1807–2007 Knowledge for Generations

Each generation has its unique needs and aspirations. When Charles Wiley first opened his small printing shop in lower Manhattan in 1807, it was a generation of boundless potential searching for an identity. And we were there, helping to define a new American literary tradition. Over half a century later, in the midst of the Second Industrial Revolution, it was a generation focused on building the future. Once again, we were there, supplying the critical scientific, technical, and engineering knowledge that helped frame the world. Throughout the 20th Century, and into the new millennium, nations began to reach out beyond their own borders and a new international community was born. Wiley was there, expanding its operations around the world to enable a global exchange of ideas, opinions, and know-how.

For 200 years, Wiley has been an integral part of each generation's journey, enabling the flow of information and understanding necessary to meet their needs and fulfill their aspirations. Today, bold new technologies are changing the way we live and learn. Wiley will be there, providing you the must-have knowledge you need to imagine new worlds, new possibilities, and new opportunities.

Generations come and go, but you can always count on Wiley to provide you the knowledge you need, when and where you need it!

Volume 3

Preface

This book is a substantially expanded sequel to the book *Bioinformatics – From Genomes to Drugs* that appeared in 2002. Since the publication of the predecessor book the field of bioinformatics has experienced continuing and substantially accelerated growth in terms of the volume and diversity of available molecular data, as well as the development of methods for analyzing and interpreting these data. This book is a reflection of the dynamic maturation of the field. Like its predecessor, it discusses bioinformatics in the context of pharmaceutical and medical challenges pertaining to the understanding, diagnosis and therapy of diseases. The previous book covered bioinformatics issues accompanying the stages from the collection of genomic data across the elucidation of the molecular basis of disease and the identification of target proteins for drug design to the search for leads for potential drugs. This book extends this schema in various ways. First, the process line from genome to drug is extended downstream towards the optimization of drug leads and further towards the personalization of drug therapies, which is also beginning to be supported with bioinformatics methods. Second, the book covers the field in substantially more breadth. The different types of available data are discussed more comprehensively and in more detail. On the sequence side, two chapters on RNA have been added. The bioinformatics analysis of evolutionary relationships is addressed in several chapters. The discussion of protein structure has been significantly expanded. There are new sections on molecular networks, mRNA expression data and protein function, covering several chapters each. The disease-specific part of the book has also been expanded, including discussions of bacterial and viral infections. Finally, several chapters on informatics technologies employed for bioinformatics are included.

Bioinformatics is continuing to present one of the grand challenges of our times. It has a large basic research aspect, since we cannot claim to be close to understanding biological systems on an organism or even cellular level. At the same time, the field is faced with a strong demand for immediate solutions, because the genomic and postgenomic data that are being collected harbor

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

many biological insights whose deciphering can be the basis for dramatic scientific and economical success, and is promising to have large impact on society.

The book is directed at readers who are interested in how bioinformatics can spur biological and medical innovation towards understanding, diagnosing and curing diseases. The book is designed to be useful to readers with a variety of backgrounds. Biologists, biochemists, pharmacologists, pharmacists and medical doctors can get an introduction into basic and practical issues of the computer-based part of handling and interpreting genomic, postgenomic and clinical data. In particular, many chapters point to bioinformatics software and data resources which are available on the Internet (often at no cost), and make an attempt at classifying and comparing those resources. For computer scientists and mathematicians, the book contains an introduction to the biological background and the necessary information in order to begin appreciating the difficulties and wonders of modeling complex biochemical and biomolecular issues by computer. Since the book caters to a readership with widely varying backgrounds, it also contains chapters with a diverse makeup. There are chapters that put the biology in the foreground and only sketch methodical issues, and a smaller number of chapters in which the algorithmic and statistical content dominates. By and large, the way in which the chapters are written reflects the viewpoint from which the authors, and that also often means the world-wide research community, approaches the respective topic.

The book contains a name and a subject index. A methodical index is integrated inside the subject index and points to those sections that present the master introductions to the quoted computational methods.

The world's leading experts have contributed their expertise and written largely autonomous chapters on the specific topics of this book. In order to render added coherence to the book, the chapters contain a large number of cross-references to aid in relating the topics of different chapters to each other. In a few cases, overlap between the chapters has been allowed to ensure the independent readability of the chapters.

I am grateful to the many people who helped make this book possible. Above all, I thank the 91 authors of contributed chapters who have shown extraordinary commitment during the draft and revision stages of their text. Ruth Christmann spent many hours helping me to master the logistic feat of collecting the texts, encouraging authors to keep to their commitments, handling versions and completing revisions with a special focus on reference lists. Joachim Büch kept the website for book authors alive and well maintained during the preparation and production process. Ray Loughlin did a superb job on copy-editing the book. Frank Weinreich and later Steffen Pauly were always responsive partners on the side of the publisher. Finally, I would like to express my deep gratitude to my wife Sybille and my children Sara and Nico who had to cope with my physical or mental absence too much while the project was ongoing. They gave the most for receiving the least.

Part 1 Introduction

1
Bioinformatics – From Genomes to Therapies

Thomas Lengauer

1 Introduction

In order to set the stage for this book, this chapter provides an introduction to the molecular basis of disease. We then continue to discuss modern biological techniques with which we have recently been empowered to screen for molecular drugs targets as well as for the drugs themselves. The chapter finishes with an overview of the organization of the book.

2 The Molecular Basis of Disease

Diagnosing and curing diseases has always been and will continue to be an art. The reason is that man is a complex being with numerous facets, many of which we do not and probably will never understand. Diagnosing and curing diseases has many aspects, include biochemical, physiological, psychological, sociological and spiritual aspects.

Molecular medicine reduces this variety to the molecular aspect. Living organisms, in general, and humans, in particular, are regarded as complex networks of molecular interactions that fuel the processes of life. This "molecular circuitry" has intended modes of operation that correspond to healthy states of the organism and aberrant modes of operation that correspond to diseased states. The main goal of molecular medicine is the identification of the molecular basis of a disease, i.e. to answer the question: "What goes wrong in the molecular circuitry?". The goal of therapy is to guide the biochemical circuitry back to a healthy state. The molecular approach has already proven

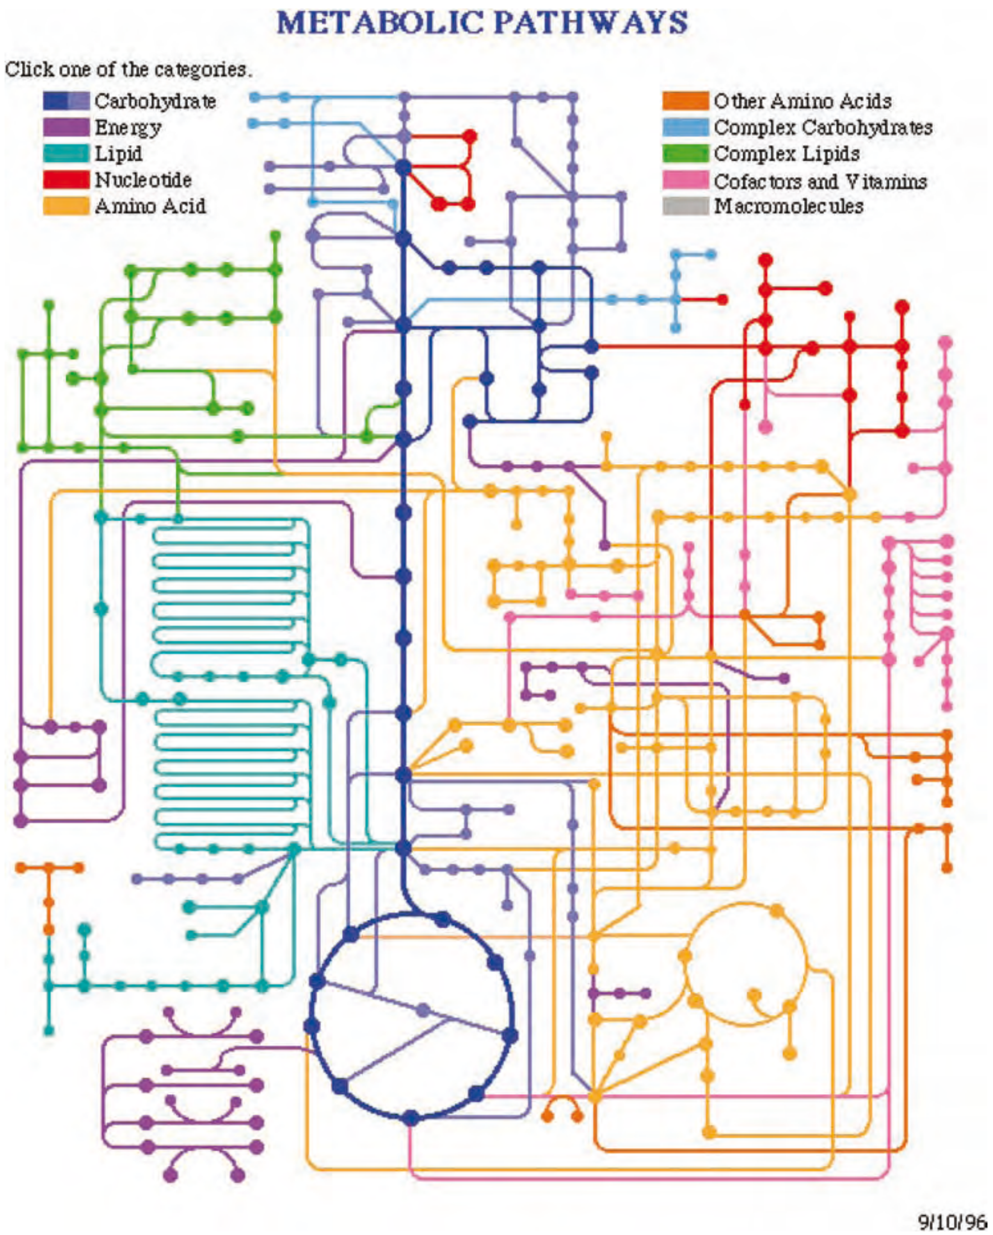
Bioinformatics – From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

its effectiveness for understanding diseases, and is dramatically enhanced by genomics and proteomics technology [5]. It is the prime purpose of this book to explore the contributions that this technology, particularly its computational aspect, can have to advancing molecular medicine.

As already noted, the molecular basis of life is composed of complex biochemical processes that constantly produce and recycle molecules, and do so in a highly coordinated and balanced fashion. The underlying basic principles are quite alike throughout all kingdoms of life, even though the processes are much more complex in highly developed animals and the human than in bacteria, for instance. Figure 1 gives an abstract view of such an underlying biochemical network, the *metabolic network* of a bacterial cell (the intestinal bacterium *Escherichia coli*) – it affords an incomplete and highly simplified account of the cell's metabolism, but it nicely visualizes the view of a living cell as a biochemical circuit. The figure has the mathematical structure of a *graph.* Each dot (*node*) stands of a small organic molecule that is metabolized within the cell. Alcohol, glucose and ATP are examples for such molecules. Each line (*edge*) indicates a chemical reaction. The two nodes connected by the edge represent the substrate and the product of the reaction. The colors represent the role that the respective reaction plays in metabolism. These roles include the construction of molecular components that are essential for life – nucleotides (red), amino acids (orange), carbohydrates (blue), lipids (light blue), etc. – or the breakdown of molecules that are not helpful or even harmful to the cell. Other tasks of chemical reactions in a metabolic network pertain to the storage and conversion of energy. (The blue cycle in the center of Figure 1 is the citric acid cycle.) A third class of reactions facilitates the exchange of information in the cell or between cells. This includes the control of when and in what way genes are expressed (*gene regulation*), as well as such tasks as the opening and closing of molecular channels on the cell surface, and the activation or deactivation of cell processes such as replication or apoptosis (programmed cell death). The reactions that regulate cellular processes are often collectively called the *regulatory network*. Recently, molecular networks that facilitate the propagation of signals within the cell are being selectively called *signal transduction networks*. Figure 1 only includes metabolic reactions, without any regulatory reactions or signal transduction cascades. Of course, all molecular networks of a cell are closely intertwined and many reactions can have metabolic as well as regulatory aspects. In general, much more is known about metabolic than regulatory networks, even though many relevant diseases involve regulatory rather than metabolic dysfunction.

The metabolic and regulatory networks can be considered as composed of partial networks that we call *pathways*. Pathways can fold in on themselves, in which case we call them *cycles*. A metabolic pathway is a group of reactions that turns a substrate into a product over several steps (pathway) or recycles



9/10/96

Figure 1 Abstract view of part of the metabolic network of the bacterium *E. coli* (from http://www.genome.ad.jp/kegg/kegg.html).

a molecule by reproducing it in several steps (cycle). *The glycolysis pathway* (the sequence of blue vertical lines in the center of Figure 1) is an example of a pathway that decomposes glucose into pyruvate. The *citric acid cycle* (the blue cycle directly below the glycolysis pathway in Figure 1) is an example of a cycle that produces ATP – the universal molecule for energy transport. Metabolic cycles are essential in order that the processes of life do not accumulate waste or deplete resources. (Nature is much better at recycling than man.)

There are several ways in which Figure 1 hides important details of the actual metabolic pathway. In order to discuss this issue, we have extracted a metabolic cycle from Figure 1 (see Figure 2). This cycle contributes to cell replication; more precisely, ;t is one of the motors that drive the synthesis of thymine – a molecular component of DNA. In Figure 2, the nodes of the metabolic cycle are labeled with the respective organic molecules and the edges point in the direction from the substrate of the reaction to the product. Metabolic reactions can take place spontaneously under physiological conditions (in aqueous solution, under room temperature and neutral pH). However, nature has equipped each reaction (each line in Figure 1) with a specific molecule that catalyzes that reaction. This molecule is called an *enzyme* and, most often, it is a protein. An enzyme has a tailor-made binding site for the transition state of the catalyzed chemical reaction. Thus, the enzyme speeds up the rate of that reaction tremendously, by rates of as much as 10^7. Furthermore, the rate of a reaction that is catalyzed by an enzyme can be regulated by controlling the effectiveness of the enzyme or the number of enzyme molecules that are available.

How does the enzyme do its formidable task? As an example, consider the reaction in Figure 2 that turns dihydrofolate (DHF) into tetrahydrofolate (THF). This reaction is catalyzed by an enzyme called *dihydrofolate reductase (DHFR).* The surface of this protein is depicted in Figure 3. One immediately recognizes a large and deep pocket that is colored blue (representing its negative charge). This pocket is a *binding pocket* or *binding site* of the enzyme, and it is ideally adapted in terms of geometry and chemistry so as to bind to the substrate molecule DHF and present it in a conformation that is conducive for the desired chemical reaction to take place. In this case, this pocket is also

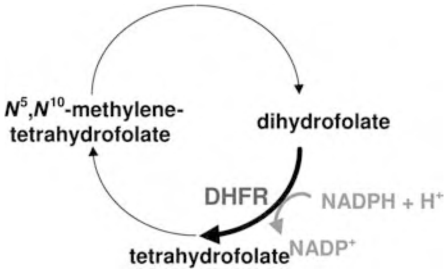


Figure 2 A specific metabolic cycle.

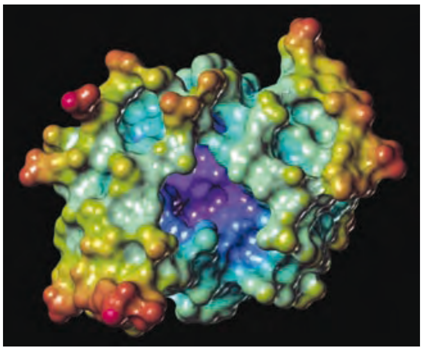

Figure 3 The 3-D structure of DHFR colored by its surface potential. Positive values are depicted in red, negative values in blue.

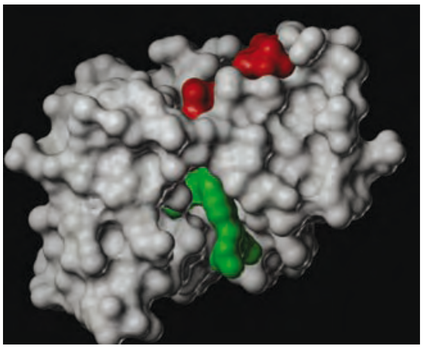

Figure 4 DHFR (gray) complexed with DHF (green) and NADPH (red).

where the reaction is catalyzed. We call this place the *active site*. (There can be other binding pockets in a protein that are far removed from the active site.)

There is another aspect of metabolic reactions that is not depicted in Figure 1 – many reactions involve *cofactors*. A cofactor is an organic molecule or a metal ion that has to be present in order for the reaction to take place. If the cofactor is itself modified during the reaction, we call it a *cosubstrate.* In the case of our example reaction, we need the cosubstrate NADPH for the reaction to happen. The reaction modifies DHF to THF and NADPH to $NADP^+$. Figure 4 shows the molecular complex of DHFR, DHF and NADPH before the reaction happens. After the reaction has been completed, both organic molecules dissociate from DHFR and the original state of the enzyme is recovered.

Now that we have discussed some of the details of metabolic reactions, let us move back to the global view of Figure 1. We have seen that each of the edges in Figure 1 represents a reaction that is catalyzed by a specific protein. (However, the same protein can catalyze several reactions.) In *E. coli* there are an estimated 1500 enzymes [6]; in human there are thought to be about least twice as many. The molecular basis of a disease lies in modifications of the action of these biochemical pathways. Some reactions do not happen at their intended rate (e.g. in gout), resources that are needed are not present in sufficient amounts (vitamin deficiencies) or waste products accumulate in the body (Alzheimer's disease). In general, imbalances induced in one part of the network spread to other parts. The aim of therapy is to replace the aberrant processes with those that restore a healthy state. The most desirable fashion in which this could be done would be to control the effectiveness of a whole set of enzymes in order to regain the metabolic balance. This set probably involves many, many proteins, as we can expect many proteins to be involved in manifesting the disease. Also, each of these proteins would have to be regulated in quite a specific manner. The effectiveness of some proteins would possibly have to be increased dramatically, whereas other proteins would have to be blocked entirely, etc. It is obvious that this kind of therapy involves a kind of global knowledge of the workings of the cell and a refined pharmaceutical technology that is far beyond what man can do today and for some time to come.

3 The Molecular Approach to Curing Diseases

For this reason, the approach of today's pharmaceutical research is far more simplistic. The aim is to regulate a single protein. In some cases we aim at completely blocking an enzyme. To this end, we can provide a drug molecule that effectively competes with the natural substrate of the enzyme. The drug molecule, the so-called *inhibitor*, has to be made up such that it binds more strongly to the protein than the substrate. Then, the binding pockets of most enzyme molecules will contain drug molecules and cannot catalyze the desired reaction in the substrate. In some cases, the drug molecule even binds very tightly (covalently) to the enzyme (suicide inhibitor). This bond persists for the remaining lifetime of the protein molecule. Eventually, the deactivated protein molecule is broken down by the cell and a new identical enzyme molecule takes its place. Aspirin is an example of a suicide inhibitor. The effect of the drug persists until the drug molecules themselves are removed from the cell by its metabolic processes and no new drug molecules are administered to replace them. Thus, one can control the effect of the drug by the time and dose it is administered.

There are several potent inhibitors of DHFR. One of them is *methotrexate (MTX)*. Figure 5 shows MTX (color) both unbound (left) and bound (right) to DHFR (gray). MTX has been administered as an effective cytostatic cancer drug for over two decades.

There are many other ways of influencing the activity of a protein by providing a drug that binds to it. Drugs interact with all kinds of proteins:

- With receptor molecules that are located in the cell membrane and fulfill regulatory or signal transduction tasks.

- With ion channels and transporter systems (again protein residing in the cell membrane) that monitor the flux of molecules into and out of the cell.

The mode of interaction between drug and protein does not always have the effect of blocking the protein. In some cases, the drug mimics a missing small molecule that is supposed to activate a protein. We call such drugs agonists.

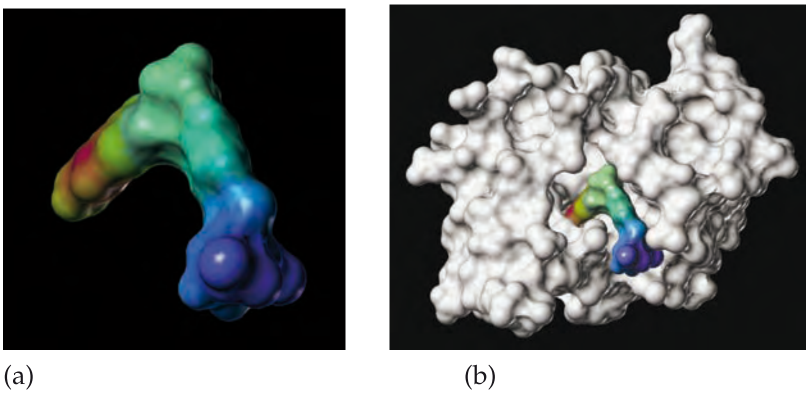

Figure 5 MTX (colored by its surface potential, see Figure 3): (a) unbound, (b) bound to DHFR (gray).

In general, we are looking for drugs that bind tightly to their protein target (effectiveness) and to no other proteins (selectivity).

Most drugs that are on the market today modify the enzymatic or regulatory action of a protein by strongly binding to it as described above. Among these drugs are long-standing, widespread and highly popular medications, and more modern drugs against diseases such as AIDS, depression or cancer. Even the lifestyle drugs that have come into use in recent years, e.g. Viagra and Xenical, belong to the class of protein inhibitors.

In this view, the quest for a molecular therapy of a disease decomposes into three parts:

- *Question 1: Which protein should we target?* As we have seen, there are many thousands of candidate proteins in the human. We are looking for one that, by binding the drug molecule, provides the most effective remedy of the disease. This protein is called the *target protein*.

