce. As attempts to provide all algorithms to address all possible morphologies are unrealistic, a more flexible approach is necessary. Specifically, basic tools can be combined with mechanisms for connecting basic analyses and integrating external, possibly user-developed, possibly legacy tools.

There are two fundamentally different approaches to image analysis: object identification and scene-based analysis. Almost all image analysis software for microscopy is based on object identification. In this approach, the object of interest is identified and separated (segmented) away from its background.

The object of interest can be a nucleus or a cell body, a subcellular organelle, etc. This approach is very natural for fluorescence microscopy because a specific fluorescent probe generates the contrast in the image, and it is natural to extract everything possible about this fluorescence signal: its distribution, intensity, shape, etc. In practice, however, the picture is never as clear as it seems it should be. Segmentation algorithms to identify objects of interest are easily fooled by irrelevant objects, fluctuations in pixel intensity that must somehow be “normalized”, the object’s shape and other characteristics that cannot be easily controlled experimentally. Algorithms that can reliably identify individual cells regardless of cell type, the manner in which they grow and the specific probe used to visualize them are extremely difficult to develop. The advantage they have over scene-based analysis is that when they do work, they can provide extremely valuable quantitative information about the objects they identify [32, 140, 141].

Scene analysis is new to microscopy, but can be thought of as a natural as well. Consider an image of a field of cells. Is it an image of one cell repeated many times, or can we analyze the field of cells as a whole? Since this approach does not rely on identifying specific objects, it can be much more robust, i.e. applicable to a much wider array of phenotypes displayed in HCS (Figure 20). Scene-based analysis relies on pattern recognition techniques or machine learning to train an image classifier. In supervised machine learning, the classifier is trained to distinguish classes of images defined as a set of negative controls and one or more sets of target phenotypes (for example, “Ruffled” and “Not Ruffled” in Figure 20). Once trained using several example images of each class, the classifier can then be used in an experiment to score images as being similar to the negative control or one of the target phenotypes. There are presently no well-characterized examples of unsupervised learning for biological image analysis, but if a reliable and relevant measure of image similarity can be determined, standard clustering algorithms can be used to automatically define phenotypic classes without manual intervention [18–20].

Image analysis systems for biology must provide entry points for extension. This requires that the data model upon which they operate must be open and well documented. It must be possible for the end-users to interject their own code at essentially any point in the analysis process. Closed monolithic systems preclude this. If there are ways for the end-user to interject their own code, then much of the system can still be used even if it was not designed to solve the particular problem at hand.

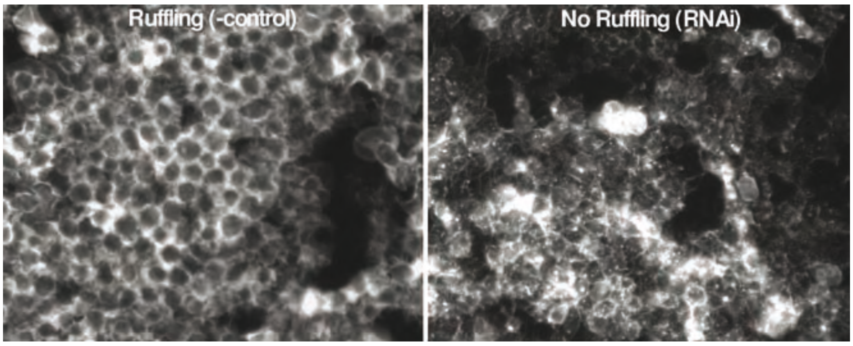

Figure 20 The ruffled appearance of these cells is caused by the extension of filapodia, which are used for locomotion. The filapodia are visualized using a fluorescent probe for the actin protein, which is a major component of these structures. The image on the right is the result of disrupting a gene required for the formation of the morphologically normal filapodia displayed on the left. These two morphologies are easily distinguished using a Bayes net classifier analyzing the field of view as a whole (10/10 images classified correctly with 85% confidence), while posing a significant challenge to object identification methods. (Images from Pamela Bradley, Harvard Medical School; image analysis and classification by the Goldberg lab at NIH.)

4.3 Analysis Workflows

Analysis protocols, in which independent computational algorithms are chained together to derive desired results, have been effectively used in a variety of fields, including genomic analysis [133, 170]. An image informatics platform can store the definitions of these protocols along with the results they produce, thus supporting reuse and comparison of results. Appropriate user tools can be used to modify and extend existing workflows for new screens. End-user tools for browsing, searching libraries of individual components and workflows can give biologists complete control over the image analysis, and a great deal of flexibility without necessarily involving additional software developers.

4.4 Provenance

The challenge of data provenance (or *lineage* – the storage and retrieval of the origins and computational history of data and results) has been extensively studied [21].

HCS informatics systems contain many possible kinds of analyses that can generate similar results. The results differ in their context even if they carry the same semantic meaning. If two different segmentation algorithms generate different particle counts, then neither count can be considered invalid or meaningless – these two conflicting scores differ somehow in the data dependency chain that led to the conflicting results. The ability to reconstruct these dependency chains and determine the provenance of a given piece of information is an essential component of an HCS informatics system. The visualization of these chains is an ongoing research effort, and it is expected that direct visualization of information flow through an HCS system would be an invaluable tool for the scientist to pick out new patterns of information and make most effective use of existing analysis tools.

4.5 Federation

Federation of information with other information sources is necessary for linking image information to data that are beyond the scope of the HCS system. It is not possible to make hard and fast rules where this transition should take place. The HCS system must be capable of maintaining references to external data sources and providing them with sufficient context so that experimental results can be easily viewed within the context of another informatics system. For example, in a compound screen, it must be possible to take a collection of hits determined by the HCS and send the list of compounds they resulted from to a cheminformatics system in order to determine the structure–activity relationships for these compounds. Similarly, for an RNAi or other genomic screen, it must be possible to ascertain what is known about the functions of the genes that were scored as hits. Clearly these are not within the scope of an HCS system, so it must maintain references to compounds and genes in order to perform these tasks using other information sources. For general issues in data federation, see also Chapter 41.

4.6 Visualization and User Tools

Effective use of an informatics system for HCS requires tools that biologists can use to locate, manage, manipulate, and interpret various types of data. Given thousands of images, divided into hundreds of sets for various experiments, simply locating raw data might be challenging, particularly when the data is not recent. Similarly, the presence of numerous analytic modules, workflows, and data types for analytic results poses challenges in navigation and searching. An integrated, extensible environment that provides linked, coordinated tools for these tasks will provide multiple perspectives on the various types, along with tools for manipulating them as necessary (Figure 20).

5 Conclusion: Research Questions and Challenges

Effective visualizations leverage the power of the human visual and perceptual system to amplify cognition [31]. Visualizations of biological data can help scientists interpret experimental results, evaluate hypotheses, generate new hypotheses and build models. Maximizing the potential of these visualizations will require development of tools that are appropriately designed to support meaningful tasks, flexible in their management and presentation of data, and integrated with other visualizations, data sources and tools.

Appropriately designed tools will be based on detailed understanding of user needs for specific data sets and tasks. Although most of the systems described in this chapter were designed to meet specific needs, descriptions of explicit needs assessments are relatively rare. Task-specific analyses of user needs can provide invaluable guidance for visualization design. Questionnaires [170] and interviews [151] are standard techniques that have proven useful for this purpose.

Evaluation is a crucial element of appropriate visualization design. Given multiple different approaches to visualization of a given data type, which (if any) is best? Two-dimensional [135], hyperbolic [92] and 3-D immersive [147] approaches have been proposed for phylogenetic and taxonomic trees. Given multiple different approaches to visualization of a given data type, which (if any) best? Without some means of identifying strengths and weaknesses of various techniques, researchers will be limited in their ability to constructively build upon prior work, or to select the most appropriate tools for their own analysis. Although controlled user studies [150] and heuristic evaluation by expert users [48, 151] have been applied to some tools, evaluation is relatively rare. Related work in human–computer interaction and information visualization research may prove useful to developers of biological visualizations: the relative strengths of 2- versus 3-D interfaces have been repeatedly examined [43] and the development of evaluation techniques for visualizations has been identified as a general challenge in information visualization [139].

Many of the visualization systems described above are limited in their flexibility. Although some systems provide linked alternative views of a data type, others are limited to a single visual representation. Many proposals tightly couple a visualization tool to a novel analysis algorithm.

Tools that support the analysis of data via multiple different linked representations may help users find patterns that would not have been visible in any single view. Support for ad hoc coordination of alternative views might be particularly powerful in this regard [132]. Decoupling of analysis algorithms from visualization tools can help scientists make meaningful comparisons between competing analytic approaches.

Extensible visualization environments and toolkits of reusable components can facilitate development of these systems. Third-party developers have used plugin architectures for Cytoscape [160] and ImageJ (http://rsb.info.nih.gov/ij) to substantially augment the capabilities of the base tools. General-purpose information visualization toolkits [12, 59, 77], as well as special-purpose toolkits for bioinformatics visualization such as GenoViz (http://genoviz.sourceforge.net) and the genome data visualization toolkit [174], can simplify system development substantially.

A final form of flexibility involves innovative use of display technologies. Tools that take advantage of high-resolution desktop displays [129], wall-sized displays [82] and immersive environments [147] provide opportunities for display of larger data sets and increased collaboration between users.

Integrated visualizations of multiple data types can provide interpretive power not available in simpler tools. Examples including multi-track genome browsers [89, 97] and microarray visualizations augmented with GO annotations [8] illustrate the possibilities, but much more can be done in this regard. Approaches such as the "omic space" model [186], which integrates several types of data in one display, may be quite powerful. Another useful approach to integration might involve connections between visualizations and accepted models for experimental and related data, perhaps including microarray [166] and microscopy [70] data models.

Visualizations should also be integrated with the experimental process as a whole. Combining with systems biology tools [90], analysis workflow tools [70,133], and analysis and data storage platforms [181] raises a number of challenges similar to those described in the above discussion of image informatics. However, the resulting systems will increase the power of visualization by providing scientists with the ability to examine raw and interpreted data and metadata in a coordinated manner. Such combinations will provide rich context and interactivity necessary for active exploration and generation of scientific insight.

Using Distributed Data and Tools in Bioinformatics Applications

Robert Stevens, Phillip Lord, and Duncan Hull

1 Introduction to Distributed Resources

The advent of the web has been both a great blessing and a bane for bioinformatics. While it has given researchers access to a large store of data and tools with which to analyze these data, this wide access does have its adverse consequences. The use of web technologies enable organizations and individuals to provide and retrieve data cheaply. This obvious blessing is accompanied by the drawback of distribution and autonomy: the need to join together distributed resources that have developed along different lines. To accomplish most bioinformatics analysis, it is necessary to use more than one resource – a genomic DNA sequence is analyzed with a gene prediction program, a hypothetical gene is translated into protein, that protein is searched against a protein data bank for possible homologs and so on. Traditionally, a bioinformatician has done this by manually cutting and pasting material from page to page on the web. Doing this programmatically necessitates networked applications or distributed computing.

This chapter explores the use of distributed and networked computing. Many of the issues these raise, e.g. fault tolerance, network latency, etc., have been discussed in detail elsewhere [27]; here, we consider those issues which are specific to bioinformatics. We take a practical and historical view, describing how bioinformatics has developed in a networked environment, but we then come right up to date by looking into the future of Grid computing. We will describe the lessons both of failed attempts to address networked applications and the success stories that have emerged.

The fundamental requirement for networked applications arises from the distribution of the laboratories working in bioinformatics, which is characteristic of biology as "small science" or a patchwork of "rival city states" [22].

When sequence data began to be generated, as long back as the late 1970s and early 1980s, researchers wished to exchange data for comparison etc. Distribution at that early stage was by means such as tape, disk and, finally, CDs.

ISBN: 978-3-527-31278-8

Basic advances in infrastructure solved the problem of transferring data. It was the advent of the web which reduced the requirement for specialist knowledge to do so. Bioinformaticians and biologists were early adopters of this technology. Most laboratories had relatively small amounts of data to present and this was often achieved by use of a text editor, and then simple use of active content via the Common Gateway Interface (CGI). The use of common protocols [HyperText Transfer Protocol (HTTP)], a relatively simple language [HyperText Markup Language (HTML)] and simple user-facing client tools ensured that this technology would become widely adopted.

One of the main virtues of the web is its lack of centralized control; this makes it scalable as there is no single point of failure or bottleneck. Both service providers and consumers are highly *autonomous* from each other. Bioinformatics has used this autonomy to the full; data was stored in nonstandard file formats, with each entity structured using an *ad hoc* ASCII encoding defined by the data holder. This result in a plethora of different file formats; the classic example in bioinformatics is the many formats for biological sequences such as nucleotide and proteins. Thus, for example, the program from EMBOSS `seqret` (http://emboss.sourceforge.net/apps/seqret.html) can take 28 different sequence formats as input and transform them to a format required by subsequent analysis tools.

Many of these resources also grew at the time before relational databases were widespread and scalable. A relational database management system (RDBMS) does provide better data management and query facilities than flat-file delivery, but at the time they were often expensive and lacked the ability to efficiently deal with the large amounts of nonscalar data necessary in biological databases. Even though many bioinformatics resources now use RDBMs, the exchange format is still largely in the legacy flat file.

Tools working over these data have developed in a similar autonomous manner. They take data in a particular format and deliver their results in a nonstandard format. Again, this is usually as some formatted ASCII text. This *heterogeneity* is one of the major hurdles in distributed computing within bioinformatics.

As with the web, this large quantity of data available to the bioinformatician is only really usable because of the use of massive hyperlinking, e.g. the current release of UniProt maintains links to over 60 other resources by cross-linking accession numbers and identifiers from each of these resources. These are usually translated into HTML links when presented to users within a browser.

There are now very many data sources and tools available. The 2005 edition of the annual database issue of *Nucleic Acids Research* describes over 700 [10] data resources, along with hundreds of analysis tools. As new biological techniques develop, such as transcriptomics and proteomics, more resources are developed to accommodate their data. Combined with the desire to perform more complex analyzes, the traditional cut and paste methods of bioinformatics have become increasingly unusable.

Bioinformaticians, therefore, began to develop programs to automate the process, gathering data and tools distributed around the network into single applications. In doing so, they had to overcome a series of problems, and it is these problems and their solutions that are the subject of this chapter. The subjects to be covered are:

- Overcoming the problems of heterogeneity between tools and resources (Section 2).
- the inclusion of data and tools hosted on another computer into an application running on a local computer (Section 4).
- Technologies for this inclusion, such as Common Object Request Broker Architecture (CORBA) and web services (Sections 4.1 and 4.3).

As we review these issues, many examples of distributed or networked applications will arise. In Section 5, we will review some case studies in networked applications in bioinformatics. We finally conclude by introducing cutting edge technologies such as the Grid. This chapter will explain the central role that distributed computing has in modern bioinformatics and provide the reader with the foundations of the field.

2 Heterogeneiety in Bioinformatics Resources

If all distributed resources worked with one standard data format and application programme interfaces (APIs), the existence of the Internet would be enough to deal with most of the problems manifest in distributed computing. The common communication protocols would enable applications to access distributed components running on a variety of machines and their various operating systems. Sadly this is not the case, and considerable difficulties are caused by their differing APIs, query languages, syntaxes, format differents and, finally, but not least, their differing semantics for their content.

This heterogeneiety is the major barrier to distributed computing. Although there is a common communication protocol through the Internet, networked applications still have to deal with the following heterogeneities [18]:

(i) System heterogeneity.

(ii) Syntax heterogeneity.

(iii) Structure heterogeneity.

(iv) Semantic heterogeneity.

System-level heterogeneity means that it is difficult to access and use applications residing on another type of computer and operating system. Recently, quite a number of cross-platform languages have arisen, including Perl and Java, which are widely used in bioinformatics. The use of these languages solves some problems, but introduces others as it often becomes necessary to get these cross-platform languages to interoperate with each other.

CORBA and web services are two technologies used to overcome these low-level problems that have seen usage in the bioinformatics arena. These really are the "plumbing" that connects distributed resources together. These will be discussed further in Section 4.

System level heterogeneity can also impact on the other levels: the line terminator differences between different platforms is really a syntactic problem; it is at this level that we start to find the examples of heterogeneity which affect bioinformatics most heavily. A cynic might observe that one necessary condition for being a bioinformatician is to have written parsers for BLAST output or Swiss-Prot records. The syntactic differences between bioinformatics resources means bioinformaticians are forever writing parsers to convert results into a form suitable for their application. A common syntax would mean that such conversions would be easier to achieve or indeed to understand what the syntax actually means – most bioinformatics flat files have no formal, computable description of their syntax.

Both the autonomy and legacy issues within bioinformatics, however, mean that such common standards are difficult to achieve. ASN.1 [4] is one such attempt at a standard syntax that was not widely adopted. eXtensible Markup Language (XML), which is covered later in Section 4.2, has and is having greater success in bioinformatics.

As well as myriad examples of syntactic heterogeneity, bioinformatics is rife with structural heterogeneiety. Even if we had a common syntax, such as XML, for formatting data, we would still have the problem of how we structure this data within the syntax. A simple case in point is the representation of authors in a literature reference. For example, compare this XML representation of one of the authors from UniProt:

```
<authorList>
   <person name="Lord P."/>
</authorList>
```

with this from GenBank:

```
<Person-id_name>
   <Name-std>
       <Name-std_last>Lord</Name-std_last>
```

```
        <Name-std_initials>P.</Name-std_initials>
    </Name-std>
</Person-id_name>
```

The former makes no attempt to structure the name, while the latter splits initials and last names. To compare these two authors then to see if the name is the same requires a set of rules to produce a normalized form. Communication between distributed, autonomous resources requires the use of the structure of the data in order to access just those parts required for analysis. Obviously, differing structures to hold data means problems for using those data.

Much of system, syntactic and structural heterogeneity would be dealt with by a common type system, as described in Section 3, and the lack of such a common system and its consequences are manifest.

Lastly, and certainly not least, is semantic heterogeneiety. This is the difference in meanings between the representations held in different resources. Karp [12] and Davidson and coworkers [6] identified semantic heterogeneity as one of the major barriers to integrating bioinfformatics applications. Ontologies, covered in Chapter 29, are seen as a technology for capturing the semantics of a domain [26]. They offer a mechanism for creating a shared understanding, via vocabulary terms, for a given domain. A particular data resource either adopts the ontology and changes their data or maps their current reprsentation into the ontology. Both of these can be seen with the Gene Ontology [28]. Swiss-Prot uses GO terms directly and mapped its current keywords into an ontology to achieve *de facto* semantic integration.

Much of the work in distributed computing or networked applications is in overcoming these four levels of heterogeneity. Dealing with heterogeneity is a prerequisite for any kind of data integration, as covered in Chapter 42. In this chapter, we concentrate on the aspects of system and syntactic heterogeneiety. The "upper" two levels of heterogeneiety are the subjects of Chapters 29 and 42.

3 Type Systems in Bioinformatics

In building bioinformatics applications, we are interested in manipulating data, but how does a programme know what operations can be performed on any given piece of data? In computer science, a type or datatype is a name for a set of values with shared properties. A *type system* uses these types to constrain the operations that may be performed on the values of a given type [29]. So, for example, the type *integer* typically describes the set of natural numbers. A type system then enforces that only integer operations such as division and multiplication can be performed on integers, and prevents or warns against nonsensical operations such as substring selection from being performed on integers. Type systems are implemented in many different ways, e.g. as part of a programming language or in a database/schema language. This easily leads to heterogeneiety when different type systems are used. Thus,it is worth examining "type" in a little depth.

Type systems differ in their complexity and expressivity, but they generally have several benefits:

- Type checking and safety – making sure only integer operations are performed on integers or "protein operation" performed upon proteins.
- Optimization – manipulating each type and its operations in the most efficient and effective manner possible on a machine.
- Abstraction – creating a model of a domain through a type system and knowing, for example, that "DNA" and "RNA" are both kinds of "nucleic acid".
- Pipeline construction – using the type system to transfer data between components with predictable outcomes.

The heterogeneity pervasive in bioinformatics means there is no globally accepted type system for describing bioinformatics data. This forms a major barrier against integration of distributed data and applications.

In a programming language, if a variable is declared to be of a given type, then a program can check that declarations are valid and safe. Thus, for example, in a statically typed language, a compiler would check that strings were not assigned to variables of type integer, by type checking the statement:

```
Integer i = "this is a string"
```

The statement assigns the value `this is a string` to a variable *i* of type *Integer*, which will cause problems when integer operations like division and multiplication are performed on that string. In a statically typed language like Java, a *compiler* will warn against these sorts of assignments at compile time. In dynamically typed languages like PERL, this type checking is done at run time by the *interpreter* and may involve automatic type coercion from one type to another.

A type system can also help the programmer to abstract away from the binary digits that the computer deals with when the program is executed. In this sense, a type system is a model of the world, which helps users of programmers to describe the data they are manipulating.

Most type systems allow further abstraction than primitive types like `string`, `integer` and `dates` by allowing user-defined or complex types to be built from primitive ones. So, for example, a bibliography might be modeled in a type system as a list of references, each with authors of type string and publication dates of type date. Again, as well as having better descriptions of the data, it is possible to define the operations performed on those descriptions, as seen in object-orientated programming languages.

Joining the inputs and outputs of two programs together, as seen in networked applications, can be facilitated by a type system. Given an instance of a type, such as a UniProt record, a type system can help to:

- Infer its type by *type inference* – this automatically assigns a type if it is not explicitly stated
- Identify a set of other types into which a UniProt record can be transformed
- Identify a set of processes that accept UniProt records as input. This includes processes that accepts parts of UniProt records, such as protein sequences and database identifiers. This can be useful when constructing programs or workflows that process data as it allows the programmer to find out what they can plug in next, at any given point in the dataflow.
- Identify a set of processes which output UniProt records. This can be useful in planning techniques, which start from an endpoint and work backwards to a starting point [3].

As a consequence of the autonomy of bioinformatics, there is no globally agreed upon and used type system for modeling bioinformatics data. Given the autonomous and distributed nature of bioinformatics, this situation is unlikely to change. Instead of a global type system, we have many different type systems implemented in the various languages used in bioinformatics. This causes heterogeneiety at the system level, as 'integer' may be represented as 2 bytes on one system and 4 bytes in another, meaning operation of the programme may not be the same. Also, complex types such as "protein Data Bank entry" will be different in each application or tool. In addition, we have the type systems of each of the 700+ [10] databases that exist in bioinformatics.

As well as having distributed data that is autonomously produced and therefore heterogeneous, bioinformatics data is often semistructured and weakly typed – the ubiquitous flat file being the best example of this. These flat file entries will often be returned as "string" to a programme. The structure and the type of the data are thus implicit, and usually have to be parsed and transformed to some type system by the application developer.

An important consequence of the lack of a type system in bioinformatics is that joining distributed resources together frequently requires the use of "shims" to align the inputs and outputs of two closely related pieces of data [14]. An example is shown in Figure 1.

These shims perform some of the operations associated with a type system in an *ad hoc* manner. They achieve this by coercing, inferring, casting and

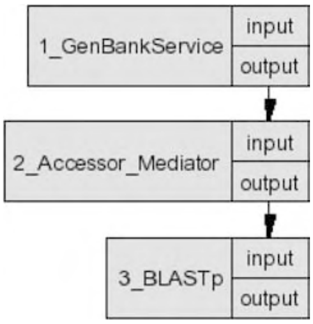

Figure 1 A shimming scenario in bioinformatics. A GenBankService (1) producing a GenBank record needs to be plugged into a BLASTp service (3), which accepts a protein sequence. Getting services (1) and (3) to interoperate requires an Accessor_mediator service (2) to extract the protein sequence from the GenBank record.

constructing types when they process the weakly typed and semistructured data that is common in bioinformatics.

A good type system is very helpful in manipulating data. Bioinformatics application builders spend much of their time overcoming the consequences of having no global type system. In the next section, we will see that describing the type of data being moved and dealing with system heterogeneity is one of the major factors in achieving distributed computing.

4 Plumbing Bioinformatics Resources

When developing applications in a distributed environment, a fundamental activity is to join resources, and pass data between data stores and analytical tools. To the programmer attempting to use distributed bioinformatics resources within a single program in this way, the fact that different resources present different programmatic interfaces (or none at all) implies that a considerable amount of effort has to be expended. For example, consider the case when a Java program needs to access a remote database written in C++ and feed some of the results to another program written in Perl. In order to do this the programmer must cope explicitly with the different languages in question – the C++ will be invoked in one way, Perl in another – and with the distribution. The C++ program is likely to be invoked differently if it were to be available on the local machine. This kind of coding requires a large amount of effort and the resultant program tends to be fragile. If it is decided to mirror the database locally, the Java program will need rewriting. If the Perl program is ported to C++, again the Java needs rewriting.

It would be possible to *integrate* all the required tools and databases in a single place – in practice this is often impractical, so instead, interoperability, providing the ability for resources to work together while remaining separate or "loosely coupled" is often more desirable. One solution to this problem is to use some *middleware* technology. As the name suggests, this technology adds a middle architectural layer which abstracts from the different languages, systems and locations. Following the example above, instead of writing code in Java to invoke the C++ database directly, both will be *wrapped* with the middleware technology. This technology then has the task of managing the communication between these wrappers around the two different implementations. While this seems overly complex, it actually simplifies many issues. The Java programmer no longer has to worry either whether the C++ database is local or remote, nor does it matter that interaction is needed with both C++ and Perl. Therefore middleware technologies offer an attractive solution to overcoming system and syntactic heterogeneity in a distributed setting.

In this section, we consider a number of middleware technologies and their use within bioinformatics. First, we describe ww CORBA (Section 4.1). This technology provides both a standard mechanism for data structuring and for providing (relatively) transparent access to the structured data across distributed systems. Second, we describe XML (Section 4.2) which provides a common syntax for structuring data. Finally, we examine web services (Section 4.3), which use HTTP – the protocol on which the web is built – to overcome system level heterogeneity, leaving syntactic problems to XML.

4.1 CORBA

CORBA is one solution to the problems of system and syntax heterogeneity. Its use in bioinformatics arose in the late 1990s and is now a mature industry standard, and has been widely proposed as a solution to the problem of distribution in bioinformatics.

CORBA attempts to present a common view of the world by presenting it from an object-modeling perspective. To continue the example introduced earlier, to the Java program using CORBA, both the C++ database and the Perl program would appear to be Java objects. Interaction with these objects would be identical to interaction with any other Java object. Similarly, on the C++ side, queries to the database would appear to be coming from a local C++ object rather than from a remote Java program.

To enable this technology, the target resources can be described in a common language. This common language can then be compiled automatically into the programming language of choice, which then enables these target resources to appear as if they are part of the local host application. A core feature of the CORBA specification is this language – the Interface Definition Language

(IDL). This language is used to describe the operations, including return types and arguments taken, that the target resources perform and it can be used by CORBA-compliant tools to generate code for both providing access to the services and the means for the services to be accessed.

As the name suggests, IDL is a language that describes an object's interface; it does not, however, describe how the behavior offered by that interface is implemented. Thus, it is independent of any individual programming language, although, in practice, it looks somewhat like C++.

The actual work of enabling this interaction between different IDL-described resources is a fairly complex procedure. By analogy to financial brokers who organize complex financial transactions, requests between CORBA objects are mediated by an object request broker (ORB). The CORBA bus is the communication system between objects used by an ORB. Different vendors supply their own ORBs, so one person's client may, in theory, use a different ORB to the one being used by the server with which they wish to communicate. This is the importance of the common part of CORBA – it is a common architecture for ORBs. One of the specifications in the CORBA standard is that ORBs will interoperate. This means that one vendor's ORB will (hopefully!) work seamlessly with another vendor's ORB. Figure 2 shows the relationship between client and server objects, their ORBs and the CORBA bus along which they communicate.