- *Question 2: Which drug molecules should be used to bind to the target protein?* Here, the molecular variety is even larger. Large pharmaceutical companies have compound archives with millions of compounds at their disposal. Every new target protein raises the question of which of all of these compounds would be the best drug candidate. Nature uses billions of molecules. With the new technology of combinatorial chemistry, where compounds can be synthesized systematically from a limited set of b uilding blocks, this number of *potential* drug candidates is also becoming accessible to the laboratory.

- *Question 3: Given a choice of different drugs to administer to a patient, in order to alleviate or cure a specific disease, what is the best selection of drugs to give to that individual patient*? Questions 1 and 2 have been posed without the specifics of an individual patient in mind. Target protein and drug were selected for all putative patients collectively. With Question 3 we are entering the more advanced stage of *personalized medicine* – we want to understand the different ways in which different patients react to the same drug.

Question 3 has only come into the focus of research recently. The inclusion of the discussion of this question presents a major new feature of this book over its predecessor.

We will now give a short summary of the history of research on all three questions.

4 Finding Protein Targets

Let us start our discussion of the search for target proteins by continuing our molecular example of DHFR/MTX. As mentioned, DHFR catalyzes a reaction that is required for the production of thymine – a component of DNA. Thus, blocking DHFR impairs DNA synthesis and, therefore, cell division. This is the reason that MTX, an inhibitor of DHFR, is administered as a cytostatic drug against cancer. Is DHFR the "right" target protein in this context? The frank answer to this question must be "no". DHFR is active in every dividing cell, tumor cells as well as healthy cells. Therefore, MTX impairs the division of all dividing cells that it can get to. This is the cause of the serious side-effects of the drug such as loss of hair and intestinal lining. We see that in this case the limits of the therapy are mostly dictated by the choice of the wrong target protein. Why then is this protein chosen as a target? The answer to this question is also very simple: we cannot find a better one. This example shows how central the search for suitable target proteins is for developing effective drug therapies.

Target proteins could not really realistically be searched for until a few years ago. Historically, few target proteins were known at the time that the respective drug had been discovered. The reason is that new drugs were developed by modifying natural metabolites or known drugs, based on some intuitive notion of molecular similarity. Each modification was immediately tested in the laboratory either *in vitro* or *in vivo*. Thus, the effectiveness of the drug could be assessed without even considering the target protein. To this day, all drugs that are on the marketplace worldwide target an estimated set of not much more than 500 proteins [3]. Thus, the search for target proteins is definitely the dominant bottleneck of current pharmaceutical research.

Today, new experimental methods of molecular biology, the first versions of which were developed just a few years ago, provide us with a fundamentally new way – the first systematic way – of looking for protein targets. The basis for all of these methods was the technological progress made in the context of the quest for sequencing the human genome [1]. Based on this

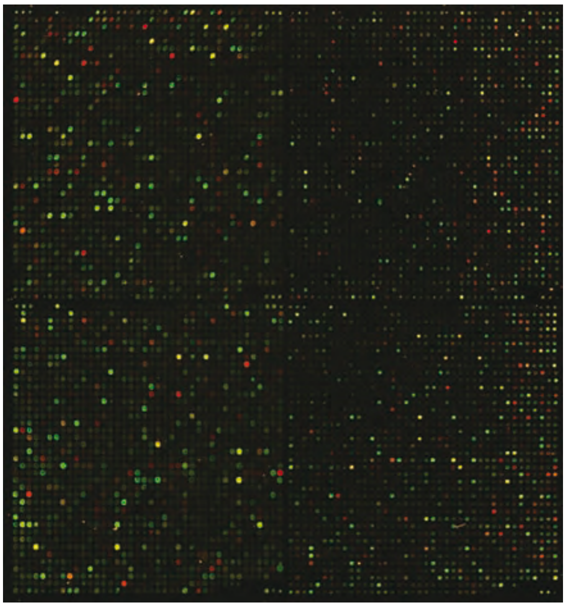

Figure 6 A DNA chip (from http://cmgm.stanford.edu/pbrown/explore/).

technology, additional developments have been undertaken to be able to measure the amount of expressed genes and proteins in cells. We exemplify this progress using a specific DNA chip technology [2]; however, the general picture extends to many other experimental methods under development.

Figure 6 shows a DNA chip that provides us with a differential census of the gene expressed by a yeast cell in two different cell states – one governed by the presence of glucose (green) and one by the absence of glucose (red). In effect the red picture is that of a starving yeast cell, whereas the green picture shows the "healthy" state. Each bright green dot indicates a protein that is manufactured (expressed) in high numbers in the "healthy" state. Each bright red dot indicates a protein that is expressed in high numbers in the starving cell. If the protein occurs frequently in both the healthy and the starving state, the corresponding dot is bright yellow (resulting from an additive mixture of the colors green and red). Dark dots indicate proteins that are not frequent, the tint of the color again signifies whether the protein occurs more often in the healthy cell (green), equally often in both cells (yellow) or more often in the diseased cell (red).

At this point, the exactly nature of the experimental procedures that generate the picture in Figure 6 is of secondary importance. What is important is how much information is attached to the colored dots in the picture. Here, we can make the following general statements.

(i) The identity of the protein is determined by the coordinates of the colored dot. We will assume, for simplicity, that dots at different locations also represent different proteins. (In reality, multiple dots that represent the same protein are introduced, on purpose, for the sake of calibration.) The exact arrangement of the dots is determined before the chip is manufactured. This involves identifying a number of proteins to be represented on the chip and laying them out on the chip surface. This layout is governed by boundary conditions and preferences of the experimental procedures, and is not important for the interpretation of the information

(ii) Only rudimentary information is attached to each dot. At best, the experiment reveals the complete sequence of the gene or protein. Sometimes, only short segments of the relevant sequence are available.

Given this general picture, the new technologies of molecular biology can be classified according to two criteria, as shown in the following two subsections.

4.1 Genomics versus Proteomics

In genomics, it is not the proteins themselves that are monitored, but rather we screen the expressed genes whose translation ultimately yields the respective proteins. In proteomics, the synthesized proteins themselves are monitored. The chip in Figure 6 is a DNA chip, i.e. it contains information on the expressed genes and, thus, only indirectly on the final protein products. The advantage of the genomics approach is that genes are more accessible experimentally and easier to handle than proteins. For this reason, genomics is ahead of proteomics, today. However, there also are disadvantages to genomics. First, the expression level of a gene need not be closely correlated with the concentration of the respective protein in the cell, although the latter figure may be more important to us if we want to elicit a causal connection between protein expression and disease processes. Even more important, proteins are modified post-translationally (i.e. after they are manufactured). These modifications involve glycosylation (attaching complex sugar molecules to the protein surface) and phosphorylation (attaching phosphates to the protein surface), for instance, and they lead to many versions of protein molecules with the same amino acid sequence. Genomics cannot monitor these modifications, which are essential for many diseases. Therefore, it can be expected that, as the experimental technology matures, proteomics will gain importance over genomics (see also Chapter 45).

4.2 Extent of Information Available on the Genes/Proteins

Technologies vary widely in this respect. The chip in Figure 6 is generated by a technology that identifies (parts of) the gene sequence. We are missing information on the structure and the function of the protein, its molecular interaction partners, and its location inside the metabolic or regulatory network of the organism. All of this information is missing for the majority of the genes on the chip.

There are many variations on the DNA chip theme. There are technologies based on so-called *expressed sequence tags (ESTs)* that tend to provide more inaccurate information on expression levels and various sorts of microarray techniques (see Chapter 24). All technologies have in common that the data they produce require careful quality control (Chapter 25). In general, it is simpler to distinguish different disease states from gene expression data (Chapter 26) than to learn about the function of the involved proteins from these data (Chapter 27). Proteomics uses different kinds of separation techniques, e.g. chromatography or electrophoresis combined with mass spectrometry, to analyze the separated molecular fractions (see Chapter 28). As is the case with genomics, proteomics technologies tend to generate information on the sequences of the involved proteins and on their molecular weight, and possibly information on post-translational modifications such as glycosylation and phosphorylation. Again, all higher-order information on protein function is missing. It is not feasible to generate this information exclusively in the wet laboratory – we need bioinformatics to make educated guesses here. Furthermore, basically all facets of bioinformatics that start with an assembled sequence can be of help. This includes the comparative analysis of genes and proteins (Chapter 37), protein structure prediction (Chapters 9–13), protein function prediction (Chapters 30–34), analysis and prediction of molecular interactions involving proteins (Chapters 16 and 17) as well as bioinformatics for analyzing metabolic and regulatory networks (Chapters 20–22). This is why all of bioinformatics is relevant for the purpose of this book.

If, with the help of bioinformatics, we can retrieve enough information on the molecular networks that are relevant for a disease, then we have a chance of composing a detailed picture of the disease process that can guide us to the identification of possible target proteins for the development of an effective drug. Note that the experimental technology described above is universally applicable. The chip in Figure 6 contains all genes of the (fully sequenced) organism *Saccharomyces cerevisiae* (yeast). The cell transition analyzed here is the diauxic shift – the change of metabolism upon removal of glucose. However, we could exchange this with almost any other cell condition of any tissue of any conceivable organism. The number of spots that can be put on a single chip goes into the hundreds of thousands. This is enough to put all of the human genes on a single chip. Also, we do not have to restrict ourselves to disease conditions; all kinds of environmental conditions (temperature, pH, chemical stress, drug treatment, diverse stimuli, etc.) or intrinsic conditions (presence or absence of certain genes, mutations, etc.) can be the subject of study.

The paradigm of searching for target proteins in genomics data has met with intense excitement from the pharmaceutical industry, which has invested heavily in this field over recent years. However, the first experiences have been sobering. It seems that we are further away from harvesting novel target proteins from genomics and proteomics data than we initially thought. However, in principle, a suitable novel target protein can afford a completely new approach to disease therapy and a potentially highly lucrative worldwide market share. For a critical review of the target-based drug development process, see Sams-Dodd [7].

Providing adequate bioinformatics support for finding new target proteins is a formidable challenge that is the focus of much of this book. However, once we have a target protein, our job is not done.

5 Developing Drugs

If the target protein has been selected, we are looking for a molecule that binds tightly to the relevant binding site of the protein. Nature often uses macromolecules, such as proteins or peptides, to inhibit other proteins. However, proteins do not make good drugs – they are easily broken down by the digestive system, they can elicit immune reactions and they cannot be stored for a long period of time. Thus, after an initial excursion into drug design based on proteins, pharmaceutical research has basically gone back to looking for small drug molecules. Here, one idea is to use a peptide as the template for an appropriate drug (peptidomimetics).

Due to the lack of fundamental knowledge of the biological processes involved, the search for drugs was, until recently, governed by chance. However, as long as chemists have thought in terms of chemical formulae, pharmaceutical research has attempted to optimize drug molecules based on chemical intuition and on the concept of molecular similarity. The basis for this approach is the lock-and-key principle formulated by Emil Fischer [4] over 100 years ago. Figures 3 to 5 illustrate that principle: in order to bind tightly, the two binding molecules have to be complementary to each other both sterically and chemically (colors in Figures 3 and 5). The drug molecule fits into the binding pocket of the protein like a key inside a lock. The lock-and-key principle has been the dominating paradigm in drug research ever since its proposal. It has been refined to include the phenomenon of induced fit, by which the binding pocket of the protein undergoes subtle steric changes in order to adapt to the geometry of the drug molecule.

For most of the past century the structure of protein-binding pockets has not been available to the medicinal chemist. Even to this day the structure of the target protein will not be known for many pharmaceutical projects for some time to come. For instance, many diseases involve target proteins that reside in the cell membrane and we cannot expect the three-dimensional (3-D) structure of such proteins to become known soon. If we have no information on the structure of the protein-binding site, drug design is based on the idea that molecules that are similar in terms of composition, shape and chemical features should bind to the target protein with comparable strength. The respective drug-screening procedures are based on comparing drug molecules, either intuitively or, more recently, systematically with the computer. The resulting search algorithms are very efficient and allow searching through compound libraries with millions of entries (Chapter 18).

As 3-D protein structures became available, the so-called *rational* or *structure-based* approach to drug development was invented, which exploited this information to develop effective drugs. Rational drug design is a highly interactive process with the computer originally mostly visualizing the protein structure and allowing queries on its chemical features. The medicinal chemist interactively modified drug molecules inside the binding pocket of the protein at the computer screen. As rational drug design began to involve more systematic optimization procedures interest arose in *molecular docking*, i.e. the prediction of the structure and binding affinity of the molecular complex involving a structurally resolved protein and its binding partner (Chapter 16). Synthesizing and testing a drug in the laboratory used to be comparatively expensive. Thus, it was of interest to have the computer suggest a small set of highly promising drug candidates. After an initial lead molecule has been found that binds tightly to the target protein, secondary drug properties have to be optimized that maximize the effectiveness of the drug and minimize side-effects (Chapter 19).

With the advent of *high-throughput screening* the binding affinity of as many as several hundred thousands drug candidates to the target protein can now be assayed within a day. Furthermore, *combinatorial chemistry* allows for the systematic synthesis of molecules that are composed of preselected molecular groups that are linked with preselected chemical reactions. The number of molecules that is accessible in such a combinatorial library can, in principle, exceed many billions. Thus, we need the computer to suggest promising sublibraries that promise to contain a large number of compounds that bind tightly to the protein (Chapters 16 and 18).

As in the case of target finding, the new experimental technologies in drug design require new computer methods for screening and interpreting the voluminous data assembled by the experiment. These methods are seldom considered part of bioinformatics, since the biological object, i.e. the target protein, is not the focus of the investigation. Rather, people speak of *cheminformatics* – the computer aspect of medicinal chemistry. Whatever the name, it is our conviction that both aspects of the process that guides us from the genome to the drug have to be considered together and we will do so in this book.

6 Optimizing Therapies

How is it that different patients react differently to the same drug? Reasons for this phenomenon can be manifold. Some are easier to investigate with methods of modern biology and bioinformatics than others. Here, we distinguish between infectious diseases and other diseases.

The molecular basis of any infectious disease is the interplay of a usually large population of a pathogen with the human host. The pathogen takes advantage of the human host or, in the case of virus, even hijacks the infected cells of the patient. Chapter 23 relates a story about the interplay of a viral pathogen with the infected host cell.

With infectious diseases, the drug often targets proteins of the infecting pathogen rather than the human host. The reason is the hope that drugs for such targets harbor less serious side-effects for the patient. However, in all infectious diseases, there is a constant battle going on between the host, whose immune system tries to eradicate the pathogen, and the pathogen that tries to evade the immune system. If the disease is treated with drugs, the administered drugs impose an additional selective pressure on the pathogen. On the road to resistance the pathogen constantly changes its genome and, thus, also the shape of the target proteins for drug therapy. Changes that are beneficial for the pathogen are those that render the drugs less effective, i.e. the pathogen becomes resistant. The results of this process are widely known. With bacteria, we observe increasingly resistant strains against antibiotic therapies (Chapter 41). With viral diseases such as AIDS the drug therapy has to be adapted continually to newly developing resistant strains within the patient (Chapter 40). Therapy selection must be individualized, in both cases, at least by taking the present strain of the pathogen into account and, at best, by also considering the individual characteristics of the host. Since the pathogen is a much simpler organism than the human host, the former is significantly easier than the latter.

Although the drug acts on its intended protein target, the drug has to find its way to the site of action and, eventually, has to be metabolized or excreted again. Along that path there are multiple ways in which the drug can interact with the patient. The resulting side-effects depend on the molecular and genetic status of the individual patient. Furthermore, the protein target often has different functions, such that its inhibition or agonistic activation can incur side-effects on molecular processes that were not intended to be changed. Again, the form and magnitude of such side-effects depends on the individual patient. This process of bringing about different reactions to drugs in different patient is much harder to analyze. The reason is that larger, often widespread, networks of interactions in the patient have to be taken in account. Analyzing them necessitates complex and accurately assembled patient histories and diverse molecular data that are seldom collected in today's clinical practice. Therefore, this approach to personalized medicine is still in its infancy (Chapter 39).

Another issue with diseases is the genetic predisposition of the human individual to the disease. Monogenetic diseases have been known for a long time and are relatively easy to analyze. Here, a defect in a single gene gives rise to the disease. However, these diseases are rare, in general. The major diseases like cancer, diabetes, and inflammatory and neurodegenerative diseases are based on a complex interplay between environmental and genetic factors with probably many genes involved. With data on the genomic differences between individuals just coming into being, the analysis of the genetic basis for complex diseases is embarking on a route that hopefully will lead to more effective means of prognosis, diagnosis and therapy.

7 Organization of the Book

This book is composed of three volumes. It is organized along the line from the genotype to the phenotype.

Volume 1: *The building blocks: sequences and structures*. This volume discusses the analysis of the basic building blocks of life, such as genes and proteins.

Volume 2: *Getting at the inner workings: molecular interactions*. This volume concentrates on the "switches" of the biochemical circuitry, the molecular interactions, as well as the circuits composed by these switches, the biochemical networks. In the former context, it partly also ventures into applied issues of drug design and optimization.

Volume 3: *The Holy Grail: molecular function*. This volume ties the elements provided by the first two volumes together and attempts to draw an integrated picture of molecular function – as far as we can do it today. The volume also discusses ramifications of this picture for the development and administration of drug therapies.

Each volume is subdivided in parts that are summarized below. The total book has 11 parts. *Volume 1* covers Parts 1–4.

Part 1 consists only of this chapter, and gives an introduction to the field and an overview of the book.

Part 2, consisting of Chapter 2, discusses bioinformatics support for assembling genome sequences. This is basic technology which is required to arrive at the genome sequence data that are the basis for much of what follows in the book. Major advances have been made in this area, especially during the finishing stages of completing the human genome sequence. The field has not lost its importance as we are embarking on sequencing many complex genomes, including over a dozen mammalian genomes. Furthermore, the technology is employed in projects that sequence closely related species, such as over a dozen species of *Drosophila*, in order to obtain a more effective database for functional genomics[1]. The authors of the chapter were part of the team that developed the assembler for the draft of the human genome sequence generated by Celera Genomics.

Part 3 is on molecular sequence analysis and comprises Chapters 3–8. Chapter 3 introduces the basic statistical and algorithmic technology for aligning molecular sequences. This technology forms the basis of much that is to follow. The author of the chapter has made seminal contributions to the field. Chapter 4 discusses methods for inferring ancestral histories from sequence data. This is one of the mainstays of comparative genomics. Similar to people, one can learn a lot about genes and proteins from looking at their ancestors and relatives, arguably more so with today's methods than from inspecting the gene or protein by itself. This attributes particular significance to this chapter in the context of this book. The authors of the chapter have made important contributions to the development of methods for inferring phylogenies and applied them to analyzing the evolution of *Homo sapiens*. Chapter 5 discusses the first major step from the genotype to the phenotype, i.e. the identification of protein-coding genes. The author of the chapter has developed one of the leading gene-finding programs. The ongoing debate on exactly what is the number of genes in the human chromosome years after the first draft of the human genome sequence was available shows that the issue of this chapter is still quite up-to-date. Furthermore, genes are a primary unit of linkage between the human genome and disease, as Chapter 38 discusses. Going into the gene's structure, most of the linkage with disease happens not in the coding regions of the genes that affect the structure of the coded protein. In general, proteins are far too well refined to be tampered with. Mostly, changing a protein means death to the individual

[1] see http://preview.flybase.net/docs/news/announcements/drosboard/GenomesWP2003.html for the respective community white paper

and only a few severe diseases (such as sickle cell anemia, Huntington's chorea or cystic fibrosis) are linked to changes in the coding regions of genes. More subtle influences of the genotype on disease involve polymorphisms in the noncoding regulatory regions of the disease gene that do not affect the structure of the protein, but the mechanism and level of its expression. This lends special importance to Chapter 6, which addresses bioinformatics methods for analyzing these regions. The author of the chapter has led the development of a widely used set of software tools for analyzing regulatory regions in genomes. The analysis of regulatory regions ventures into the more difficult to analyze noncoding regions of genes. However, the really dark turf of the human genome is presented by the long and mysterious repetitive sections. Up to 40% of the human genome is covered with these regions whose relevance (or irrelevance?) is under hot debate, especially since some of these regions seem to harbor potential silenced retroviral genes that may become active again at some suitable or unsuitable time. The identification of these regions (although not the elucidation of their function) is discussed in Chapter 7. The authors of this chapter have made seminal contributions and provided widely used software for computational gene finding, genome alignment and repeat finding. Chapter 8, finally, discussed the algorithmic and statistical basis of analyzing major genome reorganizations that happened as the kingdoms of life evolved, and that include splitting, fusing, mixing and reshuffling at a chromosomal level. Again, we are just beginning to understand the evolutionary role of these transactions. The author of this chapter has provided important contributions to the methodical and biological side of the field, many of them together with David Sankoff and Pavel Pevzner.

Part 4 of the book is on molecular structure prediction and comprises Chapters 9–15. The part starts with a chapter on a half-way approach to protein structure prediction which only aims at identifying the regions of secondary structure of the protein (α-helices and β-strands) and related variants. The resulting information on protein structure is very important in its own right and, in addition, helps guide or verify tertiary structure prediction. The authors of the chapter have made seminal contributions to protein structure prediction starting in the early 1990s that increased the prediction accuracy significantly (from around 65 to well over 70%).

The most promising approach to identifying the fold of a protein, today, selects a template protein from a database of structurally resolved proteins and models the structure of the protein under investigation (the target protein) after that of the template protein with sequence alignment methods. If the sequence similarity between the template and the target is high enough (roughly 40% or larger), then this alignment can even serve as a scaffold for providing a full-atom model of the protein structure. The respective structure prediction method is called homology-based modeling and is described in Chapter 10.

The author of this chapter has developed one of the most advanced homology-based structure prediction tools to date. If the sequence similarity between the template and target is below 40% then generating full-atom models for the target using the template structure becomes increasingly difficult and risky. In such low-sequence-similarity ranges aligning the backbone of the target protein to that of the template protein becomes the critical issue. If this is done correctly, one obtains a 3-D model of target backbone that can serve as an aid for structural classification of the target protein. Chapter 11 describes this process. The author of Chapter 11 has codeveloped a well-performing Internet server for this structural alignment task.

Homology-based modeling can only rediscover protein structures since it models the target on the basis of a known template structure. In *de novo* structure prediction, we try to come up with the structure of the protein, even if it is novel and has never been seen before. This subject is still a major challenge for the field of computational biology, but significant advances have been made in the past 10 years by David Baker's group (University of Washington, Seattle, WA) and the author of the chapter was one of the major contributors in this context. Today, there are several projects that aim at resolving protein structures globally, e.g. over whole proteomes. The approach is a combination of experimental structure resolution of a select set of proteins that promise to crystallize easily and fold into new structures, and homology-modeling other proteins using the thus increased template set. Chapter 13 describes these structural genomics projects. One author of the chapter codirects the Protein Data Bank (the main repository for publicly available proteins structures) and the other directs a major structural genomics initiative.

The last two chapters discuss structure prediction of another important macromolecule in biology – RNA. In contrast to DNA, which basically folds into a double-helical structure, RNA is structurally diverse. There is a well-understood notion of secondary structure in RNA, i.e. the scaffold that is formed by base pairs within the same RNA chain. This algorithmically and biologically well-developed field is presented in Chapter 14. The authors of the chapter have contributed a major software package for analyzing RNA secondary structures. The last chapter in this part looks at tertiary structure prediction for RNA, a comparatively much less mature field, and its author is one of the major experts in that field, worldwide.

Volume 2 covers Parts 5–7. Based on the knowledge about molecular building blocks afforded by Volume 1, Volume 2 ventures into questions of molecular function.

Part 5 starts by considering atomic events in molecular networks, i.e. the interactions between pair of molecules. Molecular interactions are important in two ways. First, understanding which molecules bind in an organism, when and how, is fundamental for understanding of the dynamic basis of life.

Second, as we have seen in the first parts of this chapter, modifying molecular interactions in the body with drugs is the main tool for pharmaceutical therapy of diseases. Drugs bind to target proteins. Understanding the interactions between a drug and its target protein is a prerequisite for rational and effective drug therapy. Part 5 addresses both these questions. The part comprises four chapters. Chapter 16 discusses protein–ligand docking, with the implicit understanding that the ligands of interest are mostly drugs or drug candidates. The chapter discusses how to computationally dock known ligands into structurally resolved protein-binding sites and also how to computationally assemble new ligands inside the binding site of a protein. The senior author is the developer of one of the most widely used protein–ligand docking tools, worldwide. Chapter 17 discusses molecular docking if both docking partners are proteins. This problem is of lower pharmaceutical relevance, as most drugs are small molecules and not proteins, but of high medical relevance, as the basis of a disease can often be an aberration of protein–protein binding events. Furthermore, the chapter also discusses protein–DNA docking, which is at the heart of gene regulation. (Here, the protein is a transcription factor binding to its site along the regulatory region of a gene, for instance.) The authors of this chapter have developed advanced software for protein–protein docking. The last two chapters in this part discuss problems in finding drugs. As described above, the drug design process is decomposed into a first step, in which a lead structure is sought, and a second step, in which the lead is optimized with respect to secondary drug properties. If the binding site of the target protein is resolved structurally, lead finding can be done by docking (Chapter 16). Otherwise, one takes a molecule that is known to bind to the binding site of the target protein as a reference and searches for similar molecules as drug candidates. Here, the notion of similarity must be defined suitably such that similar molecules have similar characteristics in binding to the target protein. Chapter 18 discusses this type of drug screening. Finally, Chapter 19 addresses the optimization of drug leads. The authors of Chapter 19 are from the pharmaceutical industry. They are experts in applying and advancing methods for drug optimization in the pharmaceutical context.

Part 5 has advanced considerably beyond fundamental research questions and into pharmaceutical practice.

In *Part 6* we take a step back towards fundamental research. This part discusses the biochemical circuitry that is composed of the kind of molecular interactions that were the subject of Part 5. Understanding these molecular networks is clearly the hallmark of understanding life's processes, in general, and diseases and their therapies, in particular. However, the understanding of molecular networks is in its infancy, and is not advanced enough, in general, to be directly applicable to pharmaceutical and medical practice. Still, the vision is to advance along this line and the four chapters in this part present various aspects of this process. Chapter 20 is on metabolic networks, the kind discussed in a little more detail in the beginning of this chapter. Metabolic networks are quite homogeneous with respect to the roles of the participating molecules. In general, we have a substrate that is converted to a product by a chemical reaction that is catalyzed by an enzyme, possibly with the aid of a cofactor. This homogeneity makes metabolic networks especially amenable to theoretical analysis. In addition, much is known about the topology (connection structure) of metabolic networks. However, we are still lacking much of the kinetic data needed to accurately simulate the dynamics of metabolic networks. The chapter presents methods for analyzing networks both statically and dynamically. The authors are among the main methodical contributors to the analysis of metabolic networks, worldwide. Chapter 21 analyzes gene regulation networks. These networks are more heterogeneous, since they incorporate different kinds of interactions – direct interactions, as when transcription factors bind to the regulatory regions of genes, and indirect interactions, as when transcription factors regulate the expression of genes that code for other transcription factors. Furthermore, proteins, as well as DNA and RNA, are involved in gene regulation. Inferring gene regulation networks necessitates much genomic information which is just on the verge of becoming available and, thus, the field is less mature than the area of analyzing metabolic networks. The author of Chapter 21 is one of the prime experts in the field of analyzing gene regulation networks. A very special type of molecular networks is concerned with transmission of information inside the cell. Usually, these signaling networks can be analyzed in terms of smaller modules than regulatory or metabolic networks. The special methods for analyzing these networks are presented in Chapter 22 by a group of outstanding experts in the field. Chapter 23 finally moves beyond the single cell and discusses interactions between a viral pathogen and its infected host cell – a major step from basic research to its application in a medical setting. This is a very young field and the author is one of its main proponents.

Part 7 is focused on a special types of experimental data that form the basis of much research (and debate) today – expression data. We have discussed the microarray (mRNA) expression data in the chapter above, when we addressed the quest of finding new target proteins for drug therapy. Expression data were the first chance to venture beyond the genome, which is the same in all cells of an organism, and analyze the differences between different cells, tissues and cell states. Therefore, these data have a special relevance for advancing molecular medicine and this justifies dedicating a separate part of the book with five chapters to them. Chapter 24 gives a summary of the whole field, from the experimental side of the technology of measuring mRNA expression and its implications on computational analysis methods to the bioinformatics methods themselves. Since expression data are typically quite noisy, with many sources of variance residing both in the technology (which can be improved, in principle) and the underlying biology (which can and should not be changed), issues of quality control of the data play a prominent role in this chapter. The author is a global expert in the field of analysis of expression data. The following four chapters go into more detail on computational issues. Chapter 25 presents statistical methods for pretreating the data so as to arrive at an optimally interpretable dataset and it is written by a leading group of researchers in the area. The following two chapters discuss two fundamentally different kinds of analysis of mRNA expression data. Chapter 26 discusses methods that analyze and group different datasets (microarrays), generated under different circumstances (e.g. from different patients or from the same patient at different time points). Such methods afford the distinction of healthy from sick individuals as well as the analysis of disease type and disease progression, thus providing effective help in disease diagnosis. Chapter 27 groups data differently. Here, we are not interested in distinguishing different experiments, but in understanding the roles of (groups of) genes in, say, the progression of a disease that has been monitored with a sequence of microarray experiments. The results of the analysis are supposed to afford insight into the disease process and clues for drug therapy. This is a much harder task than just grouping microarray datasets and it has turned out that it cannot be solved, in general, just on the basis of expression data. Therefore, this chapter also prepares for later chapters that discuss the analysis of gene and protein function in a more general context (Part 8). The authors of Chapters 26 and 27 participate in a joint German national project that aims both at advancing the methods, and at applying them to biological and medical datasets. mRNA expression data (so-called transcriptomics data, because the data assess the expression level of mRNA transcripts of genes) have the advantage of being generated comparatively easily, due to the homogeneous structure of DNA (to which the mRNA is backtranscribed before measuring expression levels). However, these data correlate only weakly with the expression level of the actual functional unit, i.e. the synthesized and post-translationally modified protein. Measuring expression directly at the protein level is a more direct approach, but experimentally significantly more challenging. Therefore, the state of the field of proteomics, which analyzes protein expression directly, is behind that of transcriptomics, as far the experimental side is concerned. Nevertheless, proteomics is rapidly emerging, with several promising experimental technologies and the respective computational methods for data assembly/analysis. Chapter 28 presents the state of this field. It is written by a leading academic group engaged in software development for the field of proteomics.

Volume 3 builds on Volumes 1 and 2, and aims at embarking along an integrated picture of molecular function, and its consequences for the development and administration of drug therapies. The volume covers Parts 8–11.

Part 8 comprises eight chapters and is devoted to molecular (mostly protein) function. We have has already addressed aspects of molecular function (e.g. the chapters on molecular interactions and molecular networks, as well as the chapters on expression data), and, along the way, it has become increasingly evident that molecular function is a colorful term that has many aspects and whose elucidation relies on many different kinds of experimental data. In fact, molecular function is such an elusive notion that we dedicate a special chapter to discussing exactly this term, and the way it is and should be coded in the computer, respectively. This Chapter 29 is written by two authors that are main proponents of advancing the state of ontologies for molecular biology. Then we dedicate four chapters to inferring information on protein function from different kinds of data: sequence data (Chapter 30), protein interaction data that are based on special experimental technologies that can measure whether proteins bind to each other or not, and do so proteome-wide, in the most advanced instances (Chapter 31), genomic context data, affording an analysis based on the comparison of genomes of many species (Chapter 32), and molecular structure data (Chapter 33). Since all of these data still do not cover protein function adequately, we add another chapter that addresses methods for inferring aspects of protein function directly from free text in the scientific literature (Chapter 34). Chapter 35 presents methods for fusing all the various kinds of information gathered by the methods presented in the preceding chapters to arrive at a balanced account of the available knowledge on the function of a given protein. Finally, Chapter 36 discusses the druggability of targets, i.e. the adequacy of proteins to serve as a target for drug design. This quality encompasses properties such as a suitable shape of the binding pocket to suit typical drug molecules and a certain uniqueness of the shape of the binding pocket, such that drugs that bind to this pocket avoid binding to other proteins that are not targets for the drug. Again, all of these chapters are written by outstanding proponents of the respective fields.

With Parts 1–8 we have covered the space from the genotype (the genome sequence) to the phenotype (the molecular function). However, we can still take additional steps to making all of this knowledge work in applied medical settings. This is the topic of *Part 9*. To this end, Part 9 focuses on the analysis of relationships and differences between genomes. In the first chapter, Chapter 37, the topic is rolled up in a general fashion by asking the question: "What can we learn from analyzing the differences between genomes?". Then, we focus on the medically most relevant differences between genomes of individuals of the same species. Specifically, we are interested in the human and in pathogens infecting the human. Chapter 38 discusses what we can learn from genetic differences between people about disease susceptibility. Chapter 39 then addresses the topic of personalized medicine: how can we learn from suitable molecular and clinical data how a patient reacts to a given drug treatment? The final two chapters address the evolution of pathogens in the human host (mostly to become resistant against the host's immune system and drug treatment). Chapter 40 discusses viral pathogens, specifically HIV, the virus that leads to AIDS. Chapter 41 covers the bacterial world. The authors of all chapters have made seminal contributions to the topic they are describing.

Part 10 is an accompanying section of the book that addresses important informatics technologies that drive the field of computational biology and bioinformatics. There are three chapters. Chapter 42 is on data handling. Chapter 43 discusses visualization of bioinformatics data; here, molecular structures are not the center of the discussion, since their visualization is in a quite mature state, but we focus on microscopic images data, molecular networks and statistical bioinformatics data. Chapter 44 focuses on acquiring the necessary computational power for performing the analysis from computer networks (intranets and the Internet). There is a special research community that provides the progress in the underlying informatics technologies and the authors of these chapters are outstanding proponents of this community.

In *Part 11*, finally, Chapter 45 addresses in a cursory manner emerging trends in the field that were too new at the time of the conceptualization of the book to receive full chapters, but have turned out to become relevant issue at the time that the book was written. Thus, this chapter gives a cautious and anecdotal look into the future of the field of bioinformatics.

The goal of this book is to provide an integrated and coherent account of the available and foreseeable computational support for the molecular analysis of diseases and their therapies. The authors that have contributed to the book represent the leading edge of research in the field. We hope that the book serves to further the understanding and application of bioinformatics methods in the fields of pharmaceutics and molecular medicine.

Part 2 Sequencing Genomes

2
Bioinformatics Support for Genome-Sequencing Projects

Knut Reinert, Daniel Huson

1 Introduction

Even though the landscape of molecular data in biology has diversified significantly in the past decade, DNA sequence data still remain the principle basis of data collection and contribute to most bioinformatics analyses. Also, the field of bioinformatics was propelled to its current magnitude mostly by the rapid development in DNA-sequencing technology. Since experimental technology only allows the reading of short stretches of DNA, encompassing just a few hundred basepairs, the assembly of these pieces into contiguous chromosomes is still a major computational challenge.

In this chapter we first describe current assembly strategies for large genomes in Section 2. We then present some of the main algorithm problems and their treatment in Section 3 and give an overview of existing assemblers in Section 4.

2 Assembly Strategies for Large Genomes

2.1 Introduction

Humans have always been fascinated by the "secret of life", i.e. the question of how new organisms come into existence, how they develop from "nothing"? What is and where is the "blueprint", the set of instructions that determines the genesis of an animal or plant? In the course of the last century, science has begun to unravel parts of the puzzle. We know now that the instructions to build a complex organism are contained in each of its cells, encoded by a

ISBN: 978-3-527-31278-8

simple, yet fascinating mechanism. In 1928, Frederick Griffith, and, later, in 1944, Oswald Avery and coworkers pointed out that DNA (consisting of four very simple biochemical building blocks named adenine, cytosine, guanine and thymine) plays a vital role in heredity. In 1953, Francis Crick and James Watson discovered the double-helix structure of DNA which suggested that a simple linear sequence of nucleic acids gives rise to an intricate code for describing the blueprint of life. It was not until 1961 that researchers revealed the *genetic code* that employs codons, nonoverlapping triplets of nucleotides, to form a redundant code for the 20 amino acids that are the basic building blocks of proteins.

For a long time it was unthinkable to determine the actual sequence of nucleotides of a DNA molecule, i.e. to *sequence* a fragment of DNA. In the 1970s, a number of different approaches to sequencing DNA were pursued, and the method developed by Fred Sanger and his group prevailed. This method and other advances in biotechnology led to the sequencing of the 49kb-bacteriophage λ genome in 1982. For this work Fred Sanger was awarded the Nobel prize in chemistry in 1980, together with Walter Gilbert and Paul Berg. In the late 1980s, the question arose whether to attempt to determine the sequence of the human genome [42,48], a formidable technological challenge, given the huge size of the genome of approximately 3 billion base pairs. As a consequence, the Human Genome Project (HGP) [30] was established in 1990 to tackle the problem, armed with with a 15-year plan and a budget of approximately US$ 3 billion.

A major milestone in genome sequencing was achieved in 1995, when the 1.8-Mb genome of *Haemophilus influenza* was completed [14]. This was followed by the sequencing of other genomes, among them most notably that of yeast [35]. A main scientific issue in the 1990s was whether large eukaryotic genomes could be sequenced using a global "whole-genome shotgun assembly" (WGS) approach or whether such genomes needed to be broken down into smaller pieces and each piece sequenced separately. The assembly of the genome of the fruit fly (*Drosophila melanogaster*) in 2000 [38], of the human (*Homo sapiens*) in 2001 [54] and of the mouse (*Mus musculus*) in 2002 [37] demonstrated that the WGS approach is indeed feasible, and WGS has now become the leading paradigm.

The sequence of the human genome is of immense medical and biological importance. Significant advances in sequencing technology (in particular, the invention of the capillary gel sequencer), the availability of sufficient computational power and storage technology, and the existence of an appropriate algorithmic approach [56] inspired the founding of a private company, Celera Genomics, in 1998 with the stated goal of sequencing the human genome at a low cost and within a very short time.

sequence both ends of clone inserts
fragments and mate pairs

Figure 1 Experimental protocol of paired-end shotgun sequencing.

This sparked off intense competition to produce a first assembly of the sequence of the human genome as quickly as possible, which led to the publication of two papers in February 2001 that both describe a draft sequence of the human genome [25,54].

All major sequencing projects are based on the same experimental technique, called *shotgun sequencing*. This technique is based on automated gel sequencers that use electrophoresis and fluorescent markers to determine the sequence of the nucleotides. The ability of these machines to read consecutive pieces of DNA degrades quickly with the length of the sequence and today a sequencing machine can read up to around 1000 consecutive base pairs of a fragment of DNA, depending on the degree of accuracy required. The sequence of a fragment determined in this way is called a *read*. The fragments are sampled from a stretch of DNA that is often referred to as the *source* sequence (the sequence that we take the fragment from) or as the *target* sequence (the sequence we want to reconstruct from the reads).

To determine the content of a long source sequence, one produces many copies of the source sequence (e.g. through cloning or growing colonies from a single progenitor) and then randomly breaks them into smaller pieces. Pieces of a given length are selected and one or both ends of such pieces are read by the automated sequencers. If both ends are read one does not only obtain the sequence at both ends of the piece of DNA, but also information about the relative orientation and distance of the two reads. This variant of shotgun sequencing was named *paired-end* shotgun sequencing by Myers and Weber [56], who also were the first to recognize the importance of collecting paired-end reads for sequence assembly. A pair of reads with associated distance information is called a *mate-pair*. Note that not all reads are in mate-pairs since the sequencing of one of the two mates can fail (see Figure 1 for an illustration

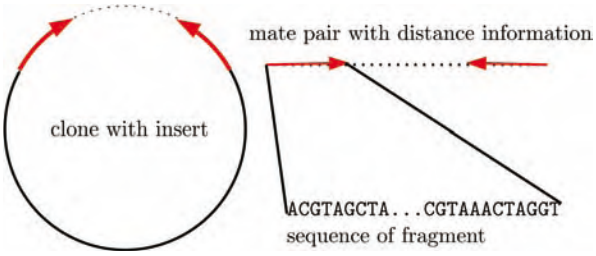

Figure 2 Fragments and mate-pairs.

of the shotgun sequencing process and Figure 2 for a more detailed illustration of a mate-pair).

The read and mate-pair information together with quality estimates of the data is fed into a computer program called an *assembler* that will attempt to reconstruct the original DNA source sequence. Note that there is no information on the location of any given read in the source sequence. However, by construction, many of the reads will come from overlapping regions of the source sequence and the first step in sequence assembly is to search for overlap alignments of high similarity between different reads. The pattern of overlaps between reads can be used to string together longer pieces of contiguous sequence, called *contigs*. The mate-pair information can then be used to order and orient sets of contigs with respect to each other, thus producing scaffolds. This process is called *sequence assembly*, and the resulting set of contigs and scaffolds is called an *assembly*. See Figure 3 for an illustration of the process.

Obviously, the large size of genomes makes sequence assembly a very difficult computational problem. Moreover, there are a number of additional difficulties. The read and mate-pair data contain errors and since DNA is a

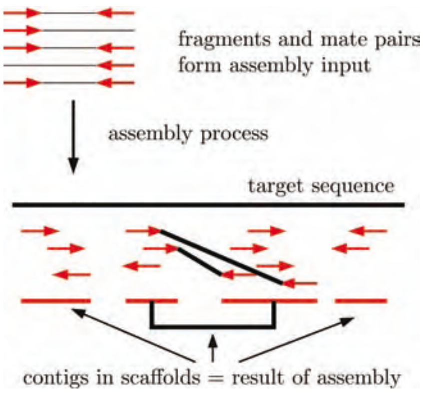

Figure 3 Pair-end reads are assembled into contigs based on how the reads overlap with each other. The contigs are then organized into scaffolds using the mate-pair information.

double-stranded molecule we do not know which strand a read is from. Also, a read may be chimeric, i.e. it may be the result of a fusion of two different pieces from different parts of the source sequence. Another problem is caused by polymorphism. If reads are taken from genomes of different individuals of the same species, they usually differ, in the case of humans at a rate of about 1 in 1000 bp. Even single organisms can be diploid or polyploid (i.e. they contain more than one copy of the same chromosome). Hence, if the data is acquired from different individuals that are not inbred, one must deal with a mixture of reads that come from seemingly different genomes. The largest difficulty is due to the fact that DNA sequences contain many different repeats of different size and fidelity. The detection and analysis of repeats is discussed in Chapter 7.

2.2 Properties of the Data

In this section we discuss some of the properties and error rates of the data generated in large genome-sequencing projects.

2.2.1 Reads, Mate-pairs and Quality Values

Sequencing large genomes is expensive, and over the past 10 years there has been a strong focus on developing faster, cheaper and more accurate ways of determining the sequence of DNA molecules. This includes substantial improvements in methods for DNA shearing, plaque and colony pickers, DNA template preparation systems, and, above of all, huge improvements in the throughput and data quality of automated sequencers (for a review, see Refs. [33,34]).

Most of the modern sequencers employ different fluorescent markers to distinguish between the four types of nucleotides. After a prefix of the fragment has left the sequencer, the marker attached to the last base of the prefix is excited by a laser and the resulting signal is measured. This analog measurement is converted into a digital base call. Each base determined in this way is assigned a quality value, given by $q = -10 \cdot \log_{10}(p)$, where p is the estimated error probability for the base [13]. For example, a quality value of 10 corresponds to an error rate of 1 in 10, whereas a quality value of 30 corresponds to an error rate of 1 in 1000. The value q is usually encoded in a single character that is stored together with the base character. Due to the nature of the sequencing process, it is clear that the distribution of the quality values is not uniform over the length of a read. The middle part usually has the best quality, whereas the quality drops at both ends of a read [12,13].