While the interaction between ORBs appears to be precisely specified, there is actually considerable scope for variation between them. For most CORBA applications, performance is constrained by network latency – the amount of time it takes to make an initial connection. Theoretically, therefore, good CORBA implementations should all have a similar performance bound by the network; however, in practice, it can vary significantly.

Although CORBAs middleware technology offers a solution to system and syntax heterogeneity, it does not of itself provide a solution to structure heterogeneity. There is nothing to prevent different resource providers modeling objects in different ways. Again, considering the earlier example, the database may return objects representing authors of bibliographic references, while the Perl program may consume similar, but different, structured objects. The Java programmer must therefore map between the different object representations.

The CORBA technology and specifications are overseen by the Object Management Group (OMG). In addition to the basic specifications, the OMG also defines a complex social process for standardizing the IDL representations for a specific domain.

Many of the standards produced by the OMG are specifications for services which support the use of distributed objects. When, for example, objects are distributed, they have to be found by programs which wish to use them. Thus, the two fundamental services offered are the *naming service*, that finds objects

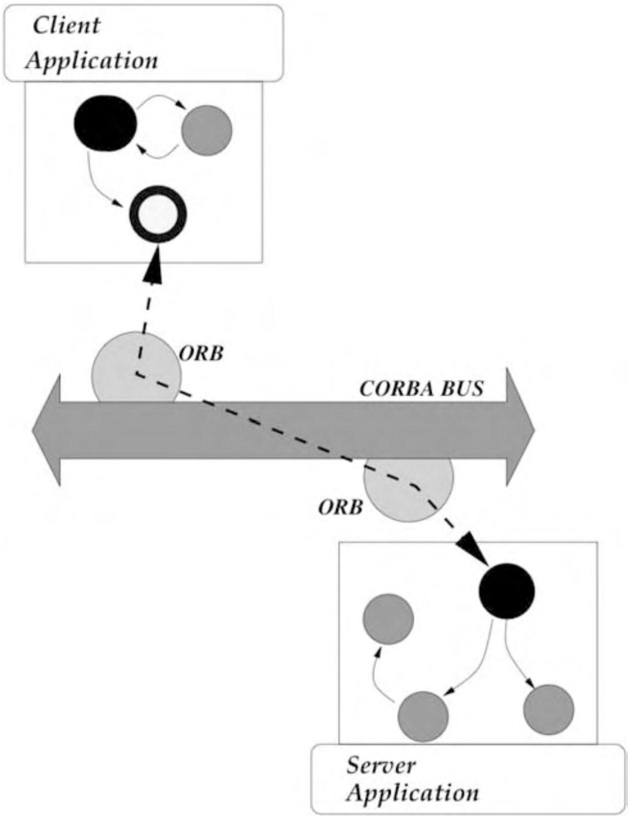

Figure 2 The CORBA bus.

by name, and the *trading service*, that finds objects by the requests they answer. Other services include object life cycle services, event services and security services. Many other services are specified within the CORBA specifications, but they all support the use of distributed objects and make use of the CORBA bus to communicate.

In addition to these generic specifications, there are also a number of bioinformatics domain specifications. The European Bioinformatics Institute (EBI), in particular, invested significant effort in providing CORBA solutions for many services, including EMBL (http://corba.industry.ebi.ac.uk). The OMG formed the Life Sciences Research Group (LSR) that has developed several standards for services including bibliography and sequence resources [5, 19, 20]. However, the uptake of CORBA by the community has not been widespread. The main reasons for this have been the perception that CORBA is too heavyweight a mechanism – the large effort required to develop the standards seen as necessary by the OMG and the implementations themselves obstructed development. Many of the early ORBs were expensive and focused on enterprise-level computing, which did not fit well with the bioinformatics cottage industry. In addition, many ORBs themselves did not actually interoperate. Finally, CORBA seemed to be plagued by continual problems with tunneling through firewalls, defeating the promise of location independence.

Despite these difficulties, CORBA now offers a usable technology. Many languages, such as Java, now provide basic ORBs which can be used for free. If a fine-grained, object-based, platform- and language-independent middleware is required, CORBA is probably still the best option.

4.2 XML in Bioinformatics

Syntactic heterogeneity is commonplace within bioinformatics. This situation is made worse by the heavy use of "flat file" formats. Many of these have no formal specification – an exact description of what is and is not allowed within a file – meaning that parsers are both hard to write and standard tools, such as lex and yacc [13], are not able to automate the process. This also creates a huge versioning problem – when the format of a BLAST record, for instance, changes there is nothing that tells you it has changed until all the software, which depend on the format, breaks.

One standard syntax which is in common use is HTML. This does a reasonably good job of describing documents so that they can be presented on the web. However, this presentational format does not reveal the underlying structure of the data, such as all the fields, etc., in a flat-file database entry. In fact, it can make the situation worse. As quite a few bioinformatics resources are available only through a web site, automated use can require "screen scraping" techniques, i.e. using a program to make an interpretation of HTML which is meant for presentation to humans. This works but is even more fragile than flat-file technology. Every time the web site presentation changes, it may potentially break downstream programs.

XML (http://www.w3.org/xml) is a potential solution to this problem. Despite its name, it is not actually a markup language, but rather a description of how to specify new markup languages or "application" of XML, such as HTML. (This is not actually true. HTML is actually an application of SGML, which is a somewhat more complex fore-runner of XML and HTML does not quite conform to the restrictions of XML. There is a new version of HTML, called XHTML, which is valid XML.) Languages such as the Standardized General Markup Language (SGML) are "languages for languages" or metalanguages. It can be used to define the structure of documents in a particular domain. So, HTML describes the structure of a web page to have a header and a body that may contain headings, paragraphs, tables, images, etc. With SGML, it is possible to define a formal grammar which specifies which tags are valid within a document and how these tags relate to each other. The meta-language is used to define what elements may appear in a document, where they can appear and how often, etc. This grammar provides a schema for the document – XML Schema.

XML is a lighter weight version of SGML, but it has a language for describing document structure – hence the term "extensible". HTML, on the other hand, is a document structure for a particular domain (presentation on the web) and is not itself extensible to another domain. XML does, however, provide a common syntax in the now familiar tree of nested elements (see the description of names in Section 3 where *elements* are enclosed in angle brackets, etc. This combination of document structure, common syntax and available tools make XML a powerful tool. It is possible, for instance, to check that a document is *valid* XML syntax – all elements are matched with closing elements and elements are properly nested. etc. Tools are also provided that take a document and together with its XML schema not only validate the document, but *verify* it against the schema. Any part of the document that contravenes the rules in the schema means a document will not verify.

Uptake of XML within the sciences has been widespread; the Chemical Markup Language (CML) is widely recognized as one of the first substantial uses of XML technologies (http://www.xml-cml.org/information/ position.html).

When it was first introduced in 1996, initial uptake of XML in bioinformatics was relatively slow, due to rapidly changing specifications and poor tool support. XML is now, however, relatively mature. There are standard parsers, APIs for the Document Object Model (DOM) and simple API for XML (SAX), cross-linking and query standards (XPointer, Xquery) and stylesheet and transformation languages (CSS and XSLT) (http://www.w3.org/xml). Another large issue has been the substantial investment in legacy tools; although both UniProt records (http://www.ebi.uniprot.org/support/documents.shtml) and National Center for Biotechnology Information (NCBI) BLAST results (http://xml.coverpages.org/ncbiDataModel.html) have been available as XML for a number of years, most tools still work on the original flat-file formats.

It is notable, however, that for newer databases, such as Interpro (http://www.ebi.ac.uk/interpro/), XML is increasingly becoming the representation of choice. It is even more widely used as an interchange language, often as a layer on top of a relational database, with languages such as Bioinformatics Sequence Markup Language (BSML) (http://www.visualgenomics.com/products/) that is mostly aimed at describing sequence features rather than sequences *per se*.

While XML has an important role to play in distributed resource management, it is important to understand what it does and does not provide. It does offer a standard syntax and language for describing and customizing the use of this syntax, i.e. it is extensible. It supplies a type system to the data it describes. It does, however, provide a "self describing" format. The presence of an <AUTHOR/> tag into a document is, intrinsically, no more informative than <H1/>. For an XML format to be useful, therefore, it must be agreed on by the entire community and the semantics, or meaning, of the individual tags clearly defined. This degree of centralization and control, in many ways, contradicts the distribution and decentralization which is characteristic of bioinformatics.

XML is not a universal solution to the problems of distributed data integration [1], but by overcoming syntactic heterogeneity it does provide valuable facilities for describing data structure which most bioinformaticians are likely to use at some point.

4.3 Web Services

While CORBA proved technically successful, in recent years web services (http://www.w3.org/TR/wsdl) have started to take over as the predominant paradigm for client–server interactions. Perhaps, partly, in response to the perceived complexity of CORBA, web services were designed to build on the success of the world wide web and one of its key messages, that many things can be achieved with a simple system. Since the initial advent of web services a panoply of toolkits and specifications have arisen, provided a fully featured and functional technology.

Web services take the same basic approach to distribution as CORBA, but with several significant differences. At heart, both CORBA and web services take a description of a service being offered and produce code for developing clients and servers. Web services takes the view that distributed tools and data are offered as "services" to applications that wish to use them. Any such *service-orientated architecture* has the following requirements:

- A standard communication protocol between services and host application.
- A uniform data representation and exchange mechanism.
- A standard language to describe the service's attributes and operations.
- A mechanism to register and discover web services.

The web services technology stack fulfills these goals. The Simple Object Access Protocol (SOAP) is the channel used for communication between a web services provider application and a client application. SOAP re-uses the HTTP for transporting messages. Messages are passed between services using XML documents. The structure for SOAP message includes an envelope and a body. The body itself describes a message to a service, e.g. a call to a particular operation or communicate failure. The envelope gives the metadata necessary for this invocation

As CORBA's IDL is used to describe services, web services use another XML document type to describe services. The Web Services Definition Language (WSDL) is used to describe the operations and attributes for a service. A WSDL description, like CORBA's IDL, is used to generate both client and server code for the service. WSDL can be used to generate a variety of programming languages on a variety of platforms. Client and server, once deployed, are ready to pass SOAP messages between one another.

Finally, just like CORBA's naming and trading services, web services need to be discovered for use. WSDL documents can be placed in a registry based on the Universal Description, Discovery and Integration (UDDI) (http://www.uddi.org) framework, and these registries can be searched to retrieve WSDL descriptions of interest. A user would then compile that file to generate a client and use information from the WSDL description to locate and use the service.

Web services take a different approach to that of CORBA. While the latter uses a remote object approach which provides the ability for passing around data and subsequent fine grained client–server interaction, with that data, web services use a "document-based" paradigm. Here, potentially complex structured data is passed between services in bulk. The hope is that instead of a series of fine-grained interactions between client and server, fewer coarser, but richer, interactions will happen – something of clear benefit when faced with any serious problems of network latency or failure.

Ironically enough, this document based, service-orientated architecture bears many similarities to the traditional bioinformatics approach of passing complex data from Perl-driven CGI scripts. However, standard technologies for describing service interfaces, for presenting these services, for structuring the documents passed between services and for discovering services, were all lacking in bioinformatics' original *ad hoc* implementation of this service-orientated architecture, and are all provided by the web services technologies.

Both web services and CORBA provide technical solutions to integration and both have been deployed in bioinformatics (see Chapter 42). Web services have had the greater uptake, due to their perceived lighter approach and ability to do bulk transfer.

There have been a number of different projects, some of which are described in Section 5, which use some or all of the web services technology stack. In addition to these projects, quite a few service providers are now providing programmatic interfaces as a web service, including for example Interpro (see http://www.mygrid.org.uk for a list of available web services).

Although bioinformaticians are using web services, there are a number of peculiarities in their usage within the domain. The intention of the design behind web services was that all the data would be modeled as XML. In bioinformatics, this is a big requirement to place on service providers, as presentation of many of the standard bioinformatics data types in XML is nontrivial. In addition, there is a large legacy with which to deal. For this reason, many of the web services use XML only as far as describing their complex, structured, flat-file results as `xsd:string` – the XML string type. In short, these web services look much like their CGI progenitors, but with a thin web services veneer.

It seems likely that the uptake of web services will continue, as a result of several synergistic advances: the web services specifications and toolkits are stabilizing, standard XML representations for bioinformatics are becoming more widespread, and, finally, client tools are becoming available.

5 Case Studies in Distributed Bioinformatics

In this section, we consider a number of different projects as case studies for the use of distributed technologies within bioinformatics. All of these projects have focused on providing a middleware layer to either integrate or inter-operate over heterogeneous data sources and to provide some degree of transparency to the distribution of the resources. Chapter 42 also describes examples of integration of distributed resources in bioinformatics.

5.1 ISYS

ISYS is described as a decentralized, integration system, as opposed to a distributed system *per se* [21]. The aim was to enable the integration of a number of different components, to allow their interoperation without a tight entanglement of their respective code bases. ISYS was particularly directed at producing user interface-driven interoperation, enabling data to be passed freely between components. ISYS achieves this with several key components:

- The ClientBus. The various components to be integrated can be registered with the ClientBus. All communication between components then passes through this system.
- An event model. The ClientBus is used to transfer Events between different components. Components can produce or consume events of different types. As ISYS is aimed at user-driven integration, these event types are quite fine grained, describing, for example, selection or deselection of items within the user interface.

- A domain model. In order to enable different components to communicate a common data model was defined using Java interfaces. Examples of the kinds of data include ISYSSequence (for nucleotide sequence) or IsysTaxon.

While ISYS was not necessarily intended as a distributed system its loose coupling does enable it to be used in this way. Distributed services can be accessed by providing Java wrappers which then call out to these services. For example, Access to the NCBI BLAST service was provided in this way.

5.2 BioMOBY

BioMOBY is an architecture for the discovery and distribution of biological data through decentralized web services [30]. The BioMOBY project has a dual development track with different architectures, known as MOBY-S and S-MOBY (http://www.biomoby.org).