Older sequencers were slab-based and parallel sequencing lanes on an agarose gel were often mis-tracked, thereby generating incorrect mate-pairs. Modern capillary-based sequencers have eliminated this problem, but even with these machines human error (rotating or mislabeling of sequencing plates) can result in a wrong association of mate-pairs, leading to chimeric mate-pairs of unrelated reads. The error rate for mis-association of mate-pairs used to be about 10% for the older slab-based sequencers, but is now about 1%. Still, most assembly algorithms insist on the presence of more than one mate-pair to infer the relative ordering of two contigs.

In order to generate many copies of a fragment before sequencing, cloning vectors such as plasmids are used. The fragment is incorporated into the cloning vector and a sufficient number of copies is extracted after cloning.

A *spur read* is a read that aligns only partially to other reads from the same region of the source sequence. Spur reads can be the result of chimeric fragments that are obtained when two unrelated fragments fuse together during the creation of a clone library. They may also arise when fragments are contaminated with DNA from the linker or cloning vector.

To address these problems, the reads and mate-pairs obtained in the shotgun sequencing process are subjected to preprocessing steps that try to detect and remove most of the mentioned artifacts. For example, in a process called *vector and quality trimming* all reads are computationally inspected for pieces of the cloning vector genome and any traces of cloning vector sequence are removed. In addition, the quality values can be used to compute the expected number of errors in a window of the read. Any region (usually at the beginning or end of a read) for which this number is too high is then discarded. Such preprocessing steps will remove many of the artifacts, but not all. Hence, an assembly algorithm has to be able to cope with these problems to some degree.

2.2.2 **Physical Maps**

A physical map (see Ref. [47] for a description of the physical map used in the assembly of the human genome) of a genome G is given by the physical location of certain markers along G. The markers are used for navigation and can also be used for anchoring an assembly at its genomic coordinates. If parts of the target sequence are stored in clone libraries, then the correct order of the markers can be used to infer the order of the clones.

One can distinguish between two different families of methods for constructing a physical map [44]:

(i) *Restriction mapping.* Here one uses restriction enzymes to digest the DNA and then uses the lengths of the restriction fragments to reconstruct the positions of the restriction sites along the sequence. However, this technique works only for quite short genomic pieces.

(ii) *Fingerprint mapping.* Here we have a set of overlapping clones that we want to order based on common fingerprints. Therefore, one needs a set of clones that covers the target sequence redundantly. To determine which pairs of clones overlap with each other, we compute a fingerprint for each clone in such a way that overlapping clones have very similar fingerprints. The overlap information is used to order both the markers and the clones.

Fingerprints can be derived in a number of ways. One approach is to digest the DNA with a suitable restriction enzyme (e.g. *Hin*dIII was used in Ref. [25]) and use the restriction fragment sizes as a fingerprint. Alternatively, a whole restriction map of a clone can be used as a fingerprint.

Another way to obtain fingerprints is to use *STS* markers, which are short (200–500 bp) DNA sequences that occur exactly once in the given genome and are detectable by polymerase chain reaction (PCR). A number of other entities can also be used as markers. An EST is an *expressed sequence tag* that is derived from a cDNA [32]. It can be detected via a hybridization experiment or by PCR. The point is that one needs reliable, (essentially) unique markers, the presence of which is easily tested for. The assumption is that two clones overlap if they share a common set of markers.

Since the process of obtaining the fingerprints is error prone, it is very difficult to obtain a complete and accurate physical map of an entire genome. Physical maps are believed to have a high error rate of 10–20% [11] which makes the construction of a (correct) minimum tiling path a daunting task.

2.3 Assembly strategies

Given their higher complexity and larger size, it is not surprising that eukaryotic genomes are much more difficult to assemble than prokaryotic genomes. The assembly of a prokaryotic genome has become a routine task, whereas the assembly of a eukaryotic genome remains difficult. In the large sequencing projects of the last decade two different strategies were employed to determine the sequence of large eukaryotic genomes, i.e. the clone-by-clone (CBC) approach, which was used by the HGP to produce their assembly of the human genome [25], and the WGS approach, which was originally applied only to small genomes and was extended to large eukaryotic genomes by researchers at Celera Genomics [38, 54].

Both approaches are based on shotgun sequencing technology, but differ in an essential preparatory step. In the CBC approach, the target sequence is broken up into a redundant collection of overlapping pieces of an easily manageable size of approximately 100–150 kb. DNA molecules of this size can be incorporated into a vector such as a BAC and they are often referred to as *bacterial artificial chromosome (BAC)* clones. The problem of determining the sequence of a BAC clone is easily solved by using shotgun sequencing and subsequent assembly. For the human genome this step reduces the problem of assembling 3 Gb to approximately 40 000 small assembly problems, each of size around 100–150 kb. This is done with the help of available physical maps and computer programs [8,29].

The CBC approach has a number of advantages. Each individual assembly problem is easily solved, since the data sets are small and contain only local repeats. In a joint effort, work can be distributed by assigning different clones to different institutions for sequencing and assembly. The assembly itself is easier and can often be done without mate-pair information. However, during the course of the HGP it became evident that these advantages come at a high price. First, the physical maps used to place the location of assembled BAC clones are incomplete and have very high error rates. Second, since overlaps of the BACs are required to determine their order, there is a certain amount of redundant sequencing necessary, which results in higher costs. Third, one needs to construct many individual libraries of sequences for both the individual BAC clones and all their fragments. This allows the introduction of many artifacts; in particular, the creation of chimeric BAC clones. Fourth, it turned out that for the final assembly mate-pairs are necessary to improve the local ordering of contigs (see also description of current assemblers in Section 4). Finally, the assignment of sequencing a subset of the clones to different institutions using different protocols and standards leads to data of uneven quality.

The WGS approach is very bold. Rather than reducing the genome assembly problem to a large set of small BAC clone assembly problems, in this approach the shotgun strategy is applied to the whole genome. This method has essentially the opposite advantages and disadvantages of the CBC approach. The computational problem of assembling the reads is by no means trivial, requiring sophisticated algorithms, sufficient mate-pair information in the input and substantial computational resources. In particular, the assembler software has to cope with the full set of repetitive elements. However, the problem of mapping the resulting contigs and scaffolds to the genomic axis is not significantly more difficult than in the CBC approach. WGS data is much less effected by uneven sampling. The main advantage of this approach is that it is far easier to automate. Only very few libraries need to be created and sequenced, and all sequenced data is processed in a single computation, usually in an incremental fashion.

There was much debate over whether the WGS approach could possibly work for large eukaryotic genomes [17, 56]. However, the feasibility of the WGS approach in conjunction with paired-end reads as input was demonstrated by the assemblies of *D. melanogaster* [38], *H. sapiens* [54] and *M. musculus* [4, 26, 37]. WGS is now the predominant approach, and most current assembly programs are based on it (see Table 1 for an overview).

3 Algorithmic Problems and their Treatment

The sequence assembly problem is to reconstruct the sequence of a target DNA molecule from read and mate-pair information, in the presence of errors and repeats. The simplest mathematical formulation of this problem is the “shortest common super-string” (SCS) problem. Given a set of strings as input, the task is to find string s that contains all input strings as substrings and is shortest among all such super-strings.

Although this formulation is an extreme simplification of the sequencing problem, it is known to be NP-hard [15] and thus is believed to be impossible to solve optimally for large instances. A more sophisticated approach is to cast the problem as a maximum-likelihood problem [41], but this has not led to a deterministic approximation algorithm.

Current assemblers were developed using an engineering approach and are not designed to optimize some explicitly stated mathematical objective function. In this section we will discuss the fundamental tasks that any assembler program must address and we will outline some of the algorithmic approaches that are employed. The process of sequence assembly must address the following fundamental tasks:

(i) *Computation of overlaps in the presence of repeats.* To determine the layout of the reads on the genomic axis each assembly algorithm is based on the fact that the sequencing is redundant, in the sense that any given position in the sequence is covered by an average of x reads, where x is usually between 3 and 12. The value of x is called the *x-coverage*. Reads that were sampled from overlapping locations in the source sequence will exhibit a high scoring overlap alignment. The goal here is to determine which pairs of reads overlap. Unfortunately, reads may also exhibit a high-scoring overlap alignment if they stem from different instances of a repeat in the source sequence.

(ii) *Layout of reads.* Based on the overlap information, a second fundamental task is to determine a layout of the reads that overlap in a consistent way. This amounts to reconstructing nonrepetitive parts of the target sequence.

(iii) *Error correction and repeat resolution.* The goal here is to distinguish between sequencing errors and differences induced by the micro-heterogeneity of different instances of a repeat, and to attempt to reconstruct parts of the repetitive sequence.

(iv) *Layout of contigs using mate-pairs.* The goal here is to use mate-pair information to order and orient contigs relative to each other.

(v) *Computation the consensus sequence.* Finally, the sequence of each contig in the assembly must be determined.

In the following sections we will discuss the main methods for solving these tasks.

3.1 Overlap Comparison of all Reads

The input to an assembly program (or "assembler") is a set $F = \{f_1, \ldots, f_r\}$ of reads, together with mate-pair information and quality values. In order to assemble a set of reads, the assembler must be able to decide whether or not two reads f_i and f_j were sampled from overlapping locations in the source sequence.

Conceptually, this can be done by computing an overlap alignment between each pair of reads or their reverse complements. The detection of an overlap does not necessarily imply adjacency in the target sequence, since an overlap can be *repeat-induced*. In Figure 4 the regions marked R_1 and R_2 indicate two instances of the same repeat with near identical sequences. Hence, reads f_k and f_l form a repeat-induced overlap, whereas reads f_i and f_j form a *true* overlap.

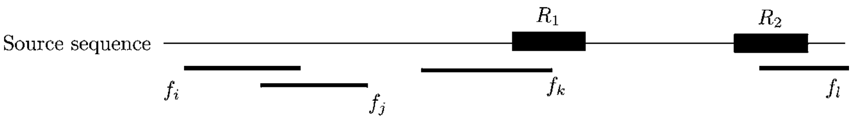

Figure 4 Reads that form true and repeat-induced overlaps. R_1 and R_2 indicate two instances of a repeat.

In a naive approach, one would require $O(r^2)$ sequence comparisons to determine all fragment overlaps. This is not feasible for large genomes where $r \approx$ 30–50 million. Since most reads do not actually overlap, this computational expense seems unnecessary. In fact, one can quickly reduce the number of required overlap computations to $O(r)$, by using the "seed-and-extend-and-refine" paradigm. All current assemblers use some version of this idea (Figure 5):

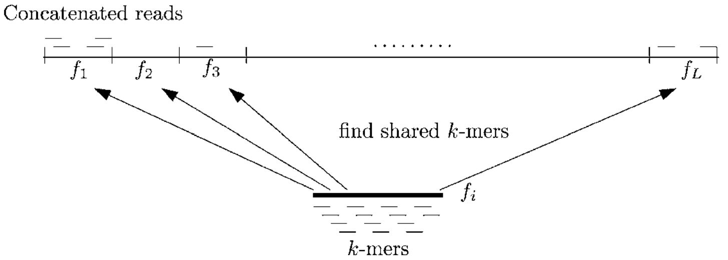

Figure 5 Overlap alignment of reads.

(i) Build a k-mer index H for all reads. This index maps any "k-mer" w (a word of length k) to the set of all occurrences of w in the reads. The value of k should be large enough such that in a random sequence of the same length as the target sequence, the expected number of k-mers is small. In contrast, k should not be too large so as to miss true overlaps due to sequencing errors. This index has two main applications:

   (a) If a pair of reads f_i and f_j do not share at least one k-mer (more sophisticated methods may have more complex requirements), they cannot possibly have a high fidelity overlap alignment and we need not attempt to compute one. If f_i and f_j contain one or more identical k-mers, these k-mers are referred to as *seeds* and the reads are candidates for an *extension*, which entails a more sophisticated and costly overlap computation (see Figure 5).

   (b) If a k-mer w appears significantly more often in the genome than expected, it probably lies in a repeat region of the genome. In this case, to avoid the computation of repeat-induced extensions, the k-mer is not used as a seed.

   A k-mer index can be computed in linear time and space. A first scan over all reads counts the number of k-mers. This allows us to efficiently allocate adjacent memory cells for all positions in the sequences that contain the same k-mer. In a second scan, the positions are written in the allocated positions (see, e.g. Refs. [5,45]).

(ii) The second phase is an extension phase, which makes use of the k-mers computed in the seed phase. Most ideas used here are very similar to BLAST [1,40]. Usually one combines two or more k-mer hits that are near to each other. Then the local alignment is extended in both directions until the quality of the extension starts to deteriorate. The result of this phase is a set of local alignments (they are depicted as longer black diagonals in Figure 6).

(iii) Finally, most algorithms end this stage by refining a set of local alignments with a fast version of the global Needleman–Wunsch algorithm. This can be done by using the shared k-mer information in a number of ways. (i) One can obtain a bound on the quality of the alignment and use it to compute a banded alignment [7]. (ii) One can compute an alignment allowing only k mismatches [6, 39, 40]. (iii) One can use the position of the shared k-mers and compute a chain of the local alignments from the extension phase together with smaller local alignments between their ends (see Figure 6 for an illustration).

The described "overlap" phase of assembly produces a collection of pairwise overlaps between reads which predominantly consists of true positive

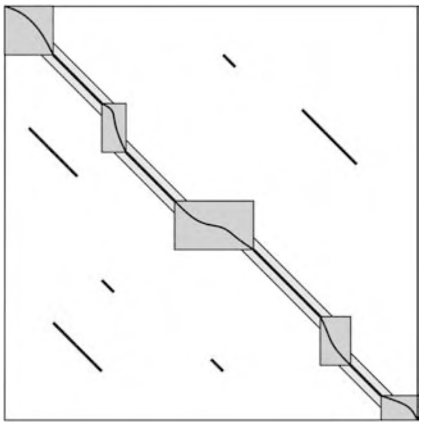

Figure 6 Seed, extend and refine paradigm. First, k-mer seeds being extended, then a banded alignment is computed that explores narrow bands around the extended seeds and, possibly, larger regions between them.

overlaps (Figure 7), i.e. overlaps that result from the fact that the involved reads stem from overlapping positions in the target sequence. However, there will be a number of false positives (repeat-induced overlaps) and false negatives (which may result from the seed-and-extend strategy missing an overlap due to sequencing errors). In Section 3.3 we will discuss how true and repeat-induced overlaps can be used to correct sequencing errors and to classify different repeat instances.

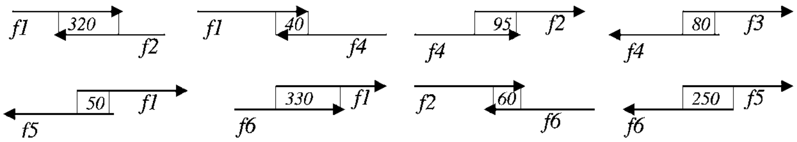

Figure 7 A collection of pairwise overlapping reads

We can view the collection of overlaps in terms of an edge-weighted, semi-directed graph, the *overlap graph* $OG(\mathcal{F})$ (Figure 8). There are two types of edges in this graph. A directed *read-edge* represents a read; the source and target nodes of the edge corresponding to the $5'$ and $3'$ ends of the read, respectively. The *weight* of a read-edge is simply the length of the corresponding read.

An *overlap-edge* represents an overlap between two reads and joins the two appropriate vertices contained in the corresponding read-edges. The weight of an overlap-edge is set to the negative length of the overlap. If the overlap corresponds to a gapped alignment of the ends of two reads, the amount of

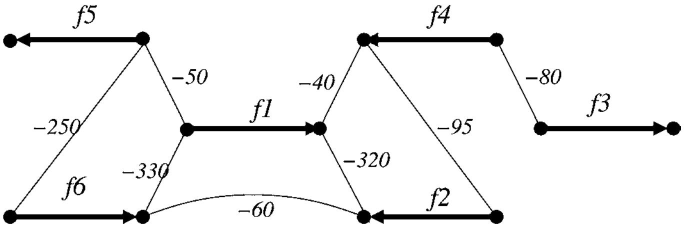

Figure 8 Overlap graph corresponding to the collection of overlaps in Figure 7. Read-edges are shown in bold.

overlap can be more accurately represented by a pair of numbers indicating the length of the two subsequences involved in the alignment.

3.2 Contig Phase: Layout of Reads

Ideally, in the absence of repeat-induced overlaps each connected component C of the overlap graph $OG(\mathcal{F})$ will correspond to a collection of reads sampled from the same local region of the target sequence. However, in practice, due to the abundance of long-range repeats, the overlap graph always consists of one huge, highly connected component.

The goal of the layout phase is to determine sets of reads that possess a consistent layout. Here, a *layout* is defined as an assignment of coordinates to all nodes of C that specify the start position s_i and the end position e_i of each read f_i in C. A layout is called *consistent* if every overlap-edge e is realized in the layout, which is the case when the coordinates assigned by the layout induce the corresponding overlap of the two appropriate reads. A layout is called *correct* if the relative positioning of the reads in the layout corresponds to their relative positioning in the source sequence. Any layout represents the reconstruction of a stretch of contiguous sequence in the target genome (a contig).

A read f_i is said to be *contained* in another read f_j if f_i is equal or highly similar to an internal portion of f_j or the reverse complement of f_j. Since contained reads contribute no additional overlap information, they are usually set aside in the layout phase of assembly. They are brought back into play later to contribute to the computation of arrival statistics and to the scaffolding of contigs using mate-pairs.

The problem of determining a minimal consistent layout of a set of overlapping reads is equivalent to the SCS. As the latter problem is known to be NP-hard [15], assemblers use heuristics to address the problem.

One widely used heuristics greedily "selects" a subset of overlap-edges S such that the union of S and the set of all read-edges F defines an alternating path of reads and overlaps that spans the set of read-edges. Initially, the edge

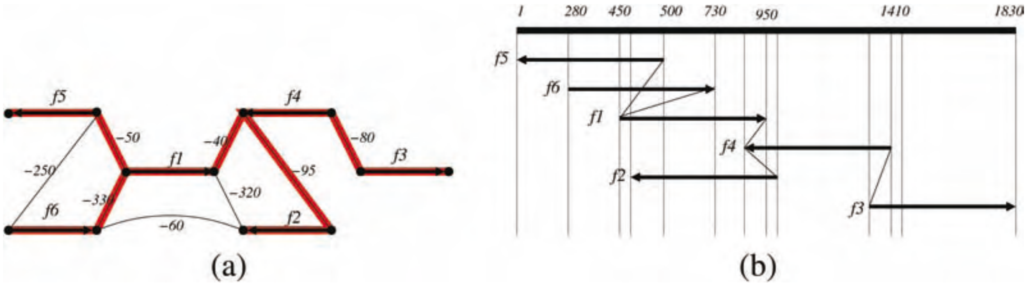

Figure 9 (a) An example of an overlap graph for six reads $\{f_1, \ldots, f_6\}$ that are as assumed to overlap as indicated in Figure 7. The edges of a maximal spanning tree are highlighted. (b) The layout of the reads is defined by the maximal spanning tree.

representing the longest overlap is selected. Then, all overlap-edges in the overlap graph are considered in ascending order of length of overlap. An overlap-edge e is selected if neither of the two nodes of e is already incident to a selected overlap edge.

Another simple heuristics for assigning the coordinates to a component C is to compute a *maximal spanning tree* that includes all read-edges, and maximizes the amount of overlap between reads (Figure 9).

In the presence of repeat-induced overlaps, any read that spans a repeat boundary may potentially overlap with reads from unrelated regions of the genome and thus bring them together in the same component C of the overlap graph. In this case, some of the overlap-edges in C will represent true overlaps, while others will represent repeat-induced overlaps. Both heuristics described above will fail to produce a correct layout whenever they utilize one or more repeat-induced overlap-edges.

As discussed before, many repeat-induced overlap-edges can be avoided in the overlap phase. To alleviate the problem further, one can attempt to distinguish between true overlaps and repeat-induced overlaps by taking a closer look at the overlap alignment. A number of mismatches in the alignment that is significantly higher than expected for the given level of sequencing error indicates that the two reads come from different instances of an inexact repeat, ideally taking the quality values into account.

Once a layout has been computed, a closer study of a multiple alignment of the reads in the layout may yield additional information, provided that sequencing errors will be randomly distributed, whereas repeat-induced discrepancies will occur in a correlated fashion. This is discussed in more detail below.

The most useful combinatorial insight is that if the reads contained in a connected component C of the overlap graph were recruited from different instances of a repeat and if some of the reads span the repeat boundaries, then

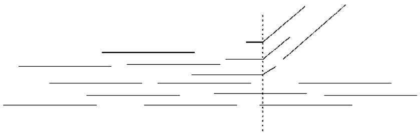

Figure 10 From left to right the reads overlap consistently until we reach the "branch point" at the position indicated by a dotted line. From this position onward, the data is partitioned into two incompatible chains of overlapping reads. Here, the reads on the left of the branch point lie in the interior of a repeat, whereas the reads that span the branch point overlap with a unique flanking sequence.

the latter reads will give rise to inconsistencies in the layout. That means, there will be overlap-edges in C that are not compatible with the overlaps induced by the layout. These incompatible overlaps will involve those reads that span repeat boundaries and a detailed analysis of the pattern of overlaps will uncover potential branch points in the layout (Figure 10).

A *branch point* is a position of a layout within a read at which a single consistent chain of overlapping reads possesses at least two different and mutually exclusive extensions. Whenever a branch point is detected, the adjacent overlaps are removed from the graph and, consequently, the connected component C is partitioned into smaller components, each giving rise to an individual contig.

As mentioned above, a consistent layout of reads defines a contig, which in this case is also called a *unitig* ("*uni*quelly assemble-able con*tig*"), as any given set of reads possesses at most one consistent layout.

Ideally, any unitig u computed in the layout phase will represent a unique stretch of the source sequence and will consist only of reads from that region. We refer to a unitig of this type as a *unique*-unitig or *U-unitig* (Figure 11). Alternatively, and in the absence of inconsistent overlaps, a unitig u may also represent a stretch of sequence that is repeated twice or more in the source sequence and may consist of reads collected from different instances of the repeat.

Methods for distinguishing between U-unitigs and non-unique unitigs make use of the sequencing coverage. For a given level of sequencing coverage, we can work out how many reads we expect to see in a unitig of a given length under the assumption that the unitig represents a unique stretch of the source sequence or that the unitig represents repetitive sequence, respectively.

In other words, a non-unique unitig can often be detected because it contains significantly more reads than expected. Let r be the number of reads and G be the estimated length of the source sequence. It can be shown [31] that for a unitig consisting of r reads and of approximate length ρ, the probability of

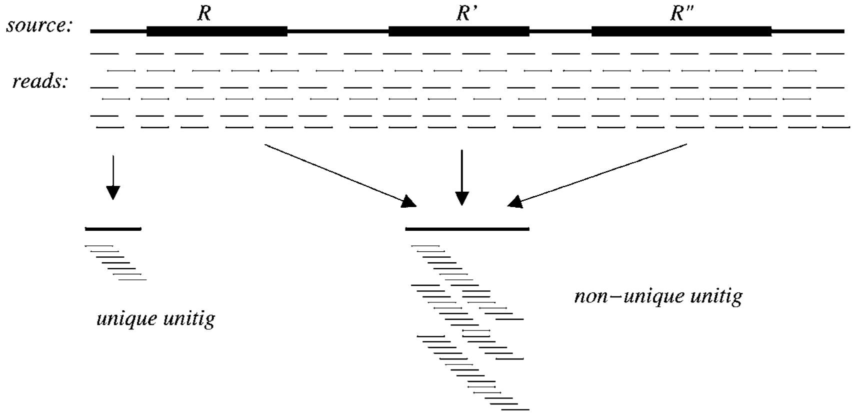

Figure 11 A unitig represents a chain of consistently overlapping reads. However, a unitig does not necessarily represent a segment of unique source sequence. For example, its fragments may come from the interior of the different instances of a long repeat, as shown here. R, R' and R'' represent three instances of the same repeat.

seeing $k-1$ start positions in an interval of length ρ is:

$$\frac{e^{-c}c^k}{k!},$$

with $c := \frac{\rho r}{G}$, if the unitig is not oversampled, and:

$$\frac{e^{-2c}(2c)^k}{k!},$$

if the unitig consists of reads recruited from two instances of a repeat. The *arrival statistic* is the log of the the ratio of these two probabilities:

$$c - (\log 2)k.$$

In practice, a unitig is considered to be unique if its arrival statistic is 10 or above, say.

3.3 Error Correction and Resolving Repeats

In the previous section we discussed how a layout of reads can be collapsed into a contig and how one can detect inconsistencies in the layout that indicate repeat boundaries or how arrival statistics can be used to classify contigs as repetitive.

In this section, we use similar techniques, but with a different goal. Branch-point detection only determines the boundary of a repetitive region to a unique region in the genome and an arrival statistic can merely point to problematic regions. Error correction and repeat resolution approaches take a closer look at the distributions of errors in the layout of a collection of reads and their main task is to determine whether a mismatch in a pairwise alignment is due to a sequencing error, a single nucleotide polymorphism (SNP) or a low copy repeat.

The errors in a repetitive contig and the errors in a nonrepetitive contig are differently distributed. In a nonrepetitive contig errors in overlaps can be explained by sequencing errors which should occur independently from each other in each read. In contrast to this, repetitive contigs by definition consist of reads that are from instances of a repeat from different genomic locations. Depending on the nature of a repeat, two instances differ from each other by a certain amount.

In order to be able to classify sequences as repetitive or nonrepetitive, one needs a suitable null model, i.e. the sequencing error rate in the local genomic region. This error rate was often assumed to be a constant that could be refined using bootstrapping methods [9]. Alternatively, it was estimated using the quality values of bases in the reads. Huang [22] estimated the amount of sequencing errors in a local neighborhood based on the overlaps of an individual read with its overlapping partners (see also Ref. [21]). Developing this idea further, one could obtain an even better estimate of the error rate by constructing a multiple alignment in the layout phase. Such approaches work well if no additional source of error confuses the estimation of the sequencing error. If, however, repetitive overlaps are present, then these approaches cannot be applied directly. Nevertheless, we can assume that we have a rather good idea of the sequencing error for a collection of overlaps.

The fact that the reads are collapsed into a contig means that this difference is small, i.e. in the range of 1–3%. This is still significantly higher than the assumed rate of SNPs and hence this *microheterogeneity* can be used for detecting the different repeat instance (Figure 12).

This simply means that we use the fact that an instance of a repeat differs slightly from other instances. Hence, reads from a certain genomic location *always* differ from the reads in the other location, except in the unlikely event that the corresponding positions are changed by a sequencing error. Some

assembly programs like Euler [43] and ARACHNE [4] have a built-in, simple error correction phase that corrects numerous mistakes.

However, since the problem is modular, several papers addressed it individually. In Figure 12 differences caused by repeats are shown in blue and differences caused by sequencing errors are shown in red. The blue columns are called *DNPs* (defined nucleotide positions) [52] or *separating columns* [28] and can be used to separate the individual copies of a repeat.

The method of Tammi and coworkers proceeds in a straightforward way. It first prepares multiple alignments which it then refines, using a realignment algorithm [2]. Then, the consensus base in a column is defined as the most frequent base of the column. Whenever we see a certain number of *coinciding* differences from the consensus, the column is a candidate for usage in repeat separation (e.g. the first blue columns in Figure 12). If another candidate column can be found, these candidate columns define a DNP (e.g. the second blue column Figure 12).

Since the above procedure identifies errors that are due to micro-heterogeneity in repeats, we can attribute the remaining errors to the sequencing phase. Hence, the DNPs can also be used for correcting sequencing errors [51].

3.4 Layout of Contigs

In the layout phase, reads are assembled into contigs based on their overlaps, as reported in the overlap graph. Ideally, one may hope that this will give rise to a small number of very large contigs, perhaps one per chromosome arm. However, due to two problems this cannot happen. (i) Shotgun sequencing produces a random sampling of the source sequence, thus the coverage fluctuates along the sequence and some regions will remain unsampled, giving rise to *sequencing gaps* (see Ref. [31] for a mathematical treatment of the statistics for the length and number of such gaps). (ii) Repeats in the source sequence lead to the break-up of potential contigs into smaller ones, as described above.

Hence, a common strategy is to arrange sets of contigs into so-called *scaffolds* or *super-contigs* with the help of mate-pair information. More precisely, a scaffold consists of an ordered list of contigs $(c_1, c_2, \ldots, c_t)$, alongside a specification of the orientation of each individual contig (i.e. whether to use c_i or the reverse complement $\bar{c}_i$) and an estimation of the distance between any two consecutive contigs. A scaffold is deemed *correct* if the relative positioning and orientation of its contigs corresponds to the true locations in the source sequence.

As described above, shotgun sequencing projects often use a *paired-end* or *double-barreled* shotgun protocol, in which clones of a given fixed length are sequenced from both ends. This approach produces pairs of reads, called

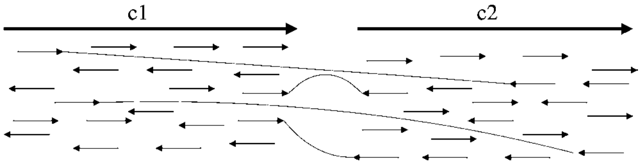

Figure 13 If two assembled contigs c_1 and c_2 correspond to neighboring regions of the source sequence, then we can expect to find mate-pairs that span the gap between them.

mate-pairs, whose relative orientation and mean distance l (with standard deviation σ) are known (Figure 2).

Standard size-selection techniques are used to produce a collection (library), of clones that have approximately the same length. A typical mixture of clone lengths is $l = 2$, 10 and 150 kb. With care, a standard deviation σ of approximately $1/10$ of l can be achieved.

Consider two contigs c_1 and c_2 produced in the layout phase of assembly. If they correspond to neighboring regions in the source sequence, we can expect to find mate-pairs that span the gap between them, as indicated in Figure 13. Such mate-pairs can be used to determine the relative orientation and estimated distance between c_1 and c_2.

Assume that the two contigs c_1 and c_2 are connected by mate-pairs $m_1, m_2, \ldots, m_k$. Each mate-pair provides an estimate of the distance between the two contigs. If these estimates are viewed as independent measurements, then they can be combined into a single estimate using standard statistical calculations.

As the assignment of reads to their mates is error prone, the existence of a single mate-pair linking two different contigs is not deemed significant. It is, however, of great statistical significance if two U-unitigs c_1 and c_2 are linked by two different mate-pairs in a consistent way. Similarly it is very unlikely that two mate-pair specification errors would put together two pairs of reads from the same two local regions of the source genome.

Assume that we are now given a collection of contigs $\{c_1, c_2, \ldots, c_k\}$ and a table of mate-pair information that links pairs of reads that are embedded in the contigs. To discuss the problem in more detail, we introduce the *contig-mate* graph. In this graph, each contig c_i is represented by a directed *contig-edge* having nodes s_i (the start node) and e_i (the end node). So-called *mate-edges* are added between such nodes to indicate that the corresponding contigs contain reads that are mates. For example, the two contigs c_1 and c_2, together with the collection of mates depicted in Figure 14 give rise to the contig-mate graph indicated in Figure 15.

If a set of different mate-pairs link two different contigs c_1 and c_2 in a consistent manner, then the contig-mate graph can be simplified by replacing

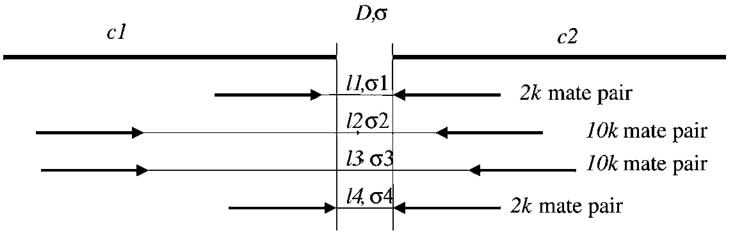

Figure 14 Here we depict two contigs that are linked by four mate-pairs. Each mate-pair provides an estimate (l_i, σ_i) of the gap between the two contigs, and simple statistics can be used to estimate a resulting mean distance D and standard deviation σ.

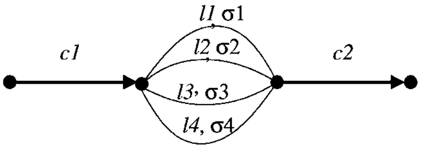

Figure 15 The two contigs and four mate-pairs shown in Figure 14 give rise to two contig-edges and four mate-edges in the contig-mate graph, as shown here.

the set of edges by a single *bundled mate-edge e*, whose mean length μ and standard deviation can be computed from the values for the original mate-edges, using straightforward statistics. Additionally, *e* is assigned a weight to reflect the number of mate-pairs that support it. Further edges can be bundled using so-called *transitive reduction*, which we do not describe here.

The goal of the *scaffolding* phase is to use the contig-mate graph to determine the true relative order and orientation of a set of contigs that are linked by mate-pairs. Most assemblers use different heuristics to address this problem.

We briefly discuss how this problem can be formalized (see Ref. [23] for details). An ordering or scaffolding of a set of contigs can be specified as a path *P* through the corresponding contig-mate graph. To this end, it may be necessary to infer "missing edges" between consecutive contig-edges in the path. To evaluate such a scaffolding one can look at all the mate-edges in the graph. We say that a mate-edge *e* is *satisfied* if the mate-pair layout implied by *e* is compatible with the ordering and orientation of contigs implied by *P*, otherwise *e* is called *unsatisfied*. Thus, the scaffolding phase can be stated as the following optimization problem: for a connected contig-mate graph, find a path *P* through the graph that contains all contig-edges, that possibly uses additional inferred edges and maximizes the number of satisfied mate-edges. This problem has been shown to be NP-hard [23].

Existing assemblers use straightforward heuristics in an attempt to form scaffolds. One heuristics that addresses the stated optimization problem directly is the "greedy path-merging" algorithm [23]. Given a connected contig-mate graph, the algorithm proceeds "bottom-up" as follows, maintaining a valid scaffolding $S \subseteq E$. Initially, all contig-edges $c_1, c_2, \ldots c_k$ are selected, but no others. At this stage, the graph consists of k selected paths $P_1 = (c_1), \ldots, P_k = (c_k)$. Then, in ordering of decreasing weight, each mate-edge $e = \{v, w\}$ is considered. If v and w lie in the same selected path P_i, then e is a chord of P_i and no action is necessary. If v and w are contained in two different paths P_i and P_j, we attempt to merge the two paths to obtain a new path P_k and accept such a merge, provided the increase of $S(G)$ (the number of satisfied mate-edges) is larger than the increase of $U(G)$ (the number of unsatisfied ones).

3.5 Computation of the Consensus Sequences

In a final step we need to determine the actual sequence for the target molecule. So far, we have discussed how to construct contigs, how to order them in scaffolds and how to address the problem of repeat resolution. The pairwise overlaps between reads provide only an approximate layout of the reads with respect to each other. To obtain a final layout, one needs to solve a special multiple alignment problem, with the following properties:

- The reads of the multiple alignment are almost identical.
- Quality values can be incorporated in the computation of the consensus sequence and be used to assign quality scores to consensus characters.
- The alignment is usually of depth 5–10 and very long (up to millions of base pairs).
- We need to compute the alignment very fast.

The fact that the initial read layout already gives an approximate alignment and the need to compute the alignment quickly results in the application of heuristics to solve the multiple alignment problem, since a generalization of the dynamic programming-based approach would result in a running time of $O(n^k)$ where k is about 5–10.

Most assemblers [4,26,50] implement the idea depicted in Figure 16 in some way. For each contig an alignment is "grown", starting with the pairwise alignment of the two left-most reads or the two reads with the best pairwise similarity. Then, the next read is aligned to the multiple alignment of the previous two reads and so on. Aligning a read to an alignment is usually done by converting the multiple alignment into a profile, and then employing an adaption of the pairwise alignment algorithm to the profile and the read (Figure 16). If quality values are at hand, they can be incorporated in to the alignment computation.

```

add next read to box