The project originated in the model organism communities where each community had developed standards for sharing data within their closed groups. Many biologists, however, now wish to ask questions requiring data from many different organisms. BioMOBY [30, 31] is an architecture for the discovery and distribution of biological data through web services. As of November 2005 it provided around 400 services for analyzing genomic data. A key feature of BioMOBY is the central registry of services, called "MOBY central", that allows different client programs (e.g. http://mobycentral.icapture.ubc.ca/cgi-bin/gbrowse_moby) to search, browse and execute services that produce or consume a given piece of data, e.g. a GenBank accession number.

5.2.1 MOBY-S

The core philosophy behind MOBY-S has been to ensure "simplicity and familiarity"; the second of these must be emphasized as MOBY-S has focused on familiarity to the bioinformatician. In short, MOBY-S has sought to minimally modify the way that bioinformaticians already work, which largely consists of web-delivered services and CGI scripts. S-MOBY adds to this in three key ways:

(i) A domain ontology. This describes the basic data types in bioinformatics and the relationships between them. In keeping with the notion of familiarity, the ontology is defined as a directed acyclic graph, a representation popularized by the GO [28] (see Chapter 29).

(ii) Messaging. An XML messaging layer has been defined. This provides a description of the wrapped data in terms of the domain ontology, as well as defining some additional relationships between the wrapped data and the information upon which it depends.

(iii) A central discovery server. In addition to the use of the ontology to describe the data provided by the services, the services themselves can be defined in terms of this ontology. This then enables the population of "Moby Central" using the ontology to describe the services.

In some ways, MOBY-S resembles web services architectures, although it predates the widespread adoption of these technologies. Mostly for this reason it does not use all of the web services technology stack.

One of the key decisions made by MOBY-S was to design for an open and extensible system. Moby Central itself is freely accessible. The ontology is accessible and extensible by service providers. MOBY-S itself does not impose any standard for representing the data that it passes around, instead leaving the structuring to the service providers and consumers. This open structure has meant that the original notion of a single Moby Central repository has become outdated; a number of different "in-house" repositories now exist.

5.2.2 **S-MOBY**

The S-MOBY project has been aimed at building on two key architectures. The first of these is the REST architecture [8] and the second is the Semantic Web [2].

As with MOBY-S, the basic idea is to produce middleware enabling the presentation of services with a defined interface and then to augment this with descriptions of these services defined in terms of an domain ontology. Unlike MOBY-S, however, S-MOBY adopted a Resource Description Framework (RDF) (http://www.w3.org/rdf/) representation for its messaging layer with the intention of enabling much deeper structuring of the core bioinformatics datatypes. Secondly with the adoption of OWL-DL (see Chapter 29) as the main formalism for representation of the domain ontology, it should be possible to enable more distribution in the development of the ontology, i.e. different users of S-MOBY should be able to define their own ontology for their own purposes. Finally, central registration of services was never envisaged to be mandatory; descriptions would be published in a standard format on the web, to enable the use of different search engines.

5.3 The Grid Future – the ^{my}Grid Project

The term "Grid" was coined in the mid-1990s, and is the focus of much attention as a distributed computing infrastructure for advanced science and engineering [9]. At its heart, the Grid is about sharing and the transient creation of *virtual organizations* of these shared entities [9]. If this were to happen, some of the same problems, but with different manifestations, are encountered as with data distribution:

- Accessing computational power of differing platforms.
- Scheduling usage across multiple resources.
- Moving data and resources to these platforms.
- Coping with issues of security and authorization.

This access to general resource sharing makes a Grid – defined as "flexible, secure, coordinated resource sharing among dynamic collections of individuals, institutions, and resources" [9]. It is easy to see how this paradigm fits into the world of bioinformatics: A sophisticated, complex bioinformatics *in silico* experiment may involve people, many forms of data, instruments, etc., and all of these could share resources in a Grid [11].

5.4 The ^{my}Grid Project

An example of Grid development is ^{my}Grid (http://www.mygrid.org.uk), a UK e-Science pilot project which is producing Grid middleware infrastructure specifically to support *in silico* experiments in biology [24, 25].

From the issues facing a scientist performing *in silico* experiments come a strong set of requirements to automate the experimental process, its repetition and to support the management of the results. ^{my}Grid addresses these requirements by regarding *in silico* experiments as *workflows* [25]. These workflows automate experiments by orchestrating the services that process data. ^{my}Grid not only supports the creation of the experimental protocol (the workflow), but also the management of the inputs, outputs, intermediates, hypotheses and findings – for the individual and wider groups of scientists. This includes an awareness of the experiments and data holdings of the user, his or her colleagues and the wider scientific community. The aim is to place the scientist at the center of a virtual bioinformatics organization and the flexibility of data management that affords that scientist a *personalized* view of his or her experiment holdings.

Each part of ^{my}Grid addresses the requirements of the research scientist, either by automating tasks or supporting the overall management of experiments and their results.

Service provision. To allow automated interaction with applications during the *in silico* experiment we must provide programmatic access to those applications. this is achieved by making each bioinformatics application available as a web service (see Section 4.3).

Writing the workflows. Automating the experimental process requires an explicit representation of that process sufficient for a computer to execute. A workflow represents a procedure, such as a bioinformatics analysis, as a set of processes and the relationships between those processes (see Chapter 42). It is the level of abstraction that is an important aspect of workflows – the user has a high-level rather than "assembly-level" access to the analysis. Thus, the user describes what he or she wishes to accomplish, not how to accomplish the goal. The ^{my}Grid team have developed the Simple Conceptual Unified Flow Language (Scufl) and an application to edit workflows (Taverna Scufl Workbench) [17] to achieve this abstraction. Thus, a biologist or bioinformatician does not need to write a large, bespoke application, but to simply describe what needs to be done and the order in which it is to be done.

Running the workflows. A workflow enactment engine, Freefluo, has been developed for the enactment of workflows written in Scufl [16]. The engine automatically calls each service in the appropriate order and passes data between services. For

Collating the results. Both final and intermediate results from running the workflow are saved either in the users' local file system or ^{my}Grid Information Repository (mIR). A major requirement is to not only automate the experimental process, but also assist the scientist in recording the origin or *provenance* of the large set of interrelated result files.

Automated provenance recording. The workflow environment has been built to automatically generate two kinds of metadata. The first is called *process provenance* and is analogous to a log – recording which services were used to generate the data. The second provides relationships *between data*. In most cases these are dependent on specific services, e.g. a BLAST service will provide a report which has "similar sequences to" the input query sequence. Therefore, each step of the workflow can be annotated with a provenance template which describes the relationship between the data flowing in and out of the process [32]. The recording of the provenance of actions taken in "joining" services, together with the storage of intermediate results, means that each run of an experiment can be fully validated by a user "tracing" back through the coordinated set of results.

Viewing the results. As much of the information has been recorded by machine it must be rendered in a human-readable form. The amount and complexity of the information also require that it must be provided in filtered views that help answer specific questions clearly.

All ^{my}Grid services can be seen in the ^{my}Grid services stack shown in Figure 3. This shows the idea of middleware appearing again: we have web services representing the distributed, heterogeneous resources. Various services in layers on top of those resources provide a collection of APIs against which a programmer can build applications. the main ^{my}Grid application is Taverna – a workflow workbench [17]. Through these technologies ^{my}Grid creates a virtual organization of bioinformatics resources in order to perform *in silico* experiments. It is a flexible tool that allows experiments to be specified, modified and shared. Experiments can be run repeatedly and reliably.

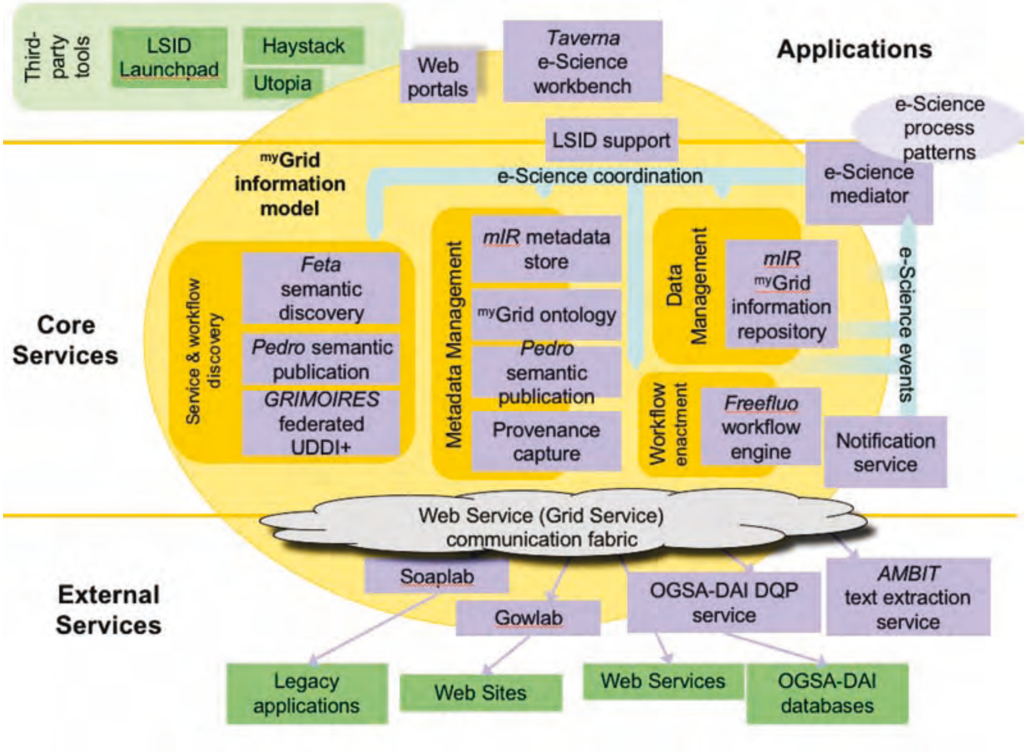

Figure 3 the ^{my}Grid technology stack.

Perhaps, this latter point appears no different from the bespoke solutions so often used in bioinformatics. However, the use of standard web services technologies ease the development of a workflow, compared to more bespoke solutions. This is particularly true as additional services become available, increase the scope of analyses which can be performed.

^{my}Grid is not the only service-orientated architecture solution working within this Grid paradigm. BIRN [15], PathPort [7], the cancer Biomedical Informatics Grid (caBIG) (https://cabig.nci.nih.gov/) and the North Carolina bioGrid (http://www.ncbiogrid.org/) are also using similar solutions within a life science setting.

6 Discussion

In this chapter, we have explored distributed computing within bioinformatics. Starting with a collection of autonomous groups producing data, bioinformatics has a legacy of distributed, massively heterogeneous data and tools. Modern bioinformatics applications have to take this situation into account by either integrating or interoperating between these heterogeneous, autonomous and istributed resources. There is a great deal of technology now on offer to support networked applications in bioinformatics. In this final section, we will explore the question of whether plumbing is enough to achieve the goals of complex, sophisticated bioinformatics analyzes.

Traditional techniques used to resolve syntactic heterogeneity are the development of resource wrappers and exchange formats. Wrappers can transform the appearance of a resource to the external world and dictate what services are available. CORBA offers a standard mechanism by which object views of resources may be developed [23]. Just as CORBA defines the syntactic view of a resource's services, XML can be used to define the syntax and structure of a resource's data. Again, such a technology works by the adoption of standards, so that similar resources use the same data format. A WSDL document describing the services can take this a stage further and we can see that the system and syntactic levels of heterogeneiety can have solutions.

These technologies, however, only offer a mechanism for *plumbing* resources together. A common structural view of a resource's data does not necessarily mean a common semantic view of the same information. At best, these mechanisms offer only an intuitive semantics. For example, an XML tag called `<sequence/>`, within a sequence database entry might have a common understanding, to humans if not machines, but it is unlikely that a tag `<gene/>` would have such an intuitive understanding. These interoperation technologies do not resolve any of the problems of heterogeneous conceptualizations or term usage, because they do not have a mechanism for describing the meaning or knowledge associated with a term. Again, we are beginning to see efforts to resolve this semantic level of heterogeneiety (see Chapter 29).

That individual resources provide access is not enough. For multi-resource applications to be developed, many resources have to work together seamlessly, to cleanly interoperate. For interoperation to be available, the providers of the common views have to describe their resources in such a manner that part of one resource can be passed to another without the intervention of the host developer. For example, the providers of a sequence similarity search tool have to make available services that accept protein sequences in a common form that can be adopted by providers of protein databanks. The alignments returned would also comply to a common description.

Obviously, such a unified, generic approach needs much effort, cooperation and planning. This presents considerable design problems. We are beginning to see the erly stages of Stein's bioinformatics nation [22], through the adoption of web services, but as yet there is no common currency or even agreement what the common language actually means. The sociology of bioinformatics makes it unlikely that a central authority will impose common type systems, etc., but the open nature of the community and the desire for computational solutions to problems will bring in *de facto* standards.

Part 11 Outlook

45 Future Trends

Thomas Lengauer

1 Introduction

When this book was conceptualized the attempt was made to take into account the major issues pertaining to the computational support of research in molecular biology, pharmaceutics and molecular medicine, and medical practice. The preparation of the book took over 2 years. In a field as dynamic as computational biology it is inevitable that new issues arise that could not be incorporated into the concept of the book at the time of its inception, yet that have gained relevance in the field and are likely to provide considerable impetus to the field in the future.

The goal of this last chapter of the book is to address some of these issues. Some of them are already quite well developed and would have deserved a separate chapter in book; others are emerging and will be ready for separate chapters in potential future editions.

Very likely, even the list of topics addressed in this book is incomplete. I ask for understanding from all those readers that are missing subjects that they feel important – I would like to hear from them!

In general, the development of computational biology follows the direction from the genotype to the phenotype (Figure 1). Most of the activities in the 1990s were targeted at compiling the parts lists of an organism (for different species). The main challenges were to list genes, identify protein sequences and collect protein structures. At the turn of the century a growing number of completely sequenced genomes were available, still mostly from simple unicellular organisms, but the sequences of a few more complex organisms were available (*Caenorhabditis elegans*, *Drosophila melanogaster*) and the human

genome sequence was around the corner. Furthermore, several technologies for transcriptomics had become available, enabling the investigation of the difference between healthy and diseased cell states on the molecular level. Today, the number of completely sequenced genomes reaches well above 300 and the number of ongoing sequencing projects transcends 1700 (http://www.genomesonline.org). Computational biology has entered the stage of uncovering the circuitry of life. The analysis of biochemical networks, be it at the metabolic, gene regulatory or signaling level, can be regarded to be central to present-day bioinformatics efforts. The investigation of protein function in this context with computational biology methods involves a wide variety of biological data, many of which would not have been envisaged 20 years ago. However, much of the research is still concentrated on intracellular processes. The single cell is the universe of today's computational biology. The analysis of intercellular communication and the self-organization of cellular communities has not yet reached the widespread attention of computational biology research. The next levels above the cell – tissues and organs – still await proper computational modeling.

We will now list a number of concrete fields of research that have recently produced exciting research results and that promise to gain importance in the field of computational biology in the future. We will only be able to hint at the results obtained and the potential for the future, but we will point to references that go into more detail on the respective subject.

2 Building Blocks – Post-translational Modification of Proteins

Post-translational modification is a central molecular process for modulating protein structure and function. However, to date, the analysis of protein function based on computational biology methods does not fully incorporate post-translational modification.

There are quite a number of post-translational modifications [69]. The most important ones are phosphorylation and glycosylation. Phosphorylation involves the attachment of phosphate groups (with the catalytic help of a protein kinase) to specific side-chains in proteins, thus modifying their structure and function, e.g. activating or inactivating the protein. Glycosylation adds multimeric sugar molecules to certain side-chains in proteins that modulate the function of the protein, e.g. in cell–cell adhesion, stabilize the protein or serve as an aid in protein folding. Information on post-translational modifications in proteins is collected in special databases [57].

Chapters 28 mentions relevant databases collecting information on post-translational modifications as well as bioinformatics programs and servers that predict sites of post-translational modifications in proteins (see also Ref. [150]). A server that offers several prediction methods for different sites of post-translational modification is available at the Technical University of Denmark (http://www.cbs.dtu.dk/services). Knowing these sites contributes to understanding the function of the respective protein, specifically to resolve its molecular function by manual inspection. In addition, the knowledge of sites of post-translational modification can be used as additional input for statistical learning techniques that use other inputs on the sequence, structure and location of the protein in order to infer protein function automatically [84]. However, today, computational biology has not much surpassed the stage of identifying the sites of post-translational modifications. Modeling of the often very subtle structural consequences is in its infancy.

Protein phosphorylation is at the heart of signaling in eukaryotic cells. Understanding phosphorylation involves studying the phosphorylating enzymes – the protein kinases. The collection of all kinases in an organism is called its kinome. Kinomics is the quest of understanding these proteins and, in this way, gaining a deeper understanding of the process of phosphorylation and its impact on cell signaling. Bioinformatics can help by offering predictions of substrates of kinases or identifying the kinase that is responsible for phosphorylating a particular site [88].

The tremendous structural diversity of multimeric sugars, so-called glycans, has motivated major efforts to understand structure–function relationships of these molecules and their interaction with proteins. The corresponding research area is called *glycomics* [142]. (More specifically, the area is called *glycoproteomics* – as opposed to *glycomics*, which encompasses the study of sugars also independently of proteins. However, often the use of the term *glycomics* is tantamount to *glycoproteomics*.) Several large consortia have formed for glycomics research, such as the US-based Consortium for Functional Glycomics (http://www.functionalglycomics.org/static/consortium), the EurocarbDB consortium funded by the EU (http://www.eurocarbdb.org) and the Japanese Consortium for Glycobiology and Glycotechnology (http://www.jcgg.jp/E/index.html). A recent review mentioning additional projects on glycans is given by Borman and Washington [28].

Glycans are chain-like or tree-like molecules that have no unique three-dimensional (3-D) structure. In contrast to protein–protein interactions that have a digital character, i.e. two proteins bind or they do not bind at any certain time, glycans bind in a more analog fashion, displaying more of a continuum of binding strengths. Singular carbohydrate–protein contacts are rather weak with association constants in the millimolar range. Nature affects biological efficiency by establishing multivalent contacts – a principle that allows for gradually increasing specificity as well as biological control and fine-tuning. Thus, glycans often serve to fine-tune a biological response. A changed glycosylation profile of proteins in a cell or at the cell surface is indicative of many diseases, such that glycomics could possibly aid disease diagnosis in similar ways as transcriptomics.

The major focus in the glycomics initiative is on measurement of glycan structures that are attached to glycosylated proteins and collection of the respective data in databases. However, first steps are also taken in the direction of analyzing these structures with bioinformatics methods [171]. Tools have been developed for extracting glycosylated protein structures from the Protein Data Base [115], modeling the structure of glycans [27] and attaching modeled glycan structures glycosylation sites of structurally resolved proteins [26] (Figure 2). Structure modeling is mainly done with molecular dynamics methods. There is also progress in analyzing the similarities and relationships between different glycans. Tree alignment algorithms have been developed in order to compare different glycans [5] and represent complex patterns in families of glycans [6]. A corresponding server is offered on the internet [7]. There are several servers that offers databases and tools for glycomics [71,114]. An up-to-date list on web links in the glymoics area is available, for instance, at the EurocarbDB web site.

We can expect the computational analysis of post-translational modification of proteins and their impact on protein function to gain in relevance significantly as computational biology matures further.

3 Regulation – Synthesis and Degradation Pipeline of RNA and Proteins

Measuring gene and protein expression is such an effective tool for discerning between different cell states that we have devoted several chapters – in fact, all of Part VII of the book – to this topic. Here, measuring gene expression on the level of mRNA transcripts has taken most of our attention. Transcriptomics takes a lopsided view of protein expression, however, because it only considers the first step in a pipeline that is responsible for the final protein expression levels, i.e. transcription. This pipeline has two main stages – mRNA expression regulation and protein expression regulation. In both stages the resulting expression level is the result of production and degradation procedures. Transcriptomics and proteomics measure the resulting balance but, in general, they do not investigate the processes achieving this balance directly. Insight into the regulatory processes achieving this balance is highly desired, however. For instance, problems with degradation processes are presumed to be at the heart of several severe diseases and ageing. Notably, neurodegenerative diseases are caused by aggregating protein products that evade degradation and destroy cells in later stages in life [37]. Manipulating protein degradation is also a target of oncogenic mutations [117]. Protein degradation is also a key step in the destruction of foreign proteins by the immune system (see also Section 8). Furthermore, deeper understanding of regulatory processes in cells will have to involve an explicit account of all steps influencing RNA and protein turnover.

In general, regulation happens at all stages of the pipeline, including mRNA synthesis and degradation, as well as protein synthesis and degradation, and the processes are more complex than originally thought. The findings of the not yet fully understood role of the so-called P-bodies in the regulation of mRNA present only one recent modification of our view of the protein production pipeline [119]. A recent review on the mRNA life trajectory is presented in Ref. [125].

There are a few studies that consider the effects of regulatory processes on protein expression downstream of mRNA at a genome-wide scale. Beyer and coworkers [18] have investigated this issue in yeast. They consider the steps of mRNA expression, protein translation and protein degradation explicitly. They also introduce a computational descriptor of the half-life of a protein. In their analysis they detect significant variation between different cellular compartments and different functional modules. Several case studies points out the essential contribution of protein degradation processes in the regulation of protein expression [91, 179].

There is an additional step that links mRNA and protein expression. This is RNA interference (RNAi), the mechanism, by which small RNA can silence already transcribed genes (or viral RNA). This topic is so important that it deserves a separate subsection.

4 Regulation – RNAi

RNAi [53] has been one of the major biological discoveries of the past decade [130]. RNAi is a mechanism by which small RNA double-stranded sequences with 21 or 22 nucleotides [so-called short interfering RNA (siRNA)] cause the cleavage of, or otherwise inhibit, other RNA (target RNA) in the cell, which is complementary to the siRNA. Target RNA can be viral RNA, which is assumed to be the evolutionary first target of the process. Thus, RNAi is a powerful mechanism of the cell fighting RNA viruses. However, the target RNA can also be mRNA of an expressed gene in the cell. Then, the siRNA effectively silences already transcribed genes. In fact, it is assumed that siRNA has the role of silencing transposable elements (jumping genes) and repetitive genes, in addition to viruses. Subsequently, it has been found that a special class of short single-stranded RNA, so-called micro-RNA (miRNA), with 19–25 nucleotides, is encoded in the genomes of most multicellular organisms specifically to silence transcribed genes in order to regulate protein translation. miRNAs are synthesized in a different but similar manner to siRNA. miRNAs are assumed to silence genes partially complementary to the miRNA sequence simply by hybridizing to them. There are several other classes of short RNA in the cell, some of which have related functions and some of whose function is not known [130].

The RNAi process is especially interesting because it is not only one of the basic regulatory processes established by nature that is conserved over a wide range of taxa, but it can also be employed effectively in the laboratory in order to "reversely" knockout genes in species without a high reproductive rate [11], is less labor-intensive than classical gene knockout and facilitates controlling gene expression over time. The technology even bears a high promise of being applicable in therapeutic settings [44, 116, 123].

The computational biology community has recently taken very strongly to the topic of RNAi. Bioinformatics efforts can be grouped into (i) assembling databases of (predicted and/or validated) short RNAs and their (predicted and/or validated) targets [64,78,156,159], (ii) developing computational methods for finding miRNAs in genomes [16, 63, 157, 175], (iii) analyzing miRNAs structurally, and (iv) searching for targets for miRNAs and analyzing miRNA–target interactions [86, 109, 144, 163]. Some of the methods analyzing the sequences, secondary structures and hybridization patterns of miRNAs are addressed in Chapter 14, their role in the analysis of gene regulatory networks is addressed in Chapter 21 and RNAi is mentioned as a novel screening method in Chapter 43. A recent overview of computational methods for predicting miRNAs and their targets is given in Ref. [15].

5 Regulation – Tiling Arrays, ChIP-on-chip and Array Comparative Genomic Hybridization (Array-CGH)

Part VII of the book has concentrated on analyzing mRNA expression data. In the past few years several variants of this technology have arisen that have not been covered substantially in Part VII. The aim of this subsection is to give an overview of these techniques and address relevant bioinformatics issues if they go beyond what has been presented in Part VII.

The "traditional" view on microarrays is that they contain spots with cDNA backtransribed from mRNA sequences that have been taken from expressed genes in the cell (see Chapter 24). Thus, a microarray covers a (usually large) number of genes that can be expressed in the cell. The microarray measurement then reveals which of these genes are expressed to what levels in a given cell state. The goal of these measurements is to get a cell-wide overview of the transcription profile of all (relevant) genes. However, in order to be put on a microarray, a gene has to be known (or at least suggested) beforehand.

The so-called "tiling arrays" aim at covering not only previously known transcribed regions, but all of a genome or a substantial part of it this way [17, 152]. This affords the search for transcribed regions of the genome that have not been known beforehand. In this way, over 10 000 transcribed sequences have been found that had not been known before [17]. These findings are the starting point for finding out about the biological relevance of these previously undetected transcripts. Possible roles include previously undetected protein-coding genes, untranslated exons and RNAs with diverse functions.

A related microarray technology affords the genome-wide experimental search for transcription factor binding sites. This technology is called ChIP-on-chip – the first (ChIP) stands for "chromatin immunoprecipitation, the second for the DNA chip. The basics of the procedure are as follows [30]. Cells (ranging from yeast to mammalian cells) are grown in culture and then fixed, e.g. with formaldehyde. In this way, DNA and proteins bound to it, e.g. transcription factors, are cross-linked. DNA fragments with the cross-linked proteins attached are enriched using a procedure called immunoprecipitation. The procedure employs monoclonal antibodies binding to the proteins. Thus, the protein can be identified during enrichment. The cross-links are then reversed and the DNA is purified enriched and labeled, e.g. with a fluorescent dye. By hybridizing this DNA to a tiling microarray one can identify where specific transcription factors bind. ChIP-on-chip technology has been applied successfully to finding binding sites for individual transcription factors and mapping gene–regulator relationships cell-wide [104]. Specially configured CHiP-on-chip experiments can reveal insights into the workings of the transcription machinery and chromatin structure, where histone-modifying proteins and other chromatin players replace transcription factors. A recent overview of uses of the CHiP-on-chip technology is presented in Ref. [70].

Yet another array technology is array-CGH (CGH stands for comparative genomic hybridziation) [111]. This technique uses a tiling array in order to detect segment copy number alterations. In this case, nuclear DNA is hybridized to a tiling array with the usual readout mechanisms. Here, the resolution is a critical issue. This is the accuracy, in base pairs, to which locations of changes in copy number can be detected. This figure is a parameter of the configuration of the tiling array. Meanwhile there are tiling arrays for this purpose that cover the entire human genome down to 80-kb resolution [83,158]. Alterations in chromosomal DNA copy number are at the basis of the genomic aberrations that occur in cancer and genetically inherited diseases. Their measurement is a very effective tool for assessing type and progression state of a tumor [140]. DNA copy numbers in array-CGH data are usually more or less constant over larger regions of a genome spanning multiple DNA fragments deposited on the array (Figure 3). This is a property not usually shared by other microarray data. A characteristic bioinformatic problem in analyzing array-CGH data is therefore to detect the locations in the genome where copy numbers change. Since the data are noisy, this is a statistical problem. Several bioinformatics platforms have been developed for managing array-CGH data [34, 35, 92, 110, 118, 173]. Statistical methods for identifying such points and the intermediate copy numbers have been put forth in Refs. [90, 137, 174].

In summary, microarray technology is an effective method of measurement of the presence and abundance of biomolecules on the genomic and transcriptomic level with a wide variety of applications. The technological variants will continue to be source of new kinds of bioinformatical analysis.

6 Regulation – Epigenetics

The epigenetics level is another level at which gene regulation takes place, and which is just at the beginning of being investigated systematically with experimental and bioinformatics methods. The term epigenetics covers all stable and heritable (or potentially heritable) changes in gene expression that do not entail a change in DNA sequence [85]. Such phenomena play a significant role in development, ageing and disease.