```
CGCCCTCGTCGTTGCTAATAGCGTTGCGC
```

Figure 16 Computation of the consensus sequence.

Once a multiple alignment has been determined, a consensus character is computed for each column of the multiple alignment. This can be done by simply voting on the majority character or, alternatively, by weighing the vote using the quality values [4]. If prior knowledge of the base composition is at hand, it can even be incorporated in a Bayesian approach [9] which computes the most likely consensus character and also derives a quality value for it. Some assembly programs employ *ad hoc* heuristics to incorporate the quality values [21] or use the approach implemented in the Phrap package [16,18,36]. Phrap avoids computing a multiple alignment altogether. Instead, it chooses a chain of single reads which are chosen such that they provide adjacent intervals of high-quality base calls. In each interval this single high-quality base is chosen for the consensus sequence.

Although this strategy does not use all available information, it avoids some artefacts introduced by the progressive method commonly used for the computation of multiple alignments. For example, Figure 17 shows a typical output of a progressive alignment on the left. Depending on the score function, the last read may result in three different alignments with other reads which are merged into a multi-alignment that introduces two Ts into the consensus sequence (depicted in blue). However, the multi-alignment on the right is more likely to be correct, since it can be explained with only two sequencing errors in the last read. Such additional characters are to be avoided, since they confound gene prediction algorithms and other

computational sequence analysis tools. A possible strategy to achieve this is to use iterative refinement strategies that correct such mistakes [2].

4 Examples of Existing Assemblers

In Table 1 we give an overview of current assemblers that are able to compute an assembly of large eukaryotic genomes and list some of the genomes that have been applied to. We use the attributes CBC and WGS to indicate whether the assembler follows more the CBC or the WGS paradigm. Assemblers that take clone information and a WGS data set as input are marked as hybrid.

Table 1 Recent assembly programs for eukaryotic genomes.

Name	Year	Strategy	Genomes (examples)
Celera	2000	WGS	*H. sapiens* [54], *M. musculus* [37], *D. melanogaster* [38], *Anopheles gambiae* [19],
GigAssembler	2001	CBC	*H. sapiens* [29]
ARACHNE	2002	WGS	*M. musculus* [4, 26]
JAZZ	2002	WGS	*Fugu rubripes*, *Ciona intestinalis* [3, 10]
RePS	2002	WGS	*Oryza sativa* [55, 57]
Barnacle	2003	CBC	*H. sapiens* [8]
PCAP	2003	WGS	*Caenorhabdtis briggsae*, *M. musculus* [20]
Phusion	2003	WGS	*M. musculus* [36]
Atlas	2004	hybrid	*Rattus norvegicus* [18, 46]

In the following we give short descriptions of the assemblers listed in Table 1. This will give the flavor of the latest algorithmic approaches and show that all assemblers use similar ideas.

4.1 The Celera Assembler

The Celera assembler was the first WGS assembler to assemble large eukaryotic genomes [38, 54]. It screens the reads, removes vector or linker sequence and keeps only the interval with an average sequence identity of 98%. The overlapper module compares all pairs of reads to detect high-fidelity overlaps. To avoid a quadratic number of overlap computations, the overlapper uses a k-mer index to exclude nonrelated pairs from the expensive overlap. This results in a read-overlap graph as described in Section 3.1. Regions of this graph are assembled into contigs whenever the initial arrangement of reads in this region is unique. The Celera assembler incorporates mate-pair information, and orders and orients the contigs. The remaining gaps are closed in a sequence of less and less conservative steps. First contigs are placed if they are "anchored" by two mate-pairs, then if they are anchored by one mate-pair and an overlap path and so on. For each contig a consensus sequence is computed based on a progressive multiple alignment and a local heuristics to remove merging artefacts.

4.2 The GigAssembler

The GigAssembler [29] was designed to assemble the human genome from the CBC data obtained from the HGP [25]. It had to assemble all BACs in a tiling layout of clones. In addition to this input set, it uses mate-pairs, mRNA and EST information to bridge gaps in scaffolds. The GigAssembler screens the input sequences for contaminations and masks known repeats. Additional sequence information (reads of mate-pairs, ESTs, mRNA and BAC end reads) is aligned to the input. Similar to the description in Section 3.1, GigAssembler builds a lookup table of 10-mers and then conducts a detailed alignment in regions where consecutive 10-mers match. The main routine of the GigAssembler builds sequence contigs (called "rafts") from overlapping initial sequence contigs within a clone. Then it builds clone contigs (called "barges") from overlapping clones, and orders and orients the resulting contigs into "supercontigs". These assemblies are combined into full chromosome assemblies.

4.3 The ARACHNE Assembler

The ARACHNE assembler was developed by a group at the MIT that was also a major partner in the HGP. In its first version [4] its functionality was tested by reassembling the genomes of *H. influenza*, *Saccharomyces cervisiae* and *D. melanogaster*, as well as the two smallest human chromosomes, 21 and 22. A later version of ARACHNE [26] was used in the public assembly of the mouse genome. ARACHNE appears to be modeled after the Celera assembler, with a few differences.

As a true WGS assembler its input consists of a set of reads and mate-pairs where the mate-pairs are taken from carefully length selected clone libraries. An overlap phase is conducted as outlined in Section 3.1. In addition, it employs an error correction phase using multiple alignments deduced from the pairwise overlaps.

The contig assembly phase differs from the one employed in the Celera assembler, since it directly incorporates mate-pairs by identifying "paired reads", which are reads of two mate-pairs where the two left and the two right reads overlap, respectively. This is a clever way to form contigs that are consistent in overlap and mate-pair information.

ARACHNE computes repeat boundaries by inspecting the pairwise overlaps. To detect remaining repetitive contigs ARACHNE uses an arrival statistic similar to the one described above, together with the fact that repetitive contigs are likely to have mate-pairs that link them in a contradictory way to other contigs.

ARACHNE uses mate-pairs to build scaffolds using a greedy algorithm that gives priority to merging contigs that are supported by the most links involving the shortest distance. This phase is followed by an attempt to fill gaps using contigs that were previously labeled as repetitive. Since the first labeling was conservative, this will often succeed. A consensus sequence is derived by heuristicly computing a multiple alignment.

4.4 The JAZZ Assembler

The JAZZ assembler is a modular assembler making use of different, sometimes already existing modules. The input reads are trimmed with respect to a window average of the quality values. In addition, they are checked for vector contamination which is then removed. The overlap phase is similar to the description of Section 3.1. An index of 16-mers is constructed. All 16-mers that occur too often are not used for triggering a more expensive alignment step. Then all reads that share more than ten non repetitive 16-mers are aligned using a banded Smith–Waterman algorithm. JAZZ constructs a scaffolded layout of reads. In particular, JAZZ postpones the computation of contigs until the consensus phase, which employs a consensus algorithm similar to Phrap. JAZZ tries to close gaps in scaffolds that are due to repeats in the genome.

4.5 The RePS Sssembler

The RePS uses also Phrap as its main assembly engine. It was primarily used to assemble the rice genome [55]. RePS masks out repeated 20-mers. The masked reads are handed to Phrap. As a post-Phrap step, RePS uses mate-pairs to fill gaps and build scaffolds. The strategies RePS uses are concepts borrowed from the Celera assembler.

4.6 The Barnacle Assembler

Barnacle [8] is an assembler that was used to reassemble the human genome from the public CBC data. In contrast to GigAssembler it does not make use of a physical map, but uses mate-pairs and clone data only (possibly augmented with chromosome assignments). Barnacle computes all pairwise local alignments of the input sequence. This is done using a strategy as described in Section 3.1. Using those overlaps, contigs in the input set are merged whenever possible, thereby reducing the number of contigs by an order of magnitude. The clone overlaps are deduced (two clones overlap if, and only if, at least one contig pair of the corresponding clones overlaps) and conflicts are resolved by heuristically enforcing the layout graph (clones are vertices, overlaps induce edges) to be an interval graph. Barnacle orients the contigs starting from the interval representation of clones and assign coordinates to sub-contigs. Again, possible inconsistencies result in the discarding of the contigs involved.

4.7 The PCAP Assembler

The PCAP assembler is a true WGS assembler that incorporates many aspects of the well known CAP3 assembler [21]. One interesting aspect of PCAP is the way repeats are identified *de novo* during the overlap computation. For this, the set of reads is partitioned into subsets that can be distributed on many computers. Then, in an iterative process, repeats are identified during the overlap computation and used to avoid the computation of repeat induced overlaps. To do this, some overlaps are computed and repetitive regions are identified based on those overlaps. These repeats are used in the next round of overlap computations, and so on.

The overlaps themselves are computed in a manner similar to the approach outlined in Section 3.1. Prior to the construction of contigs, the depth of coverage at every point in the initial layout determined by the overlaps is computed. Using the depth of coverage, overlaps are assigned a score that reflects whether they are repeat induced or not. Only overlaps that are likely to be unique are used in the contigging step. In addition, poor ends of reads are located and clipped and chimeric reads discarded (all based on pairwise overlaps).

Contigs are formed by inspecting read overlaps in decreasing order of their adjusted score. Then the CAP3 algorithm for scaffolding is applied. It consists of finding groups of mate-pairs that indicate a mis-assembly of the contig. If such mate-pairs can be found, the contig is corrected and the mate-pair consistency is checked again.

A simple gap filling strategy based on finding overlap paths is applied, multiple alignments are computed and a consensus sequence is derived as in CAP3. The computation of the consensus sequence involves a heuristic procedure that makes use of the quality values of the reads.

4.8 The Phusion Assembler

The Phusion assembler was primarily designed to assemble the mouse genome from a WGS data set at 7.5× coverage [36] and was developed in parallel with the ARACHNE assembler [4, 27]. It is a modular assembler in the sense that it incorporates an older program, i.e. Phrap, as an integral part of its operation. It screens the input reads for poor quality reads, which are completely removed, and conducts a screening for vector contamination.

Phusion computes a histogram of all k-mers for a suitable *k*. Similar to the Atlas assembler, it uses this histogram to exclude *k*-mers that occur too seldomly (probably sequencing errors) and too often (probably repeats). The remaining *k*-mers are used to group the reads into contiguous groups, which are then passed to Phrap for assembly. This strategy is quite similar to the Atlas assembler and the compartmentalized assembler used by Celera to assemble a version of the human genome [24].

Phusion uses Phrap as its assembly engine and iteratively computes assemblies of sets of reads. It checks the consistency of the mate-pairs in this set. Whenever an inconsistency is detected, Phusion splits the set and reassembles the parts using Phrap. This results in a number of contigs that might share sequence parts. Phusion tries to join contigs based on the number of shared reads and sequence overlaps, a strategy not unlike that of the GigAssembler [29]. The resulting, larger contigs are scaffolded, using the mate-pair information.

4.9 The Atlas Assembler

The Atlas assembly system is a suite of programs that form a hybrid assembler which uses reads from WGS and from CBC data sets. Thus, it is very similar to the compartmentalized assembler developed at Celera Genomics [24,54].

Atlas trims the input reads based on the error rate in a local window. It builds a *k*-mer index of the WGS reads, since these cover the genome uniformly. Similar to the Phusion assembler, it uses the fact that seldomly occurring *k*-mers are likely to contain sequencing errors, while abundant *k*-mers are likely to be repetitive. Atlas establishes the "rarity" of a *k*-mer in the overlap phase, using such *k*-mers to seed a banded alignment as described in Section 3.1.

The WGS reads are binned by using the localized BAC clone reads to "catch" the corresponding WGS reads. The reads in each BAC bin are assembled using Phrap. Since Phrap does not use mate-pairs during the assembly, the resulting contigs are checked for consistency and, if found to be inconsistent, split using the mate-pair information. The same information is then used to scaffold the resulting contigs. The improved BACs are called *eBACs*.

Atlas performs a meta-assembly of the eBACs. Based on overlap information and independent mapping data, a tiling path of eBACs is computed. The assembly induced by this tiling path is refined using *rolling-Phrap*, which is an iterative procedure calling Phrap in a window that is cleverly moved over the tiling path. The resulting large contigs are linked using mate-pairs and localized BAC reads, and then anchored on the genomic axis using external mapping data.

4.10 Other Assemblers

There are a number of other assemblers that are not described here, either because they have been outdated by more recent developments (e.g. Refs. [14, 50]) or because they have not been used to assemble large eukaryotic genomes. Specifically, we would like to mention the Euler (or Euler-DB) assembler [43], which formulates the assembly problem differently, using a *k*-mer graph.

The last years have seen the development of a host of different assembly programs, which nevertheless share a significant portion of algorithmic ideas. In general, sequence assembly can be seen as a concatenation of algorithmic modules with well-defined interfaces. Hence, we believe that it would be worthwhile to combine the best implementations of these modules, an approach that has been taken by the Amos consortium hosted by The Institute for Genomic Research (TIGR) [53].

5 Conclusion

Assembling whole eukaryotic genomes was deemed impossible only 15 years ago. Yet, an initiative was founded to tackle the seemingly gargantuan task of assembling the human genome. Whole-genome assembly of eukaryotic genomes, once strongly criticized as impractical, has now been successfully applied to a number of large genomes and has become the standard approach. This would not have been possible without bioinformatics support, the development of efficient assembly algorithms and solid engineering to implement those algorithms into robust computer programs that also handle all peculiarities of the data that are not captured in the mathematical models.

Acknowledgements. We would like to thank the Informatics Research group at Celera Genomics which, under the guidance of Gene Myers and Granger Sutton, developed the first large-scale whole genome shotgun assembler, and used it to assemble *D. melanogaster*, *H. sapiens*, and *M. musculus*. Another detailed and careful description of the shotgun assembly problem can be found in [49]. We would like to thank Gene Myers for reviewing an earlier version of the manuscript. His comments helped to greatly improve the chapter.

Part 3 Sequence Analysis

3 Sequence Alignment and Sequence Database Search

Martin Vingron

1 Introduction

In evolutionary studies two characters are called homologous when they share common evolutionary ancestry. Genes may also be homologous, which usually is reflected by similarity among their DNA or amino acid sequences. Furthermore, homology among genes frequently implies that they are functionally similar. Thus, there are two good reasons to compare the sequences of genes or proteins, i.e. the unraveling of evolutionary relationships and extrapolating function from one gene to another.

The basis for the study of sequence similarity is the comparison of two sequences which will be dealt with in Section 2. Sequence comparisons are performed in large numbers when searching sequence databases for sequences that are similar to a query sequence. Algorithms for this purpose need to be fast, even at the expense of sensitivity. Section 3 discusses the widely used heuristic approaches to database searching. However, the algorithms we are designing for the purpose of quantifying sequence similarity can only be as good as our understanding of evolutionary processes and thus they are far from perfect. Therefore, results of algorithms need to be subjected to a critical test using statistics. Methods for the assessment of the statistical significance of a finding are introduced in Section 4.

Genes do not come in pairs, but rather in large families. Consequently, the need arises to align more than two sequences at a time, which is done by multiple alignment programs. Computationally a very hard problem, it has attracted considerable attention from the area of algorithm development. Section 5 presents the basic approaches to multiple sequence alignment.

Bioinformatics – From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

Section 6 builds on the knowledge of a multiple alignment and introduces how to exploit the information contained in several related sequences for the purpose of identifying additional related sequences in a database. The last section covers methods and resources to structure the entire space of protein sequences.

2 Pairwise Sequence Comparison

2.1 Dot plots

Dot plots are probably the simplest way of comparing sequences [55]. A dot plot is a visual representation of the similarities between two sequences. Each axis of a rectangular array represents one of the two sequences to be compared. A window length is fixed, together with a criterion under which two sequence windows are deemed to be similar. A typical choice for this similarity criterion would be a certain fraction of matching residues within a window. Whenever one window in one sequence resembles another window in the other sequence, a dot or short diagonal is drawn at the corresponding position of the array. Thus, when two sequences share similarity over their entire length a diagonal line extends from one corner of the dot plot to the diagonally opposite corner. If two sequences only share patches of similarity this is revealed by diagonal stretches.

Figure 1 shows an example of a dot plot. There, the coding DNA sequences of the α- and β-chains of human hemoglobin are compared to each other. For this computation the window length was set to 31. The program adds up the matches within a window and the gray value at the position corresponding to the center of the window is set according to the quality of the match at that position. One can clearly discern a diagonal trace along the entire length of the two sequences. Note the jumps where this trace changes to another diagonal of the array. These jumps correspond to the position where one sequence has more (or fewer) letters than the other one. Figure 1 was produced using the program "dotter" [71].

Dot plots are a powerful method of comparing two sequences. They do not predispose the analysis in any way such that they constitute the ideal first-pass analysis method. Based on the dot plot the user can decide whether they deal with a case of global, i.e. beginning-to-end, similarity or local similarity. "Local similarity" denotes the existence of similar regions between two sequences that are embedded in the overall sequences which lack similarity. Sequences may contain regions of self-similarity which are frequently termed internal repeats. A dot plot comparison of the sequence itself will reveal internal repeats by displaying several parallel diagonals (see also Chapter 7).

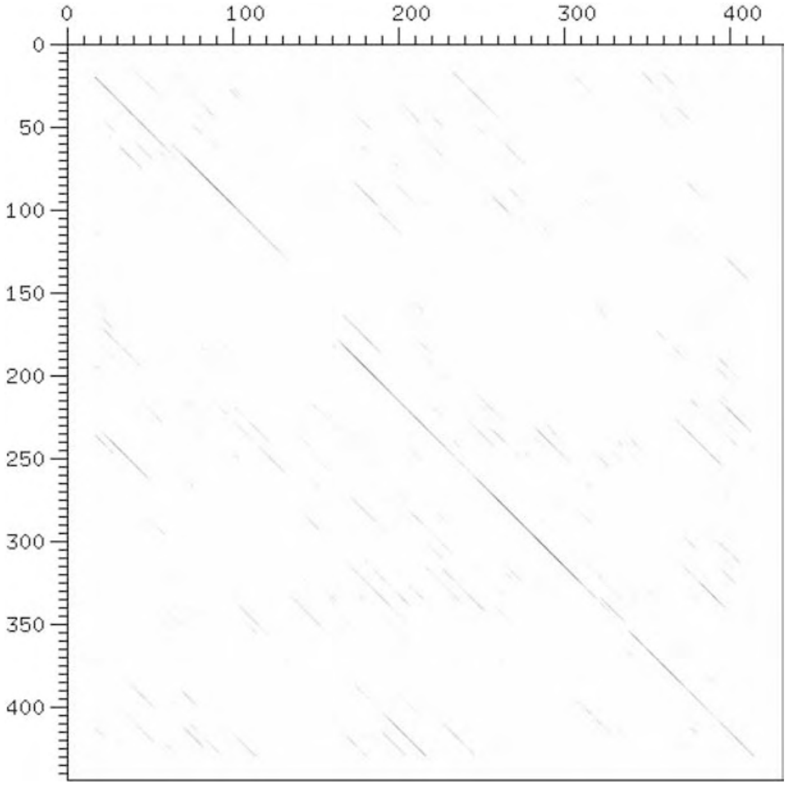

Figure 1 Dot plot comparing two hemoglobin sequences. The horizontal axis corresponds to the sequence of the human β-hemoglobin chain; the vertical sequence (numbered from top to bottom) represents the human α-hemoglobin chain.

Instead of simply deciding if two windows are similar, a quality function may be defined. In the simplest case, this could be the number of matches in the window. For amino acid sequences the physical relatedness between amino acids may give rise to a quantification of the similarity of two windows. For example, when a similarity matrix on the amino acids (like the Dayhoff matrix, see below) is used one might sum up these values along the window. However, when this similarity matrix contains different values for exact matches this leads to exactly matching windows of different quality. The dot plot method of Argos [5] is an intricate design that reflects the physical relatedness of amino acids. The program dotter [71] is an X-windows-based program that allows for displaying dot plots for DNA, for proteins and for comparison of DNA to protein.

2.2 Sequence Alignment

A sequence alignment [81] is a scheme of writing one sequence on top of another such that the residues in the same position are deemed to have a common evolutionary origin. If the same letter occurs at the same position in both sequences, then this position has been conserved in evolution (or, coincidentally, mutations from another ancestral residue have given rise to the same letter twice). If the letters differ it is assumed that both derive from the same ancestral letter, which could be one of the two or neither. Homologous sequences may have different length, though, which is generally explained through insertions or deletions in sequences. Thus, a letter or a stretch of letters may be paired up with dashes in the other sequence to signify such an insertion or deletion. Since an insertion in one sequence can always be seen as a deletion in the other one sometimes uses the term "indel" (or, simply, "gap"). Figure 2 depicts an example of an alignment. The sequences aligned there are the proteins derived from the coding sequences compared in Figure 1. Note that the first stretch of contiguously aligned amino acids (up to the WGKV match) corresponds to the first diagonal stretch in the dot plot of Figure 1. The subsequent insertion of 2 amino acids in the α-chain corresponds to linking this first diagonal to the second one, which is located around position 100. Likewise, the next five-letter gap in the alignment corresponds to the join from the second diagonal to the third, starting around position 200 in the dot plot.

In such a simple evolutionarily motivated scheme, an alignment mediates the definition of a distance for two sequences. One generally assigns a score of zero to a match, some positive number to a mismatch and a larger positive number to an indel. By adding these values along an alignment one obtains a score for this alignment. A distance function for two sequences can be defined by looking for the alignment which yields the minimum score.

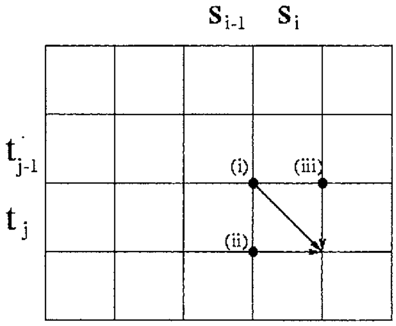

Figure 3 Schematic representation of the edit matrix comparing two sequences. The arrows indicate how an alignment may end according to the three cases described in the text.

Naively, the alignment that realizes the minimal distance between two sequences could be identified by testing all possible alignments. This number, however, is prohibitively large; luckily, using dynamic programming, the minimization can be effected without explicitly enumerating all possible alignments of two sequences. To describe this algorithm [64] denote the two sequences by $s = s_1, \ldots, s_n$ and $t = t_1, \ldots, t_m$. The key to the dynamic programming algorithm is the realization that for the construction of an optimal alignment between two stretches of sequence $s_1, \ldots, s_i$ and $t_1, \ldots, t_j$ it suffices to inspect the following three alternatives:

(i) The optimal alignment of $s_1, \ldots, s_{i-1}$ with $t_1, \ldots, t_{j-1}$, extended by the match between s_i and t_j;

(ii) The optimal alignment of $s_1, \ldots, s_{i-1}$ with $t_1, \ldots, t_j$, extended by matching s_i with a gap character "–";

(iii) The optimal alignment of $s_1, \ldots, s_i$ with $t_1, \ldots, t_{j-1}$, extended by matching a gap character "–" with t_j.

Each of these cases also defines a score for the resulting alignment. This score is made up of the score of the alignment of the so far unaligned sequences that used plus the cost of extending this alignment. In case (i), this cost is determined by whether or not the two letters are identical; in cases (ii) and (iii), the cost of extension is the penalty assigned to a gap. The winning alternative will be the one with the best score (Figure 3).

To implement this computation one fills in a matrix the axes of which are annotated with the two sequences s and t. It is helpful to use north, south, west and east to denote the sides of the matrix. Let the first sequence extend from west to east on the north side of the matrix. The second sequence extends from north to south on the west side of the matrix. We want to fill the matrix starting in the north-western corner, working our way southward row by row, filling each row from west to east. To start, one initializes the northern and western margin of the matrix, typically with gap penalty values. After this initialization the above rules can be applied. A cell (i, j) that is already filled contains the score of the optimal alignment of the sequence $s_1, \ldots, s_i$ with $t_1, \ldots, t_j$. The score of each such cell can be determined by inspecting the cell immediately north-west of it [case (i)], the cell west [case (ii)] and the one north [case (iii)] of it, and deciding for the best scoring option. When the procedure reaches the south-eastern corner, that last cell contains the score of the best alignment. The alignment itself can be recovered as one backtracks from this cell to the beginning, each time selecting the path that had given rise to the best option.

The idea of assigning a score to an alignment and then minimizing or maximizing over all alignments is at the heart of all biological sequence alignment. However, many more considerations have influenced the definition of the scores and made sequence alignment applicable to a wide range of biological settings. First, note that one may either define a distance or a similarity function of an alignment. The difference lies in the interpretation of the values. A distance function defines positive values for mismatches or gaps and then aims at minimizing this distance. A similarity function assigns high values to matches and low values to gaps, and then maximizes the resulting score. The basic structure of the algorithm is the same for both cases. In 1981, Smith and Waterman [69] showed that for global alignment, i.e. when a score is computed over the entire length of both sequences, the two concepts are in fact equivalent. Thus, it is now customary to choose the setting that gives more freedom for appropriately modeling the biological question of interest.

In the similarity framework one can easily distinguish among the different possible mismatches and also among different kinds of matches. For example, a match between two tryptophans is usually regarded to be more important than a match between two alanines. Likewise, the pairing of two hydrophobic amino acids like leucine and isoleucine is preferable to the pairing of a hydrophobic with a hydrophilic residue. Scores are used to describe these similarities and are usually represented in the form of a symmetric 20×20 matrix, assigning a similarity score to each pair of amino acids. Although easy to understand from the physical characteristics of the amino acids, the values in such a matrix are usually derived based on an evolutionary model that enables one to estimate whether particular substitutions are preferred or avoided. To be more precise, the similarity score for 2 amino acids is defined as the logarithm of the likelihood ratio of the two residues being homologous versus finding them at their corresponding positions due to chance. This approach has been pioneered by Dayhoff [17] who computed a series of amino acid similarity matrices. Each matrix in this series corresponds to a particular evolutionary distance among sequences. This distance is measured in a unit called 1 PAM, for 1 Accepted Point Mutation (in 100 positions). The matrices carry names like PAM120 or PAM250, and are supposed to be characteristic for evolutionary distances of 120 or 250 PAM, respectively. Other more recent series of matrices are the BLOSUM matrices [27] or the VT series of matrices [57]. For every matrix one needs to find appropriate penalties for gaps.

The treatment of gaps deserves special care. The famous algorithm by Needleman and Wunsch [60] did not impose any restrictions on the penalty assigned to a gap of a certain length. For reasons of computational speed, later gap penalties were restricted to a cost function linear in the number of deleted (inserted) residues [64]. This amounts to penalizing every single indel. However, since a single indel tends to be penalized such that it is considerably inferior to a mismatch, this choice resulted in longer gaps being quite expensive and thus unrealistically rare. As a remedy, one mostly uses a gap penalty function which charges a *gap open penalty* for every gap that is introduced and penalizes the length with a *gap extension penalty* which is charged for every inserted or deleted letter in that gap. Clearly, this results in an affine linear function in the gap length, frequently written as $g(k) = a + b * k$ [80].

With the variant of the dynamic programming algorithm first published by Gotoh [23] it became possible to compute optimal alignments with affine linear gap penalties in time proportional to the product of the lengths of the two sequences to be aligned. This afforded a speed-up by an order of magnitude compared to a naive algorithm using the more general gap function. A further breakthrough in alignment algorithms development was provided by an algorithm that could compute an optimal alignment using computer memory only proportional to the length of one sequence instead of their product. This algorithm by Myers and Miller [59] is based on work by Hirshberg [29].

Depending on the biological setting, several kinds of alignment are in use. When sequences are expected to share similarity extending from the beginning of the sequences to their ends, they are aligned globally. This means that each residue of either sequence is part either of a residue pair or a gap. In particular, it implies that gaps at the ends are charged like any other gap. This, however, is a particularly unrealistic feature of a global alignment. While sequences may very well share similarity over their entire length (see the example dot plot of two hemoglobin chains in Figure 1), their respective N- and C-termini usually are difficult to match up, and differences in length at the ends are more of a rule than an exception. Consequently, one prefers to leave gaps at the ends of the sequences unpenalized. This variant is easy to implement in the dynamic programming algorithm. Two modifications are required. First, the initialization of the matrix needs to reflect the gap cost of zero in the margin of the matrix. Second, upon backtracking, one does not necessarily start in the corner of the matrix, but rather searches the margins for the maximum from which to start. Variants of this algorithm that penalize only particular end-gaps are easy to derive and can be used, for example, to fit one sequence into another or to overlap the end of one sequence with the start of another.

In many cases, however, sequences share only a limited region of similarity. This may be a common domain or simply a short region of recognizable similarity. This case is dealt with by so-called local alignment in an algorithm due to Smith and Waterman [69]. Local alignment aims at identifying the best pair of regions, one from each sequence, such that the optimal (global) alignment of these two regions is the best possible. This relies on a scoring scheme that maximizes a similarity score because otherwise an empty alignment would always yield the smallest distance. Naively, the algorithm to compute a local alignment would need to inspect every pair of regions and apply a global alignment algorithm to it. The critical idea of Smith and Waterman was to offer the maximization in each cell of the matrix a fourth alternative: a zero to signify the beginning of a new alignment. After filling the dynamic programming matrix according to this scheme, backtracking starts from the cell in the matrix that contains the largest value.

Upon comparing a dot plot and a local alignment one might notice regions of similarity visible in the dot plot, but missing in the alignment. While in many cases there exist gap penalty settings that would include all interesting matching regions in the alignment, generally it requires the comparison with the dot plot to notice possible misses. This problem is remedied by an algorithm due to Waterman and Eggert [82] which computes suboptimal, local and nonoverlapping alignments. It starts with the application of the Smith–Waterman algorithm, i.e. a dynamic programming matrix is filled and backtracking from the matrix cell with the largest entry yields the best local alignment. Then the algorithm proceeds to delineate a second-best local alignment. Note that this cannot be obtained by backtracking from the second-best matrix cell. Such an approach would yield an alignment largely overlapping the first one and thus containing little new information. Instead, those cells in the dynamic programming matrix are set to zero from where backtracking would lead into the prior alignment. This can be regarded as "resetting" the dynamic programming matrix after having deleted the first alignment. Then the second best alignment is identified by looking for the maximal cell in the new matrix and starting backtracking from there. Iteration of this procedure yields one alternative, nonoverlapping alignment after the other in order of descending quality. Application of this algorithm avoids possibly missing matching regions because even under strong gap penalties the procedure will eventually show all matching regions.

There is an interesting interplay between parameters, particularly the gap penalty, and the algorithmic variant used. Consider a pair of sequences whose similar regions can in principle be strung together into an alignment. Under a weak gap penalty the Smith–Waterman algorithm has a chance to identify this entire alignment. On the other hand, not knowing about the similarity between the sequences ahead of time, a weak gap penalty might also yield all kinds of spurious aligned regions. The Waterman–Eggert algorithm is a valid alternative. The gap penalty can be chosen fairly stringently. The first (i.e. the Smith–Waterman) alignment will then identify only the best-matching region out of all the similar regions. By iterating the procedure, though, this algorithm will successively identify the other similar regions as well. For a detailed discussion of these issues, see Vingron and Waterman [79].

3 Database Searching I: Single-sequence Heuristic Algorithms

This section takes a first look at the problem of identifying those sequences in a sequence database that are similar to a given sequence. This task arises, for example, when a gene has been newly sequenced and one wants to determine whether a related sequence already exists in a database. Generally, two settings can be distinguished. The starting point for the search may either be a single sequence, with the goal of identifying its relatives, or a family of sequences, with the goal of identifying further members of that family. Searching through a database needs to be fast and sensitive, but the two objectives contradict each other. Fast methods have been developed primarily for searching with a single sequence and this will be the topic of this section.

When searching a database with a newly determined DNA or amino acid sequence – the so-called query sequence – the user typically lacks knowledge of whether an expected similarity might span the entire query or just part of it. Likewise, they will be ignorant of whether the match will extend along the full length of some database sequence or only part of it. Therefore, one needs to look for a local alignment between the query and any sequence in the database. This immediately suggests the application of the Smith–Waterman algorithm to each database sequence. One should take care, though, to apply a fairly stringent gap penalty such that the algorithm focuses on the regions that really match. After sorting the resulting scores the top scoring database sequences are the candidates of interest.

Several implementations of this procedure are available, most prominently the SSEARCH program from the FASTA package [63]. There exist implementations of the Smith–Waterman algorithm that are tuned for speed like one using special processor instructions [85] and, among others, one by Barton [9].

Depending on implementation, computer and database size, a search with such a program takes on the order of 1 min.

The motivation behind the development of other database search programs has been to emulate the Smith–Waterman algorithm's ability to discern related sequences while at the same time performing the job in much less time. To this end, one usually makes the assumption that any good alignment that one wishes to identify contains, in particular, some stretch of ungapped similarity. Furthermore, this stretch will tend to contain a certain number of identically matching residues and not only conservative replacements. Based on these assumptions, most heuristic programs rely on identifying a well-matching core and then extending it or combining several of these. With hindsight, the different developments in this area can further be classified according to a traditional distinction in computer science by which one either preprocesses the query or the text (i.e. the database). Preprocessing means that the string is represented in a different form that allows for faster answers to particular questions, e.g. whether the string contains a certain subword.

The FASTA program (part of a package [63] that usually goes by the same name) sets a size k for k-tuple subwords. For DNA sequences, the parameter k might typically be set to 7, while for amino acid sequences 2 would be a reasonable choice. The program then looks for diagonals in the comparison matrix between the query and search sequence along which many k-tuples match. This can be done very quickly based on a preprocessed list of k-tuples contained in the query sequence. The set of k-tuples can be identified with an array whose length corresponds to the number of possible tuples of size k. This array is linked to the indices of the positions at which the particular k-tuples occur in the query sequence. Note that a matching k-tuple at index i in the query and at index j in the database sequence can be attributed to a diagonal by subtracting one index from the other. Therefore, when inspecting a new sequence for similarity one walks along this sequence inspecting each k-tuple. For each of them one looks up the indices of the positions at which it occurs in the query, computes the index-difference to identify the diagonal and increases a counter for this diagonal. After inspecting the search sequence in this way a diagonal with a high count is likely to contain a well-matching region. In terms of the execution time, this procedure is only linear in the length of the database sequence and can easily be iterated for a whole database. Of course this rough outline needs to be adapted to focus on regions where the match density is high and link nearby, good diagonals into alignments.

The other widely used program to search a database is called BLAST [1,3]. BLAST follows a similar scheme in that it relies on a core similarity, although with less emphasis on the occurrence of exact matches. This program also aims at identifying core similarities for later extension. The core similarity is defined by a window with a certain match density on DNA or with an amino acid similarity score above some threshold for proteins. Independent of the exact definition of the core similarity, BLAST rests on the precomputation of all strings which are similar in the given sense to any position in the query. The resulting list may contain on the order of 1000 or more words, each of which if detected in a database gives rise to a core similarity. In BLAST nomenclature this set of strings is called the neighborhood of the query. In fact, the code to generate this neighborhood is exceedingly fast.

Given the neighborhood, a finite automaton is used to detect occurrences in the database of any string from the neighborhood. This automaton is a program constructed "on the fly" and specifically for the particular word neighborhood that has been computed for a query. Upon reading through a database of sequences, the automaton is given an additional letter at a time and decides whether the string that ends in this letter is part of the neighborhood. If so, BLAST attempts to extend the similarity around the neighborhood and if this is successful reports a match.

As with FASTA, BLAST has also been adapted to connect good diagonals and report local alignments with gaps. BLAST converts the database file into its own format to allow for faster reading. This makes it somewhat unwieldy to use in a local installation unless someone takes care of the installation. FASTA, however, is slower, but easier to use. There exist excellent web servers that offer these programs, in particular at the National Center for Biotechnology Information [43] and at the European Bioinformatics Institute [41] where BLAST or FASTA can be used on up-to-date DNA and protein databases.

According to the above-mentioned distinction among search methods into those that preprocess the pattern and those that preprocess the text, there also is the option of transforming a DNA or amino acid database such that it becomes easier to search. This route was taken, for example, by a group from IBM developing the FLASH [14] program. They devised an intricate, although supposedly very space-consuming technique of transforming the database into an index for storing the offsets of gapped k-tuples. The QUASAR program by Burkhard and coworkers [13] preprocesses the database into a so-called suffix array, similar to a suffix tree, yet simple to keep on disk. Programs in practical use for quickly searching entire genomes are BLAT [50] and SSAHA [61].

With the availability of expressed sequence tags (ESTs) it has become very important to match DNA sequence with protein sequence in such a way that a possible translation can be maintained throughout the alignment. Both FASTA and BLAST packages contain programs for this and related tasks. When coding DNA is compared to proteins, gaps are inserted in such a way as to maintain a reading frame. Likewise, a protein sequence can be searched versus a DNA sequence database. The search of DNA versus DNA with an emphasis on matching regions that allow for a contiguous translation is not so well supported. Although a dynamic programming algorithm for this task is feasible, the existing implementation in BLAST compares all reading frames.

4 Alignment and Search Statistics

Alignment score is the product of an optimization, mostly a maximization procedure. As such it tends to be a large number sometimes suggesting biological relatedness where there is none. In pairwise comparisons the user still has a chance to study an alignment by eye in order to judge its validity; however, upon searching an entire database automatic methods are necessary to attribute a statistical significance to an alignment score.

In the early days of sequence alignment, the statistical significance of the score of a given pairwise alignment was assessed using the following procedure. The letters of the sequences are permuted randomly and a new alignment score is calculated. This is repeated roughly 100 times, and the mean and standard deviation of this sample are calculated. The significance of the given alignment score is reported in "number of standard deviations above the mean", also called the Z-score. Studying large numbers of random alignments is correct, in principle. However, the significance of the alignment should then be reported as the fraction of random alignments that score better than the given alignment. The procedure described assumes that these scores are distributed normally. Since the random variable under study – the score of an optimal alignment – is the maximum over a large number of values, this is not a reasonable assumption. In fact, the lack of fit quickly becomes obvious when trying to fit a normal distribution to the data. The second argument against this way of calculating significance is a pragmatic one: the procedure needs to be repeated for every alignment under study because the effect of the sequence length cannot be accounted for.

Based on the work of several researchers [48, 70], it has meanwhile become apparent that alignment score as well as scores from database searches obey a so-called extreme-value distribution. This is not surprising given that extreme-value distributions typically describe random variables that are the result of maximization. In sequence alignment, there are analytical results confirming the asymptotic convergence to an extreme-value distribution for the case of local alignment without gaps, i.e. the score of the best-matching contiguous diagonal in a comparison [18]. This is also a valid approximation to the type of matching effected in the database search program BLAST. Thus, this approach has become widely used and, in fact, has contributed significantly to the popularity of database search programs because significance measures have made the results of the search much easier to interpret.

The statistical significance of an event like observing a sequence alignment of a certain quality is the probability to observe a better value as a result of chance alone. This quantity is refereed to as the p-value. For example, a p-value of 10^{-3} is interpreted as expecting to see an excess of the given threshold in one in a 1000 experiments. To compute this one needs to model chance alignments, which is precisely what the statistician means by deriving the distribution of a random variable. The probability that a chance result would exceed an actually obtained threshold S is 1 minus the value of the cumulative distribution function evaluated at that threshold. In sequence alignment, this cumulative distribution function is generally expressed as [48]:

$$\exp(mnKe^{\lambda S})$$

where m and n are the lengths of the sequences compared, and K and λ are parameters which need to be computed (where possible) or derived by simulation. K and λ depend on the scoring matrix used (e.g. the PAM120 matrix) and the distribution of residues. Hence, for any scoring system these parameters are computed beforehand and the statistical significance of an alignment score S is then computed by evaluating the formula with the length of the two sequences compared.

The most prominent case for which the parameters K and λ can be defined analytically is local alignment without gaps. Algorithmically this amounts to computing a Smith–Waterman alignment under very high gap penalties such that the resulting alignment will simply not contain any gaps. Since this notion of alignment also guides the heuristic used by the BLAST database search program, the resulting statistical estimates are primarily used in database searching. In this application, one of the lengths is the length of the input sequence and the other length can be chosen on the order of the length of the concatenated sequences from the database that is being searched. Alternatively, one can think of the database search as a repetition of many individual pairwise comparisons, which amounts to repeating the experiment "sequence comparison" many times. In this setting, the number of false positives one expects to find can be determined as the product of the p-value of the individual comparison and the number of times the experiment is repeated, i.e. the number of sequences in the database. This expected number of false positives is referred to as the E-value. A typical E-value threshold for a database search would be, for example, 1, indicating that the score cutoff is chosen such that among the sequences faring better than the cutoff one expects to find one false-positive hit.

When gaps are allowed, the determination of K and λ is more complex because an approximation of the distribution function of alignment score by an extreme-value distribution as above is not always valid. Generally speaking, it is allowed only for sufficiently strong gap penalties where alignments remain compact as opposed to spanning the entire sequences. Under sufficiently strong gap penalties, though, it has been demonstrated that the approximation is indeed valid just like for infinite gap penalties [79]. However, it is not possible any more to compute the values of the parameters K and λ analytically. As a remedy one applies simulations in which many alignments of randomly generated sequences are computed and the parameters are determined based on fitting the empirical distribution function with an extreme-value distribution [83]. As in the case above, this procedure allows for determining parameters beforehand and computing significance by putting the lengths of the sequences into the formula.

The question remains of how to determine whether approximation by an extreme-value distribution is admissible for a certain scoring scheme and gap penalty setting one is using. This can be tested on randomly generated (or, simply, unrelated) sequences by computing a global alignment between sequences under that particular parameter setting. If the result has a negative sign (averaged over many trials or on very long random sequences), then the approximation is admissible. This is based on a theorem due to Arratia and Waterman [6], and subsequent simulation results reported by Waterman and Vingron [84]. In particular, a gap open penalty of 12 with an extension penalty of 2 or 3 for the case of the PAM250 matrix, as well as any stronger combination, allows for approximation by the extreme-value distribution.

In database searching the fitting need not be done on randomly generated sequences. Under the assumption that the large majority of sequences in a database are not related to the query, the bulk of the scores generated upon searching can be used for fitting. This approach is taken by Pearson in the FASTA package. It has the advantage that the implicit random model is more realistic since it is taken directly from the data actually searched. Along a similar line of thought, Spang and Vingron [72] tested significance calculations in database searching by evaluating a large number of search results. Their study showed that one should not simply use the sum of the lengths of all the sequences in the database as the length parameter in the formula for the extreme-value distribution. This would overestimate the length that actually governs the statistics. Instead, a considerably shorter effective length can determined for a particular database using simulations. This effect is probably due to the fact that alignments cannot start in one sequence and end in the next one, which makes the number of feasible starting points for random alignments smaller than the actual length of the database.

5 Multiple Sequence Alignment

For many genes a database search reveals a whole number of homologous sequences. Then, one wishes to learn about the evolution and the sequence conservation in such a group. This question surpasses what can reasonably be achieved by the sequence comparison methods described in Section 3. Pairwise comparisons do not readily exhibit positions that are conserved among a whole set of sequences and tend to miss subtle similarities that become visible when observed simultaneously among many sequences. Thus, one wants to simultaneously compare several sequences.

A multiple alignment arranges a set of sequences in a scheme such that positions believed to be homologous are written in a common column (Figure 4). As in a pairwise alignment, when a sequence does not possess an amino acid in a particular position, this is denoted by a dash. There also are conventions similar to the ones for pairwise alignment regarding the scoring of a multiple alignment. The so-called sum-of-pairs (SOP) [2] score adds the scores of all the induced pairwise alignments contained in a multiple alignment. For a linear

Figure 4 Example of a multiple sequence alignment: an alignment of amino acid sequences of myoglobins and hemoglobins from a number of species. Each sequence begins in the top block and continues in the bottom block. The color code indicates physicochemical attributes of amino acids. The bar diagram below the alignment quantifies the degree of conservation in the column above.

gap penalty this amounts to scoring each column of the alignment by the sum of the amino acid pair scores or gap penalties in this column. Although it would be biologically meaningful, the distinctions between global, local and other forms of alignment are rarely made in a multiple alignment. The reason for this will become apparent below when we describe the computational difficulties in computing multiple alignments.

In general, the columns of a multiple alignment cannot be determined based on the set of all pairwise alignments. Quite the contrary, pairwise alignments may contradict each other in that one set of alignments opts to place, say, residue *a* from sequence *i* in one column with residue *b* from sequence *j*, while from another set of pairwise alignments it may follow that *a* should be in one column with another letter *c* from sequence *j*. If one wishes to assemble a multiple alignment from pairwise alignments one has to avoid "closing loops", i.e. one can put together pairwise alignments as long as no new pairwise alignment is included involving a sequence which is already part of the multiple alignment. In particular, pairwise alignments can be merged when they align one sequence to all others, when a linear order of the given sequences is maintained or when the sequence pairs for which pairwise alignments are given form a tree. While all these schemes allow for the ready definition of algorithms that output multiply aligned sequences, they do not include any information stemming from the simultaneous analysis of several sequences.

An alternative approach is to generalize the dynamic programming optimization procedure applied for pairwise alignment to the delineation of a multiple alignment that maximizes, for example, the SOP score. The algorithm used [80] is a straightforward generalization of the global alignment algorithm. This is easy to see, in particular, for the case of the column-oriented SOP scoring function avoiding an affine gap penalty in favor of the simpler linear one. With this scoring, the arrangement of gaps and letters in a column can be represented by a Boolean vector indicating which sequences contain a gap in a particular column. Given the letters that are being compared, one needs to evaluate the scores for all these arrangements. However conceptually simple this algorithm may be, its computational complexity is rather forbidding. For *n* sequences it is proportional to 2^n times the product of the lengths of all sequences. The space requirement of this algorithm is on the order of the product over the lengths of the *n* sequences, which constitutes an even greater obstacle to its practical application.

There exists software to compare three sequences with this algorithm that additionally implements a space-saving technique [46]. For more than three sequences, algorithms have been developed that aim at reducing the search space while still optimizing the given scoring function. The most prominent program of this kind is MSA2 [25,44]. An alternative approach is used by DCA

[36, 73], which implements a "divide-and-conquer" philosophy. The search space is repeatedly subdivided by identifying anchor points through which the alignment is highly likely to pass.

However, none of these approaches scales well to large numbers of sequences to be aligned. The most common remedy is reducing the multiple alignment problem to an iterated application of the pairwise alignment algorithm. However, in doing so, one also aims at drawing on the increased amount of information contained in a set of sequences. Instead of simply merging pairwise alignments of sequences, the notion of a profile [24] has been introduced in order to grasp the conservation patterns within subgroups of sequences. A profile is essentially a representation of an already computed multiple alignment of a subgroup of sequences. This alignment is "frozen" for the remaining computation. Other sequences or other profiles can be compared to a given profile based on a generalized scoring scheme defined for this purpose. The advantage of scoring a sequence versus a profile over scoring individual sequences lies in the fact that the scoring schemes for profile matching reflect the conservation patterns among the already aligned sequences. (Profiles are discussed in more detail in Chapter 11.)

Given a profile and a single sequence, the two can be aligned using the basic dynamic programming algorithm together with the accompanying scoring scheme. The result will be an alignment between sequence and profile that can readily be converted into a multiple alignment now comprising the sequences underlying the profile plus the new one. Likewise, two profiles can be aligned with each other, resulting in a multiple alignment containing all sequences from both profiles. Various multiple alignment strategies can be implemented with these tools. Most commonly, a hierarchical tree is generated for the given sequences, which is then used as a guide for iterative profile construction and alignment. This alignment strategy is called "progressive", and was introduced in papers by Taylor [76], Corpet [16] and Higgins [28]. Higgins' program Clustal [42] and, in particular, its latest version ClustalW are probably the most widely used programs for multiple sequence alignment [47]. Two recent variants of progressive alignment are MUSCLE [21] and PROBCONS [19]. Other programs in practical use are the MSA2 program and DCA. Lee and coworkers [54] developed a program that focuses on fast alignment of highly similar sequences, e.g. ESTs, using an algorithm termed partial order alignment.