In order for a gene to be expressed it must be accessible to the molecular transcription machinery of the cell. However, chromosomes are packed up in the chromatin in ways that are only partially understood today and are beginning to be analyzed at a genome-wide scale [112]. Different molecular mechanisms that are controlled enzymatically protect the gene from being transcribed or expose it to the transcription machinery.

We summarize these processes as they are found in mammals. The process that is closest to the DNA sequence is methylation. Methylation involves the attachment of a methyl group to the cytosine in a CpG pair (Figure 4). Methylation is catalyzed by the enzymes DNMT1, DNMT3A and DNMT3B, i.e. several methyltransferases. In the human genome, almost all interspersed CpG dinucleotides are methylated [149], which has been interpreted as a host defense mechanism against retrotransposable elements. However, so-called CpG islands which are characterized by a low degree of CpG depletion, i.e. a comparatively large amount of CpG dinucleotides, often remain unmethylated. Such islands tend to occur in the vicinity of gene promoters. A methylated CpG island protects its nearby gene from being transcribed – the gene is effectively switched off. Differential methylation of the maternal and paternal allele of a gene is the basis for the mechanism of imprinting that selectively switches off maternal or paternal genes during development.

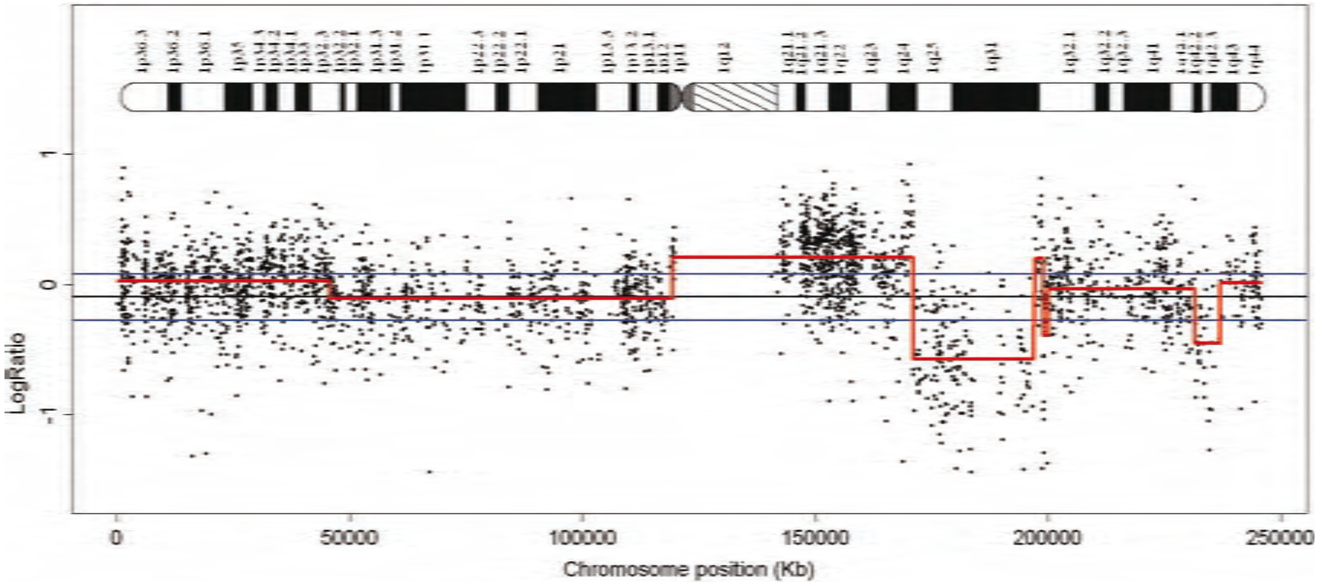

Figure 3 Profile of relative copy numbers along chromosome 1 derived from array-CGH data of a prostate cancer sample. The point cloud represents the CGH data. The baseline in black represents the average copy number; upward (downward) deviations represent larger (smaller) copy numbers. The red line is a fitted piecewise-constant function. This reflects the underlying model that the copy numbers change in steps representing losses or gains of chromosomal segments.

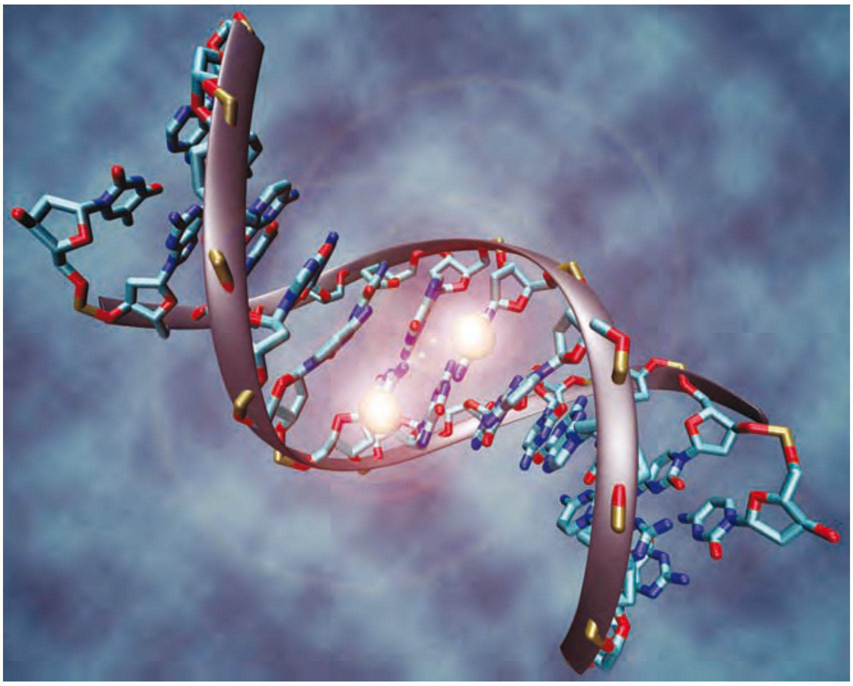

Figure 4 Rendering of a methylated CpG. The two methyl groups are enlarged for better visibility.

There are several experimental methods for measuring methylation patterns along DNA sequences with different levels of positional resolution along the DNA sequence [127]. The process of bisulphate-assisted sequencing affords single-base resolution, in principle [56, 68]. A method involving restriction enzymes has low sequence resolution and is used to generate data only at the CpG-island level rather than at higher resolution [182] – a disadvantage that is mitigated by the fact that CpG-island methylation is highly bimodal (i.e. CpG islands tend to be completely methylated or completely unmethylated). A third method uses a micorarray-based immunocapturing approach similar to the ChIP technology which achieves a resolution of about 80 kb [176] (see also Chapter 21) and is expected to achieve a resolution of about 1 kb as genome-wide high-resolution tiling arrays become available. For many questions a resolution which is less than a single base is sufficient, since methylation happens in clusters along the DNA sequence.

Methylation data are collected in several projects the most comprehensive of which is the Human Epigenome Project (http://www.epigenome.org/index.php) [141], which is carried out by an EU-funded consortium. Attempts to further coordinate epigenetic data collection are underway [89]. An important challenge to the epigenetics community will be to establish standardized data formats and quality control in a similar way as it was done within the expression microarray community ([29] and also Chapter 24). Bioinformatics can contribute to this process both by standardization, and by providing tools and databases in order to simplify adhering to the standards [4, 23].

Bioinformatics analysis of biologically or medically relevant epigenetic problems is a currently emerging field which has been named *computational epigenetics* [22]. Relevant research problems in this direction include the following. (i) Does DNA sequence influence methylation patterns? If so, which aspect of DNA sequence is the most informative one for methylation and how large is the respective correlation? Initial results indicate that DNA sequence does influence methylation substantially. Feltus and coworkers detected an influence of DNA sequence features on aberrant methylation [52]. Rollins and coworkers [149] have published a genome-wide analysis that finds relations between methylation status and CpG depletion in different cellular compartments based on data generated with the restriction enzyme method. Bock and coworkers [22] have analyzed the data by Yamada and from the Human Epigenome Project, and found that DNA sequence of a CpG island and its neighborhood is quite indicative of methylation status. The most informative aspects of sequence with correlation coefficients around 0.5 and higher include CG-rich sequence motifs, repetitive DNA and aspects of DNA 3-D structure, notably the rise and the twist of the DNA double helix [131]. (ii) Can we predict methylation state from sequence [19]? The fact that aspects of sequence are informative about methylation status suggests that we can predict methylation status from sequence [19]. In fact, Bock and coworkers have devised a method based on support vector machines (SVMs) that achieved more than 90% accuracy in both a cross-validation experiments and a blind test [22]. (iii) In general, a wide host of data-mining methods can and surely will be applied to finding patterns in methylation data and investigate their correlation with phenotype. (iv) How can we support the effective design of epigenetic cancer biomarkers with computational methods [98]?

While methylation is at the center of current experimental and bioinformatics efforts in epigenomics, there are other levels of regulation in epigenomics. Methylation only concerns a modification of the DNA molecule. In chromatin the DNA is wrapped around histone in an intricate and, today, quite well understood fashion. Making the DNA sequence accessible to the transcription machinery involves unwrapping it. This process is much less well understood, but elements of it are being uncovered. Certain post-translational modifications of histone proteins that affect their structure and thus the packing density of chromatin are a central element of this process. The pattern of post-translational modification of the different histones in the chromatin complex is called the histone code and is a major object of study in experimental epigenetics. The histone code is read by proteins with specific domains – the bromodomain and the chromodomain. These proteins initiate downstream biological responses pertaining to chromatin packing. The whole process is of great importance in diseases like cancer. Modelling these phenomena with computational methods and applying pattern recognition methods to the relevant data is still in the future. The ENCODE Project [1] is already producing a deluge of data in this area, for which efficient analysis methods have yet to be devised.

In summary, epigenetics forms the bottom-most level of what can be considered a three-level hierarchy of gene regulation. Methylation and histone modification provide the most durable control over time of which genes are expressed. This is assumed to be the level on which cell types are being defined. At the second level, transcription factor binding controls more short-term expression levels by processes that react to changes in cell state and environment. Finally, at the topmost level, RNAi secures the gene expression process against external downstream manipulations (e.g. from pathogens) and enables a more specific control than transcription factor binding (see Section 5). Ultimately, gene regulation will only be understood by discovering how these three levels interact and cooperate with mRNA degradation processes and regulatory processes at the protein level (see Section 3).

7 Protein Function – Alternative Splicing

Alternative splicing is an essential ingredient of the biology of higher eukaryotes. It is one of the two central processes by which the protein universe is expanded beyond the number of genes (the other being post-translational modification; see Section 2). Despite this, alternative splicing is only addressed at one place in this book, i.e. in Chapter 3, and there it is mainly discussed as an obstacle for accurate gene prediction. Therefore, we add a short section on the topic here.

The estimated number of human genes that can be alternatively spliced reach from 50% [128] to over 80% [120]. The average number of splice variants per gene is around 3 [181]. The average number of splicing fragments per multi-exon gene is 3.5 [181]. Genes from different functional classes tend to have different numbers of splice variants [128]. Thus, there are about 3 times as many human proteins as there are genes, bringing the estimated number of human proteins to about 80 000. (Post-translational modification adds another factor of about 10 to this, resulting in just under 1 million protein variants.) The number of splice variants can lie in the tens of thousands, such as for the *Dscam* gene in *D. melanogaster* that is responsible for neural development of the fly. Genes are spliced specifically, e.g. depending on cell type or developmental stage. Therefore, traditionally splicing has been investigated in specific, usually simple model systems with few splice variants. Splicing is effected by a macromolecular complex called the spliceosome which assembles around the (immature) pre-mRNA in order to implement the splicing operations. The assembly of the spliceosome and binding to the pre-mRNA is effected by a tissue-specific combinatorial interplay of sometimes more, sometimes fewer regulators. Similar to transcription, regulators can have a positive (agonistic, enhancer) or negative (antagonistic, silencer) effect. This results in the implementation of what might be called "cellular splicing codes". However, exactly how these codes are defined remains unclear [120].

More recently, global approaches have been followed for identifying splice variants. These approaches are traditionally based on the collection of expressed sequence tags (ESTs) [124]. Bioinformatic fragment clustering together with appropriate screening procedures in order to weed out false positives reveals splice variants. More recently, microarrays have been applied [87]. Here, alternative splice forms show up as characteristic expression profiles that, if there are only few variants, are qualitatively different and thus can usually be easily discerned from changes in gene expression. As the number of splice variants increases, the profiles are less and less easily distinguished from changes in gene expression. Bioinformatics approaches to this problem have been presented by Le and coworkers [100] and Pan and coworkers [132]. Spliceforms can also be found via comparative genomics [160]. Databases of splice variants of genes include ASD [162], ASP [181], DEDB (for *D. melanogaster*) [101], FAST DB [42], HOLLYWOOD [77] and SpliceInfo [79].

Splice variants of a gene can be visualized plausibly in a graph form (see Figure 7 in Chapter 3). There are different approaches to constructing such graphs [73, 102]. Splice forms are paths through this graph which can be enumerated completely, in principle [107]. From this collection those splice forms have to be deleted that are unlikely to be expressed. Several methods have been devised for doing so [128, 181].

Most of the splice variants seem to have functional relevance, such as the in-frame addition or removal of a functional unit. Here, the insertion or deletion of complete functional domains occurs more frequently than expected by chance, in contrast to the disruption of domains [95]. The resulting splice variants can differ in structure not only marginally, but fundamentally [165]. However, there are also inclusions or excisions of short fragments during splicing. Such variants choose between different alternatives for the N- or C-terminus, for instance, or insert or delete short internal segments that tend to have a nonloop structure and exert important influences on protein function [177].

The global investigation of splicing regulation is also underway. For instance, given a regulating protein, one can search for regulatory sites in the pre-mRNA to which it binds. *In vitro* approaches towards this goal include SELEX (systematic evolution of ligands by exponential enrichment) by which regulatory sequences are determined [31,93]. There are also *in vivo* approaches based on the transfection of cells. Most interesting for us are the computational approaches. These are usually based on a data set of sequences that are assumed to be enriched in binding sites of interest. Short motifs (e.g. hexamers) are then searched in these data sets. Significantly enriched motifs are assumed to be putative binding sites.

Conversely, given some regulatory sequence, one can search for the regulating protein. Variants of the ChIP technology discussed in Section 5 can be applied here. Combinations of the two techniques SELEX and CHiP can be used to hone in on regulators and regulatory sequences in a more focused fashion.

The hardest problem is to assign functions to regulators in terms of determining the resulting splicing pattern. This would be tantamount to resolving the cellular splicing code. However, there is compelling evidence that this code reaches beyond mRNA regulation and involves post-translational modification of regulators. Deciphering it will likely necessitate investigating the kinetics of the whole process [120].

Reviews on alternative splicing are presented in Refs. [103,120,124].

8 Interaction Networks – Immunoinformatics

Immunoinformatics [24] is the term used for bioinformatics efforts that are aimed at analyzing and modeling aspects of the immune system and its components. The field is has been forming for over half a decade – it is also called *computational immunology* [136] or *immunological bioinformatics* [113]. If applied on a cell-wide basis, one speaks of *computational immunomics* (http://research.i2r.a-star.edu.sg/IIMMS/). This book handles important aspects of immunoinformatics in Chapter 40.

Immunoinformatics aims at analyzing, modeling and predicting molecular aspects of the immune system. A major goal of immunoinformatics is the development of effective vaccines. Another is to understand the evolution of a pathogen in the presence of selective pressure exerted by the host's immune system. A third can be to analyze the effect that the diversity of the immunotypes in a population has for the spread of an epidemic.

Many people believe the immune system to be the most complex biological subnetwork in mammals and bioinformatics of the immune system can be regarded as a limited variant of general bioinformatics that comprises all levels of analysis that we have discussed in this book, from the assembly of building blocks via the analysis of binary and ternary interactions to the analysis of interaction networks and the integrated simulation of several phases spanning protein degradation, transport, molecular recognition and activation of downstream immune processes. The maturation of the field also mirrors that of all of bioinformatics – a first emphasis is on the assembly of building blocks and the analysis of molecular interactions. Interaction networks and integrated simulation follow later, and are still in the early stages of development.

This section does not afford enough space to go into detail on this subject. Two books [24, 113] are suggested for a more detailed account of the subject. However, we will touch briefly on those problems on which most research efforts are expended. Very roughly, the immune systems affords protection against foreign invaders and harmful mutants arising internally (such as malignant tumor cells). The basic molecular processes of the immune system comprise recognition of such harmful substances, specific constituent molecules called *antigens*, and mounting an immune response as the result of such recognition. Immunoinformatics today focuses on the first part – recognition. This recognition can happen directly in the extracellular fluids, such as the blood serum, by proteins termed *antibodies* (humoral immune response) or on the surface of cells after the antigen has been processed internally to the cell (cellular immune response). Cellular recognition is afforded by intracellular processes that digest relevant proteins into small peptides that are presented at the cell surface. In both cases, i.e. humoral and cellular immune responses, recognition of the antigen is manifested by a binding event of an agent of the immune system (an antibody for the humoral response and a T cell for the cellular response) to the surface-presented antigen, which is then also called an *epitope*. This binding event unleashes the cascade of immune responses.

Antigens can be recognized either in their complete form (in the case of humoral response) or via short peptides resulting from the digestion of a protein antigen internally to a cell (in the case of cellular response). The digested peptides are bound to specific molecules of the immune system belonging to the so-called major histocompatibility complex (MHC). MHC molecules are also equivocally called human leukocyte antigen (HLA) molecules. The resulting MHC–peptide complex is then translocated to the cell surface. MHC molecules are highly diverse throughout the human species. This diversity is the major measure of security for the species to survive an epidemic mounted by a new attacking pathogen – different individuals will be able to mount differing immune responses to the same pathogen. Thus, while many individuals may not survive any specific attack, the pathogen is unlikely to defeat the whole species. High HLA diversity thus also tends to correlate with high pathogen diversity [138]. The diversity of the molecules is also a major obstacle in vaccine design, and thus an important topic of bioinformatics study (see chapter 13 in Ref. [113]).

There are basically three classes of molecules that afford molecular recognition of antigens:

1. MHC class I molecules present intracellular antigens to cytotoxic T cells (Figure 5a).

2. MHC class II molecules present endocytosed antigens to T helper cells (Figure 5b).

3. Antibodies produced by B cells bind to undigested antigens during the humoral response.

The tasks of these molecules dictate their shape and influence the difficulty of the respective epitope prediction problem.

Ad 1: Endogenous antigens are processed by the MHC-I pathway which first digests an intercellular protein with the proteasome and then uses the peptide transporter TAP (transporter associated with antigen processing). TAP delivers the digested protein fragment to the MHC-I molecule within the endoplasmic reticulum, the MHC-I molecule binds to the peptide and the resulting complex leaves the endoplasmic reticulum. It is then transported though the Golgi apparatus and makes its way to the cell surface. The resulting peptides almost always comprise nine amino acid residues. Thus, the MHC-I molecule has a closed pocket that can accommodate a nonapeptide. This uniformity of the MHC-I binding sites also makes the bioinformatics problem of determining just which peptides bind to it easiest. Binding prediction is mostly performed by analyzing only sequence features of the antigen and not modeling the molecular complex structurally. A variety of machine learning methods have been applied to distinguish binders from nonbinders and to estimate binding affinity (see Ref. [54] and chapter 6 of Ref. [113]). During the final step of immunological recognition certain MHC-bound peptides (the epitopes) are identified by T cell receptors (TCRs).

The binding event of the peptide to the MHC-I molecule is only the final step in a cascade of processes that starts with the digestion of the relevant antigenic protein by the proteasome of the cell and continues with the transport of the peptide to the endoplasmic reticulum where it is loaded onto the MHC-I molecule. Both steps have a significant influence on the final epitope. The proteasome prefers certain peptide cleavage sites over others, and the TAP transporter exerts additional specificity on certain peptides. Both steps have been analyzed with sequence-based bioinformatics methods (see chapter 7 of Ref. [113]). However, in contrast to MHC binding, the data for proteasomal cleavage sites and for TAP-binding affinity are quite sparse, leading to comparatively poor prediction performance. Nevertheless,

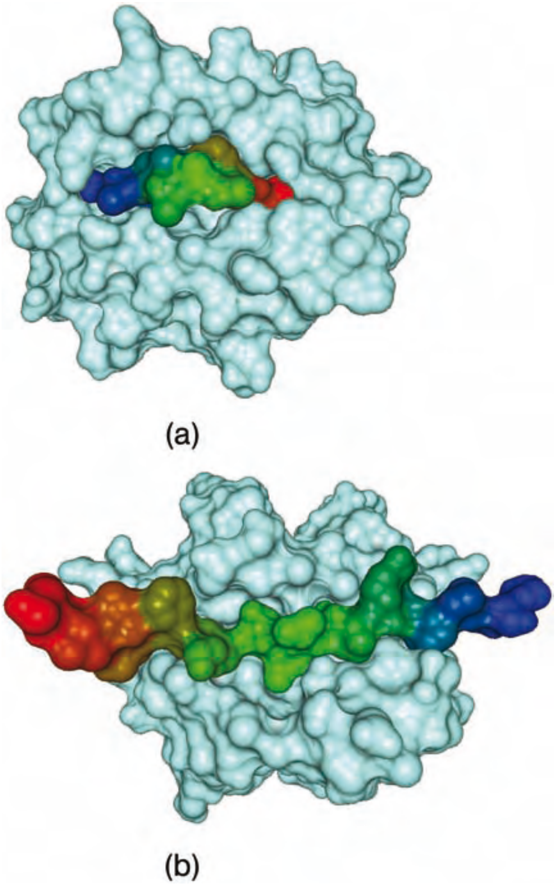

Figure 5 (a) MHC-I molecule with bound peptide: MHC-I molecules have a closed binding site and thus bind peptides with strongly restricted lengths of around 9 amino acids. (b) MHC-II molecule with bound peptide: MHC-II molecules have an open binding sites that accommodates peptides with more widely varying lengths of antibody (Images courtesy O. Kohlbacher).

solutions for an integrated analysis of all three steps of the MHC-I pathway, i.e. proteasome cleavage, TAP processing and MHC-I binding, are under development [46, 99]. See also Ref. [166] for a recent critical evaluation of the existing approaches in the light of transplantation medicine.

Ad 2: Foreign invaders are not screened from the cytosol, but from endocytosed proteins. The respective antigen-presenting pathway, i.e. the MHC-II pathway, cannot guarantee a length of nine residues for the peptide. Rather, peptides can be between eight and 20 residues in length. Thus, the pocket of the MHC-II molecule is open at both sides, antigens bind to it more diversely and the corresponding bioinformatics problem is harder. Also, integration of the analysis of the steps in the MHC-II pathway has not progressed as far as for the MHC-I pathway (see Ref. [54] and chapter 8 of Ref. [113]). This is mostly due to the lack of knowledge about the pathway.

So far, we have only discussed the analysis and prediction of surface presentation of peptides via binding of the peptide to an MHC molecule. The final recognition event is facilitated by the TCR binding to the MHC–peptide complex and eliciting an immune reaction, which qualifies the peptide as an epitope. This final step excludes about half of the MHC binders. On the basis of the respective immunological data one can use statistical learning methods such as support vector machines to predict such T cell epitopes from sequence [183, 185]. However, the TCR is extremely polymorphic, with up to billions of variants in a single individual. This probably imposes natural limits on the effectiveness and relevance of predicting binding to the TCR.

Ad 3: The humoral immune response is afforded by antibodies that are produced by B cells. B cells bind to antigens by their immunoglobulin receptors. The antibody is a soluble form of the B cell receptor (BCR) that is produced in large quantities during a humoral immune response. The BCR does not bind to digested antigen in the form of short peptides, but to the surface of undigested complex molecules. This also results in a higher structural diversity of the BCR. One of the key differences to T cell epitopes is that B cell epitopes need not be contiguous peptides. Rather, they can consist of surface patches of the antigen that are comprised of noncontiguous pieces of sequence. The bioinformatics analysis of the resulting recognition event is very hard, probably requiring the incorporation of structure, with few structure data being available Furthermore, the BCR is as polymorphic in individuals as the TCR. Thus, it is not surprising that the epitope prediction problem for the BCR is not very well understood to date ([21], see also chapter 10 of Ref. [113]).

Organism-wide data on the molecular basis of the immune systems are collectively called the immunome data [134]. Immunome data are collected in a number of databases concentrating on immune molecules [105, 147], their binding antigens [143] and both [154, 168].

The prediction methods discussed so far focus on sequence features of the epitope. Prediction methods including molecular modeling also exist, including variants of the 3-D quaternary structure–activity relationship method ([47, 186], see also Chapter 18). Structural analysis can also include docking methods [148]. Full-fledged structural analysis with molecular dynamics methods has been limited to single cases because of high computational demand, e.g. Ref. [172].

The ultimate goal behind the identification of epitopes and the analysis of their interaction with protein receptors of the immune system is the development of effective vaccines [40] (see also chapter 11 of Ref. [113]). This goal essentially amounts to selecting a peptide that is close enough to a suitable epitope from the proteome of the pathogen to be highly immunogenic, i.e. to produce the desired immune response in the vaccinated host. At the same time, the vaccine must be chosen such that a wide variety of HLA types recognize it, i.e. that it is effective in a wide part of the population [41]. The T cell epitope is critical here, because T cells are needed to orchestrate the "immune memory". Here, a single epitope may be sufficient or several selected epitopes may be necessary for eliciting immune response [126]. Not every epitope that can bind to a receptor is relevant, though. For instance, epitopes that are identical or highly similar to endogenous "self"-epitopes will not elicit an immune response. We can try to trim down the set of relevant epitopes by comparing the genomes of related virulent and avirulent pathogens, and select those for screening that are unique to the virulent strains. Comparative genomics can also help in selecting vaccine candidates from an organism that is related to, but not identical to, the pathogen – as in the case of smallpox vaccine which is taken from the cowpox virus – or one can focus on pathogen-specific proteins or those that are preferentially secreted by the pathogen in the host environment. On this selected set of antigen candidates, epitope prediction can then ensue.

Immunoinformatics is still in its infancy. The level of bioinformatics methods is largely limited to sequence analysis. The data situation is sparse. However, the field is in the process of organizing itself and is maturing more and more rapidly.

9 Cell Engineering – Synthetic Biology

Synthetic biology has been a dynamically rising paradigm in the past few years, even though the idea has been around for several decades, and corresponding research has enriched biology and biotechnology for quite some time. Synthetic biology is the result of marrying biology with engineering. Both areas have fundamentally different character and this fact is at the foundation of many of the complexities that underlie the quest of understanding living systems. Let us contrast the evolutionary approach taken by nature with the rational approach taken by an engineer. There are fundamental differences on at least two counts. (i) The (human) engineer has comparatively little resources to build a system (a few hundred or thousand person-years at most, for a single design project). In contrast, Nature develops living systems over thousands or millions of years within large populations. (ii) The engineer requires understanding of his system. This is not an issue for Nature. Nature is thought to work solely to optimize the fitness of the organism or species, respectively, in its complex environment. As a result, engineered systems tend to be modular and exhibit high degrees of symmetry. For instance, computer chips with many millions of transistors result from highly regular designs, in which at most a few thousand transistors have been inspected individually and the others arise by replication. Natural systems do display modularity, at times, but have much less of a separation between different roles and functions of their components. One example is the multiple functions observed for many proteins.

Practically throughout the whole book we have stressed the analysis approach towards understanding the function of living systems. The only place in which an engineering approach was followed was in drug design (Chapters 16, 18 and 19), which can be thought of as a variant of synthetic chemistry. Still, an engineering approach can incur substantial benefits not only for chemical, but also for biological systems. In an engineering approach to biology we would not inspect the unaltered evolved biological system, but we would change it, often with the idea to simplify it substantially. The goal of the change would be to enhance desired properties of the system or to decouple parts of it from the complex biological environment, in order to be able to study them without undesired interference by processes that are not the object of the current study. In the past several components of biological systems have been the objects of an engineering approach, such as DNA and proteins. More recently, biochemical networks were also subjected to engineering endeavors. Today, there is significant effort in engineering cellular subsystems for various purposes. This quest is still predominantly an experimental one, but it is closely linked to modeling, which can serve as a rather easily manipulable platform for early conceptualization and parameter analysis, and thus help to guide experimentation. This is why this new approach to biology is also of importance in the context of this book.

We will now briefly summarize some of the developments that have taken place in synthetic biology [14].

9.1 Genetic Engineering

Recombinant DNA can be considered as an early and very effective application of the engineering approach to genetics. The technology for manipulating DNA sequences for biotechnology purposes is far advanced. Beyond directly biotechnological purposes such as transporting genetic elements into host organisms or knocking out specific genes attempts have also been made to use DNA manipulation as a tool for performing computation (*DNA computing* [2], see also Refs. [155, 167] for more recent variants on this theme), although this quest has never matured to substantial applicability. Furthermore, engineering projects have attempted to alter the DNA backbone such as to lead to a molecule with comparable recognition properties that can more easily pass through cell membranes in order to silence DNA inside the cell or expanding the nucleobase alphabet in synthetic approaches to systems emergent properties of life [14].

9.2 Protein Engineering

Proteins also have been objects of engineering approaches. Biotechnological objectives were to create proteins that fold more stably under natural or unnatural conditions (e.g. with respect to temperature or pH [106]), or to design proteins that selectively recognize target molecules [20] or have some desired catalytic function [49]. Also, there is activity in the molecular engineering of motor proteins [169]. This field overlaps with the field of nanobiotechnology [10, 133]. In addition, many of the studies follow basic research goals of being able to understand and predict protein-like behavior like folding properties [96]. Proteins are engineered by modifying the amino acid chain of natural proteins, either in an educated trial-and-error fashion or guided by design principles such as rational design [76] or guided evolutionary design [50] supported with laboratory or software tools [49]. Building units can be either single amino acids or more complex subunits of the protein such as secondary structure elements [62]. In general protein engineering is a high complex task, because global properties of the protein cannot be expected to result from a simple combination of independent contributions of its amino acids.

9.3 Genetic Networks

The recent surge in synthetic biology came as engineers first were able to manipulate genetic networks according to preconceived design goals. One breakthrough was the design of a genetic toggle switch using interacting repressor genes in *Escherichia coli* [51, 59]. The toggle switch or flip-flop, as it is called in engineering, is a bistable element that is a basic component of many electronic systems involving memory. Logic gates such as AND, OR and an inverter can be engineered as well [72], making the vision of engineering general cellular logic approachable [67]. The interior calculation performed by a gene network could be linked to phenotypic readout, thus making the result of the calculations visible from the exterior world [94]. Furthermore, more finely graded responses could also be evoked from the engineered operation of genetic networks. One basis for this is to explore the analogous structure–function relationships at the level of protein domains [48]. In general, an entire engineering discipline is embarking on utilizing biological components [121]. The field is embarking beyond the single cell onto controlling cell–cell communication in multicellular systems. Modeling is an important aspect of synthetic biology [9]. The handling of noise is a characteristic problem of developing circuitry that has to function in an intracellular environment [161]. Understanding this phenomenon will help us greatly to advance our understanding of intracellular processes.

One can envision three goals of synthetic biology of gene circuits. The first is to study biological processes at the level of intentionally simplified circuitry in order to better decouple phenomena that are highly intertwined in evolved organisms. The resulting insights could be the basis for more adequate models. The second is to design non-natural circuits that perform as desired *in vivo*. By doing so one can investigate what are the advantages of evolved circuits over engineered ones, thus again affording an avenue towards understanding hidden secrets of biological design. Probably the most challenging question is how an engineered circuit operates in the environment of an evolved organism. The ultimate test here would be to replace an evolved circuit with an engineered one [161]. While we would not expect this to lead to better designs, we would certainly learn much about why Nature is doing things the way she does.

10 Imaging

Imaging is rapidly rising in importance in bioinformatics. Since vision takes such a large part of our sensory input, it is natural that we want to express data in images. So far, molecular structures have been the prime target of representation via (3-D) images (see Part IV of the book). The field is at the brink of expanding efforts in imaging into many different areas, spanning the cellular to the organism level. In fact, it is a plausible prognosis to make that image analysis will be a substantial aspect of bioinformatics in the years to come. Chapter 43 contains a technical discussion of some aspects of light microscopy imaging. In this section we hint at a few additional results and trends in the area of imaging biological systems.

10.1 Obtaining Pictures of Cellular Structures

There are several research efforts directed at getting more global images of cellular structures. Here, we discuss an effort to get 3-D (still) images of cells through electron tomography. In this approach, the cell is frozen and, in this state, subjected to a variant of tomography that applies electron beams instead of X-rays. Electron beams are applied in order to achieve higher resolution. Just as in traditional X-ray tomography, appropriate deconvolution procedures on the resulting data afford a 3-D picture of the cell [12]. Current technology is at a resolution of 40–50 Å. An improvement to 20 Å is considered possible. The goal is to be able to discern macromolecular complexes, such as ribosomes, proteasomes, ion channels, components of the cytoskeleton and the like. At 40-Å resolution, large complexes can be distinguished. At 20-Å resolution, we should be able to discern medium-size complexes. Image analysis then incorporates a template-based approach [25, 55], in which a database of images of the relevant macromolecular complexes is available. The templates are matched with relevant parts of the 3-D image in order to identify the locations of the respective complexes. Then, if available, the low-resolution structures can be overlaid with representative high-resolution images of the complexes affording, in principle, a high-resolution image of the complete cell. The construction of template libraries can be supported with the data from structural genomics initiatives [151] (see Chapter 13). Problems with low resolution, low signal-to-noise ratio, missing data resulting in nonisotropic resolution and crowding of the macromolecules still lie in the way of clearly separating different molecular complexes [66, 153]. Thus, intermittently, an approach mixing experimental with computational procedures employs labeling proteins with accessible epitopes using ligands carrying gold nanoparticles. Such proteins can then be identified more easily in the macromolecular crowd. Labeling works better for membrane proteins with extracellular epitopes than inside the cell, where it requires non-invasive genetic manipulations.

Images of cells from *Dictyostelium discoideum* [122] and *Spiroplasma melliferum* [97] have been generated in this way, and afforded unprecedented insights into the internal organization of the cell (Figure 6). In general, it is impressive how much our intuitive picture of a cell is changed by the availability of global cell images. The cell is an extremely crowded environment – thicker than lentil soup – and notions like transport and diffusion receive a different connotation in the presence of such images.

The EU is funding a Network of Excellence on 3-D electron microscopy that bundles many of the European activities in the area
(http://www.3dem-noe.org).

There are also cell imaging efforts based on light microscopy [164]. With the advent of green fluorescent protein (GFP) technology which can now utilize several colors, fluorescence labeling in order to visualize intracellular molecules, structures and processes has received a vital push. GFP is used to visualize targeted structures in cells, such as G-protein activity, special signaling events and calcium dynamics. Confocal light microscopy, which only collects light emerging from the focal plane, yields 3-D images, but with live samples the classical wide-field microscopy with subsequent computational deconvolution of the data is still the preferable technology for this purpose.

In addition, special laser technology affords us with the facility to press the resolution of light microscopy below the usual limit of about half the wavelength of the applied light [74,75]. This technology, which is just emerging, has

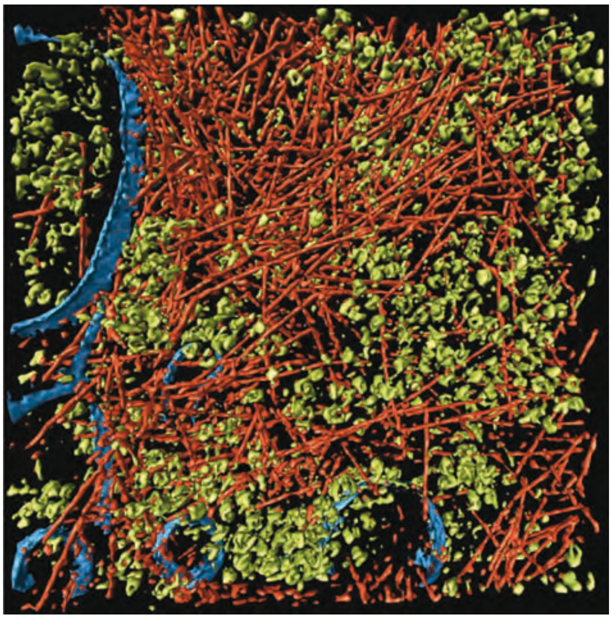

Figure 6 Visualization of part of a cell with intracellular structures. Actin filaments (reddish), other macromolecular complexes, mostly ribosomes (green), and membranes (blue). (From Ref. [122].)

the advantage that, in principle, it is applicable to live samples rather than just fixated cells. Making this technology work for biological specimens would be no less than a breakthrough.

Chapter 43 contains a more detailed discussion of light microscopy imaging of cellular structures and processes.

10.2 Movies of Cellular Processes

So far, we have discussed still imaging of cellular structures. Of course, getting direct information along the time dimension is another very effective input into the analysis of biological processes. Thus, 4-D imaging of cellular structure, i.e. making movies of them, is a vivid research field [61]. The restraint that the sample be viable throughout the experiment is mandatory here, of course, and can be a great challenge. The other significant concern is the limited amount of light output that is usually available in such an experiment.

An especially attractive target for 4-D imaging has been the mechanics of eukaryotic cell division. Movies have been made on how chromosomes rearrange during the early stages of mitosis [61] and of the rearrangement of the mitotic spindle during the later stages of mitosis [65]. The cytoskeleton is an especially interesting target because of its relative rigidity [13]. Other cellular structures are more amorphous, making quantitative structural measurements very difficult. In order to deal with this problem, artificial landmarks can be introduced in cells in an approach called pattern photobleaching. Virtual reality viewers are employed to visualize the resulting data [60]. The resulting data can also be input to quantitative models of the investigated cellular processes [65].

10.3 Organism Development

Imaging can go beyond single cells and cover the whole organism. One special case is monitoring the location of prespecified expressed [184] genes, the movement of cells [146,180] or the development of morphology of cellular structures [178] during organism development. Such studies are being undertaken, e.g. in *Drosophila* and *Xenopus* [170], with a certain focus on neuronal development. The analysis of data resulting from *in situ* imaging of expressed genes affords special bioinformatics techniques that merge image analysis (Chapter 43) with the analysis of expression data (Chapters 24ff.). First steps in this direction have been undertaken [135].

11 Modeling Organs

From a basic research point of view, the ultimate vision of computational biology could be formulated as the ability to simulate biological processes on a hierarchy of levels, starting from the bottom-most level that considers molecular processes, and reaching to higher levels that, ultimately, represent the macroscopic physiology and biomechanics of organ systems. The notion of the *physiome* has been coined to encompass the totality of all physiologically relevant information pertaining to this modeling hierarchy. While such a comprehensive goal may seem utopic, there are actually concerted efforts embarking along this path. The International Union of Physiological Sciences has introduced the Physiome Project [38, 80, 81]. This project provides a web site (http://www.physiome.org/) that collects world-wide contributions towards filling in the gigantic simulation landscape presented by the goals of the project. At heart, the Physiome Project is a computational project. However, completing it requires a wide variety and large volume of new data. In order to reach through the different model hierarchies, effective approaches towards multiscale modeling are of central importance [39]. The Physiome Project is structured into model subcategories. In the past, physiological modeling has concentrated on a few organ systems. The heart is definitely one of the best researched organs, in this respect, with detailed models being available from the electrophysiology of the heart at the molecular level over the microstructure of cardiac tissue and the organization of fibers in the heart muscle to mechanical models for heart beat that include the spread of electrical activation wavefronts throughout the heart muscle and the pressures in the coronary arteries [82, 129]. These models have to be linked together now. Blood flow [32, 33] through the lung has also been modeled at an organ-wide level. A proposal has been made to model bone [43].

Of course, physiome modeling has direct medical application, since disease is an aberration of normal biology and can probably best be understood as such. However, there are also modeling efforts that are directly targeted at disease, i.e. the direct modeling of tumor growth. Tumor growth is the result of several processes such as rapid cell proliferation with loss of apoptosis, tissue invasion and angiogenesis. Lastly, the effect of radiation therapy and chemotherapy can be modeled. Models for many of these aspects have been developed independently, some of which are already quite interdisciplinary (e.g. see Ref. [36] for cell proliferation, Ref. [139] for tissue invasion, Refs. [8, 108] for angiogenesis, Refs. [58, 145] for the effect of drug treatment and Ref. [45] for radiation therapy). The adaptation of such models to each other and their integration is still for the future, but people are working in this direction [3].

12 Outlook

This points addressed in this chapter are by no means comprehensive. Rather, they reflect the exposure and judgment of the author with respect to emerging and promising themes. Many of the research activities in these areas are currently still driven by experimental issues, but all of them harbor great potential for further bioinformatic development. Probably it would be a futile exercise to attempt a comprehensive balanced overview of all promising open leads in bioinformatics and the experimental technologies relevant for the field, anyway. However, as a collection, these topics bear witness to the tremendous dynamics of the field. Bioinformatics is going to continue for quite some time to be a productive source of extremely exciting scientific problems that combine great challenges for basic research with often immediate application relevance. In the view of the author, these characteristics presently single out bioinformatics among all scientific disciplines.

Acknowledgments

I thank Mario Albrecht, Iris Antes, Christoph Bock, Francisco Domingues, Oliver Kohlbacher, Claus-Wilhelm von der Lieth, Jochen Maydt, Jörg Rahnenführer, Kirsten Roomp, Laura Tolosi, Martin Vingron and Nils Weinhold for helpful suggestions on this chapter, pointers to relevant literature and the preparation of figures.