Progress has been made also on the problem of local multiple alignment. The algorithm behind the Dialign [37, 56] program relies on collecting local similarities among all pairs of sequences and then assembles those into multiply aligned regions. Similarly, T-Coffee [62] allows for inclusion of both local and global alignments, as well as other possible information like structural similarity, and merges those consistently into a multiple alignment.

Since iterative profile alignment tends to be guided by a hierarchical tree, this step of the computation also influences the final result. Usually the hierarchical tree is computed based on pairwise comparisons and their resulting alignment scores. Subsequently, this score matrix is used as input to a clustering procedure like single linkage clustering or UPGMA (unweighted pair group method with arithmetic mean) [74]. However, it is well understood that in an evolutionary sense such a hierarchical clustering does not necessarily result in a biologically valid tree. Thus, when allowing this tree to determine the multiple alignment there is the danger of pointing further evolutionary analysis of this alignment in the wrong direction. Consequently, the question has arisen of a common formulation of evolutionary reconstruction and multiple sequence alignment. The cleanest, although biologically somewhat simplistic, model attempts to reconstruct ancestral sequences to attribute to the inner nodes of a tree [65]. Such reconstructed sequences at the same time determine the multiple alignment among the sequences. In this "generalized tree alignment" one aims at minimizing the sum of the edge lengths of this tree, where the length of an edge is determined by the alignment distance between the sequences at its incident nodes. As to be expected, the computational complexity of this problem again makes its solution unpractical. The practical efforts in this direction go back to the work of Sankoff [65, 66]. Hein [26] and Schwikowski and Vingron [68] produced software [38, 40] relying on these ideas.

With the increased interest in analysis of regulatory regions in DNA, the problem of finding subtle local similarities, in particular in DNA sequences, has received much interest. Many programs for the detection of common sequence motifs use probabilistic modeling and/or machine learning approaches. In particular, the mathematical technique of the Gibbs sampler has lent its name also to a motif-finding program, the Gibbs Motif Sampler [31,53]. Bailey and Elkan [7] designed the MEME [33] program which relies on an expectation maximization algorithm. A number of pattern-finding programs have been compared by Tompa and coworkers [78].

6 Multiple Alignments, Hidden Markov Models (HMMs) and Database Searching II

Information about which residues are conserved and thus important for a particular family is crucial not only for the purpose of multiply aligning a set of sequences, but is also very valuable in the context of identifying related sequences in a database. A multitude of methods has been developed that aim at identifying sequences in a database which are related to a given family. The first one was the notion of a profile that was described above and was actually introduced in the context of database searching. As in multiple alignment, profiles help in emphasizing conserved regions in a database search. Thus, a sequence that matches the query profile in a conserved region will receive a higher score than a database sequence matching only in a divergent part of an alignment. This feature is of enormous help in distinguishing truly related sequences.

Algorithmically, profile searching simply uses the dynamic programming alignment algorithm for aligning a sequence to a profile on each sequence in the database. Of course, this is computationally quite demanding and much slower than the heuristic database search algorithms like BLAST or FASTA. Typically, the multiple alignment underlying the profile describes a conserved domain which one expects to find within a database sequence. Therefore, in this context, it is important that end gaps should not be penalized. Furthermore, gap penalties for profile matching frequently vary along the profile in order to reflect the existence of gaps within the underlying multiple alignment. Through this mechanism one attempts to allow new gaps preferentially in regions where gaps have been observed already. However, different suggestions exist as to the choice and derivation method for these gap penalties [77].

In 1994, Haussler and coworkers [52] and Baldi and coworkers [8] introduced HMMs for the purpose of identifying family members in a database. An HMM is a generative probabilistic model in the sense that we can think of it as a machine that generates strings of symbols; in biological applications, typically the letters of a biological sequence. It has "states" and each state will output a symbol according to a distribution associated to this state. After a state has output a symbol, a transition to one of its successor states occurs according to a specified transition probability. These transitions are Markovian, meaning that the transitions leading out of a state are governed only by this state's transition probabilities and not by how the machine got to arrive in this state. The "hidden" element in the HMM comes from the image that an observer gets to see the generated symbol series and then needs to infer which series of states gave rise to it or what the underlying distributions might look like. HMMs and related algorithms are discussed in depth by Durbin and coworkers [20].

The structure of a *profile HMM* mimics a multiple alignment. We think of it as a machine that emits a sequence which would typically be randomly drawn based on a given multiple alignment, according to the distribution of letters in its columns. If gaps were forbidden, the emitted sequence would essentially draw one letter from each column of the alignment. Insertions and deletions, however, imply that the generated sequence may differ in length from the multiple alignment, with some columns possibly skipped or new letters inserted in the emitted sequence. Figure 5 schematically shows the

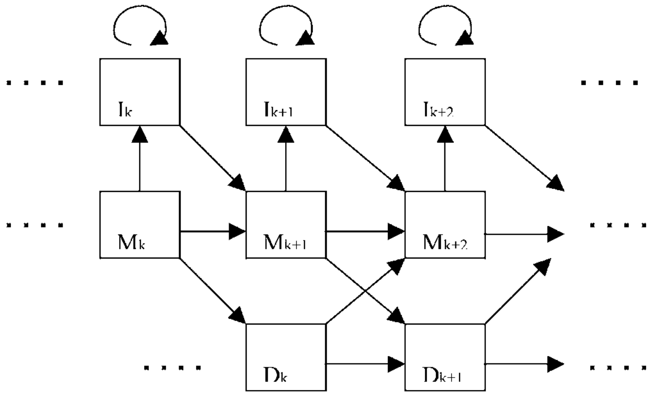

Figure 5 Sketch of the structure of a profile HMM.

states and transitions that realize this structure. The middle row represents a series of match states (M). These represent the columns of the given alignment and emit letters according to a distribution that is supposed to fit the corresponding column of the alignment. A transition into an insert state (denoted I, arranged in the top row) lets the machine emit an additional letter, with the possibility of remaining in this insert state and emitting more additional letters as indicated by the self-loop at the insert nodes. The transition from a match state into a delete state (D, bottom row) leads to the emitted sequence skipping one or more of the following columns of the alignment, which corresponds to a deletion in the emitted sequence with respect to the alignment.

In this manner, the profile HMM can output sequences which, by way of their generating state sequence, are aligned relative to the given multiple alignment. The task of aligning a sequence to a profile HMM can therefore be phrased in the probabilistic setting of "What is the most likely sequence of states to have given rise to this sequence?". This is solved by the so-called Viterbi algorithm, which largely resembles the classical dynamic programming sequence alignment algorithm in its structure. Alternatively, one can ask for the probability of the observed sequence as such, independent of which path generated it. This is computed by summing over the different state sequences that could have produced the sequence. Here, the fully probabilistic formalization is superior to an *ad hoc* score definition which would not allow for posing and answering this question. Algorithmically, this summation can be computed efficiently by the so-called forward algorithm.

There is a standard learning algorithm, the Baum–Welch algorithm, to determine emission and transition probabilities of an HMM given a set of learning data. When training a profile HMM, one has the sequences of the multiple alignment at hand, which may be too small a set for parameter determination in many cases. The problem becomes manageable, though, when one uses the residue distributions in the columns as a guideline for the emission probabilities and chooses the transition probabilities to reflect, in essence, the way gaps should be handled. Adding a possible correction (the "pseudocounts") for sampling artifacts, this choice of parameters can either be used directly or as a starting configuration for a subsequent application of the Baum–Welch algorithm in order to refine parameter estimation. Nevertheless, training an HMM is a very difficult problem and the Baum–Welch algorithm may only find a local optimum.

The first application of HMMs in sequence analysis seems to be due to Churchill [15], who applied the technique to the segmentation of sequences based on their composition. Profile HMMs followed later, addressing the same problem as multiple alignment profiles. A widely used implementation of profile HMMs is the HMMER package [32]. The two concepts of HMMs and profiles are formally very similar, although set in a different language. Bucher and Karplus [12] introduced generalized profiles, and showed that the two concepts are equally powerful in their abilities to model sequence families and detect related sequences. Nevertheless, due to the coherent probabilistic description language and a broad spectrum of good software implementations, HMMs have found widespread acceptance. Many other areas in computational molecular biology, e.g. gene finding, have also profited greatly from the introduction of HMMs.

The fact that a profile or HMM can pick out new sequences also related to the given family suggests that these should be used to update the profile or HMM used as search pattern. This idea leads to iterative search algorithms which search the database repeatedly, each time updating the query pattern with some or all of the newly identified sequences. PSI-BLAST [3] is a very successful implementation of this idea. It starts with a single sequence, and after the first search constructs profiles from conserved regions among the query and newly identified sequences. Without allowing for gaps (to increase search speed) these new profiles are used to repeat the search. Generally, PSI-BLAST quickly converges after updating these profiles again and generally is very successful in delineating all the conserved regions a sequence may share with other sequences in a database. In the realm of HMMs, SAM is a very careful implementation of the idea of iterated searches [39, 49].

It is the generally held view that searching a database with a profile or HMM produces extreme-value distributed random scores just like single-sequence database searching. The quality of the fit to the extreme-value distribution may, however, depend on the particular given alignment. This has been substantiated with mathematical arguments only for the case of ungapped profile matching [22]. Nevertheless, this basic understanding of the statistical behavior of database-matching methods is a crucial element of iterative search programs. Without clear and reliable cutoff values one could not decide which sequences to integrate into the next search pattern and would run the danger of including false positives, thus blurring the information in the pattern.

Both single-sequence search methods and profile/HMM-based methods have been thoroughly validated during recent years [11]. Databases of structurally derived families, e.g. SCOP [34, 58], have made it possible to search a sequence database with a query, and exactly determine the number of false positives and false negatives. For every search one determines how many sequences one misses (false negatives) in dependence of the number of false positive matches. If the sequence statistics is accurate, the number of false positives correlates well with the E-value, i.e. the number of false positives expected by chance. This way of validating search methods allows for making objective comparisons and for determining how much quality one actually gains with slower methods over faster, less accurate methods.

7 Protein Families and Protein Domains

The companion question to the one that assigns related sequences from a database to a given query sequence or family is the question that tries to assign to a query sequence the family of which it is a member or the domains that it contains. One resource for this purpose is the InterPro database [4], which contains amino acid patterns that are descriptive for particular domains, families or functions. The InterPro database summarizes information from several other motif databases including, among others, Prosite [30] and Pfam [10]. One can either scan a sequence against this database [86] or rely on precomputed information that is stored along with the sequences in the databases. The Pfam database contains precomputed HMMs for protein domains. A query sequence can be matched against this library of HMMs in order to identify known domains in the query sequence. Here, too, match statistics plays a crucial role in order to determine the significantly matching domains. A server that allows one to scan a sequence versus all Pfam domains can be found at the Sanger center [45]. Software has also been developed to recognize the Pfam HMMs in either coding DNA or in genomic DNA. In the latter case, the program combines the HMM matching with the distinction between coding and noncoding DNA.

Apart from finding and cataloguing domains of proteins, efforts have also been made to structure the space of all protein sequences into homologous groups or orthologous families. Linial and coworkers have developed the Protonet [67] system, hierarchically structuring the set of all proteins. Krause and coworkers [51] developed SYSTERS [35] to delineate protein families and supply consensus sequences of these families to be searched with a DNA or protein query sequence. Koonin and coworkers put special emphasis on the delineation of orthologous genes, and collect this information in the COG and KOG databases [75].

8 Conclusions

The problems and methods introduced above have been instrumental in the advance in our understanding of genome function, organization and structure. While some years ago human experts would check every program output, nowadays sequence analysis routines are being applied in an automatic fashion creating annotation that is included in various databases. This holds true for similarity relationships among sequences and extends all the way to the prediction of genomic structure or to function prediction based on similarity. Although the quality of the tools has increased dramatically, the possibility of error and, in particular, its perpetuation by further automatic methods exists. Thus, it is apparent that the availability of these high-throughput computational analysis tools is a blessing and a problem at the same time.

Phylogeny Reconstruction

Ingo Ebersberger, Arndt von Haeseler, and Heiko A. Schmidt

1 Introduction

In 1973 Theodosius Dobzhansky said "Nothing in biology makes sense except in the light of evolution" [27]. Although more than 30 years old, the citation still remains valid. Biologists nowadays use the massive amount of sequence data to infer the phylogenetic relationship of contemporary organisms. DNA, long words over a finite alphabet of four nucleotides, is transmitted from one generation to the next. The copying process and environmental factors lead to an accumulation of mutations in the sequence. Such mutations manifest themselves as slight changes in the DNA sequence, so-called *substitutions*. The vertical transmission (in time) of DNA together with the discrete nature of the mutations makes the molecule an ideal target to study phylogenetic relationship of organisms. Consequently, sequence-based phylogenies of organisms have been determined from many different genes. Such gene-trees have provided surprisingly new and sometimes controversial insights into the evolutionary relationships of organisms. However, research and debates still focus on the best methodology. That is, how do we measure similarity or dissimilarity, how can we model the process of substitution, how can we accurately infer the tree? Despite this ongoing discussion, molecular phylogenies are nowadays a routine tool for biologists interested in the evolution of organisms.

Moreover, the application of molecular phylogenies goes beyond the reconstruction of phylogenetic trees for organisms. Gene trees or, more general, sequence trees serve as an important source of information to understand how sequences are related. From this relatedness it is then possible to infer the function of an unknown sequence (see also Chapter 32). Not only function can be inferred, but also structure can be deduced from trees (Chapter 11). From sequence trees we can deduce the evolutionary history of the sequences themselves. We can determine regions that are conserved or highly variable and we can detect sequences that show a highly aberrant substitution pattern. Moreover, we can detect duplications of genes or parts of the genome; thus,

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

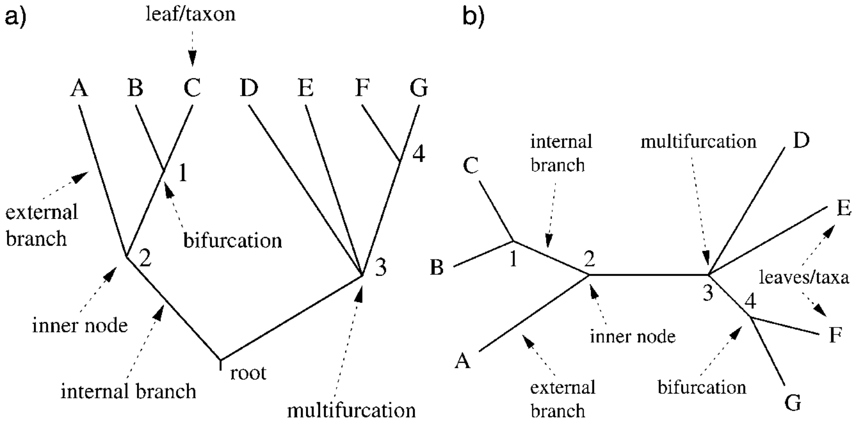

Figure 1 Phylogenetic relationships among a set of seven taxa represented by a rooted (a) and an unrooted (b) tree.

trees serve as analytical tools in comparative genomics (Chapter 37). Even the coevolution of host–pathogen interactions (Chapter 41) is mirrored in the similarity of trees from both groups.

Again, the conclusions strongly depend on the accuracy of the reconstruction method. To critically evaluate the result a basic understanding of the different approaches to phylogenetic inference is required. In this chapter we present a very basic introduction. We set the stage by a brief introduction in the terminology, followed by a summary about current approaches to model evolutionary changes (Section 2). Section 3 describes the three fundamental principles of phylogenetic inference, i.e. maximum parsimony, distance-based and maximum likelihood (ML) inference. The subsequent section deals with the optimization problem of finding the "best" tree(s) with respect to some objective function. With the advent of phylogenomics one wants to reconstruct a species tree from a collection of multiple genetic loci. This question leads naturally to supertree methods introduced in Section 5. Finally, Section 6 summarizes attempts to infer evolutionary relationships if the data do not evolve according to a tree. Processes like horizontal gene transfer or recombination destroy the tree-likeness of the data. In such instances it is better to reconstruct networks rather then trees.

1.1 Reconstructing a Tree from its Leaves

The fundamental axiom in evolutionary biology is the assumption that any two taxa share a common ancestor at some time point in their history. Thus, following backward in time the lineages along which these taxa have evolved, they will eventually coalesce. Considering a large set of taxa, consecutive coalescent events result in an ever-decreasing number of predecessors until only two lineages remain. The ancient taxon in which these lineages eventually merge then represents the most recent ancestor common to all taxa in the dataset. The correspondence to a tree is apparent and it is therefore of little surprise that trees play the key role in phylogenetic research. The dominant role of trees in the area of phylogeny reconstruction is already manifested in the phylogeneticist's vocabulary (Figure 1). Contemporary taxa are dubbed *leaves*, leaves are connected via *external branches* to *internal nodes* (their common ancestors) and internal nodes themselves are connected via *internal branches*. Nodes that give rise to two descendants are termed *bifurcations*, nodes with a larger number of descendants are referred to as *multifurcations* (Biologists usually judge it as unlikely that three or more lineages emerged at precisely the same time from a shared ancestor; thus, we will concentrate on bifurcating trees.) Eventually, if the direction of the evolutionary process is known the ancestor of all leaves in the tree is identified. To stay in the picture, this node is termed the *root*. If directional information is not available, the relationships of the taxa is represented in an *unrooted tree*. However, in this case the temporal succession of ancestors remains undetermined. The reconstruction of the phylogenetic relationships for a set of taxa and their representation by a tree can be separated into two subproblems. (i) What is the order individual taxa split from their shared ancestors, i.e. what is the topology of the tree? (ii) What is the evolutionary time that has passed since any two taxa last shared a common ancestor, i.e. how long are the corresponding branches of the tree? In most cases no hard evidence (such as a comprehensive fossil record) exists to directly reconstruct the evolutionary steps transforming one ancestral taxon into its descendants. Rather, we get hold only of the end-points of this process and are more or less ignorant about anything that has happened in the past. Thus, we are facing the problem of reconstructing the phylogenetic tree just by looking at its leaves.

1.2 Phylogenetic Relationships of Taxa and their Characters

Although one is typically interested in the relationships of the taxa, the reconstruction procedure is usually not based on the taxon as a whole. For practical reasons one vicariously concentrates on individual characteristics of these taxa, usually either morphological or molecular features. We will refer to such representative characteristics as *characters* and to their peculiar expression in the individual taxa as the *character state*.

To collect the raw data for phylogenetic analyses, the variety of states for a particular character in a set of taxa has to be assessed first. Next, the possible transformations of the character states during evolution has to be reconstructed, which can then be used for phylogenetic inference. Irrespective of what type of character has been chosen, two general approaches can be followed to trace the phylogenetic signal in the data. One can identify those (evolutionary novel) character states that are shared among a subset of the taxa. Such a congruency is interpreted as a result of shared descent [68]. Based on the pattern and extent of congruent character states, the degrees of relationships among the taxa can then be inferred. Alternatively, the extent of evolutionary change for the particular character between any pair of taxa can be assessed. From the resulting pairwise evolutionary distances again a phylogenetic tree can be reconstructed. We will outline both approaches in greater detail below (Section 3). Eventually, the evolutionary history of the particular character is extrapolated to the taxon level.

Inherent to any character-based strategy for phylogeny reconstruction is the assumption that comparisons are performed only between homologous characters, i.e. characters related by descent. Although the assignment of homology constitutes one of the major issues in evolutionary studies [68, 114, 134], we will take for granted that this postulation is met.

1.2.1 The Problem of Character Inconsistencies

To date, tree reconstruction is frequently based on more than only a single character. This adds the advantage that different characters can complement each other by adding resolution to different parts of the tree. However, the reverse effect occurs as well: trees reconstructed from different characters can disagree. Given that incompatible groupings of taxa are supported significantly by the respective data, two alternative explanations are possible. First, the incompatible groupings are based on a misinterpretation of the data. For example, taxa can share the same character state not due to a shared ancestry, but rather because the particular state arose independently at least twice during evolution. Phylogeny reconstruction methods that model the evolutionary process (see Sections 3.2 and 3.3) usually account for this problem. However, if such parallel, convergent or back mutations remain unrecognized (or are neglected) an erroneous tree reconstruction is possible. In the second explanation, the evolution of each character state is correctly reconstructed. Such genuine discrepancies between inferred trees have various causes. Among the most frequently stated are processes like the random sorting of ancestral polymorphisms (e.g. Ref. [130]) and horizontal gene transfer [25, 28, 91] (Figure 2). If one is suspicious that either of these scenarios could apply, several independently evolving characters should be analyzed. The most frequently observed tree is then usually the tree reflecting the evolutionary relationships of the taxa as a whole. Alternatively, if it seems appropriate to visualize such discrepant phylogenetic signals in the data, a network rather than a tree can be chosen to represent the phylogeny of the taxa (see Section 6).

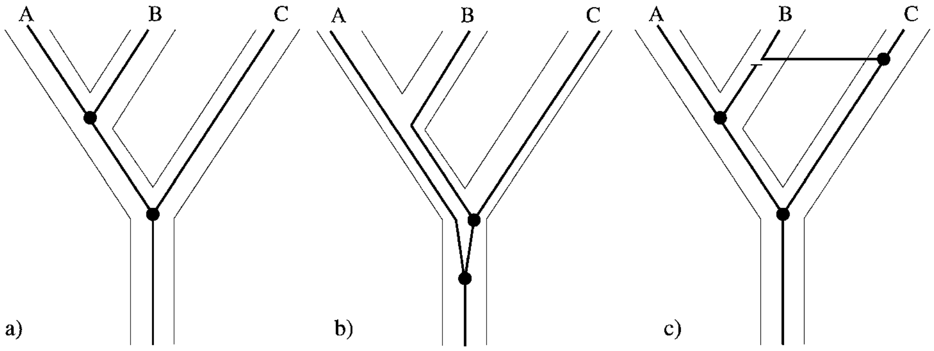

Figure 2 Trees for individual characters (inner trees) can differ from the species tree (outer trees). (a) The phylogenetic history of the character follows that of the species. (b) The random sorting of ancestral polymorphisms at subsequent speciation events. (c) Horizontal gene transfer, i.e. the lateral transfer of individual genes or DNA sequences between species. Both random sorting of ancestral polymorphisms and horizontal gene transfer can result in phylogenies that are incongruent to the species tree or to trees reconstructed from other characters.

1.2.2 **Finding the Appropriate Character Set**

In theory, phylogenetic relationships can be reconstructed from any set of homologous characters subject to evolutionary change. Depending on the scope of a study and the collection of taxa, however, certain types of characters might be more suitable than others. Changes in shape, or morphology in general, are the most conspicuous effects of evolution. Therefore, the field of phylogeny reconstruction was dominated by the analysis of morphological characters for a long time. However, with the expansion of molecular biology the focus has shifted considerably. Initially, the immunological and electrophoretic analysis of structural and electrical properties of proteins [85], presence or absence of genomic features such as restriction enzyme recognition sites [47], or DNA–DNA hybridization [45, 137] were used to measure the extent of character change on the molecular level. As time proceeded, the presence and absence or linear order of regulatory elements and genes (see also Chapter 8), and recently even expression data [83] have been employed for phylogenetic inference. However, the most dominant role is still taken by the direct comparison of biological sequences. Sequences change in the course of time and any two sequences derived from a common ancestor will diverge. The pattern and extent of differences between two related sequences is then used to reconstruct their evolutionary history. Initially, due to experimental constraints, the comparison of protein sequences was prevalent. Nowadays, analyses rely almost entirely on DNA sequences and even those studies comparing amino acid sequences usually derive these from the corresponding DNA sequences. The advantages of DNA sequence data are apparent. DNA sequences can be obtained with considerable ease from any taxon and even the comparison of entire genomes has now become feasible. Allowing for some simplifications, each nucleotide position in the DNA sequence can be regarded as an independently evolving character and the number of possible states is strictly limited to the four bases: adenine (A), guanine (G), cytosine (C) and thymine (T). Eventually, different DNA sequences in a genome can evolve with different rates. This allows for easy adaption of the dataset to the evolutionary time scale for which phylogenetic resolution is required.

2 Modeling DNA Sequence Evolution

The substitution of nucleotides in a DNA sequence, i.e. the replacement of one nucleotide by a different one, is usually considered a random event. As a consequence, an important prerequisite for the reconstruction of phylogenetic relationships among species is the prior specification of a *model of substitution*, which provides a statistical description of DNA sequence evolution [97]. If we consider the substitution of one nucleotide by another one at any given site in a sequence as a random event and, furthermore, assume that a series of such random events occurs during some time interval, then theses events form a homogeneous Poisson process [37], if two very mild assumptions are met:

(i) The occurrence of a substitution in the time interval (t_1, t_2) is independent of a substitution in another time interval (t_3, t_4), where (t_1, t_2) and (t_3, t_4) do not overlap.

(ii) There is a constant $\mu > 0$, such that for any time interval $(t, t + h)$, $h > 0$ and h small, the probability that one event occurs is independent of t and is proportional to μh. The probability that more than one substitution occurs during $(t, t + h)$ becomes vanishing small as $h \to 0$.

The latter condition implies the so-called time homogeneity and, moreover, it implies that the probability of one substitution is proportional to the length of the time interval, i.e. the size of h. As substitutions are assumed to occur spontaneously and independently from past or future substitutions, homogenous Poisson processes are a simple approach to model the evolution of DNA. Moreover, under conditions (1) and (2) the number of substitutions $X(t)$ that occur up to any arbitrary time t is Poisson distributed with parameter μt [37]. Thus:

$$P_i(t) = [(\mu t)^i \exp(-\mu t)]/i! \,, \tag{1}$$

is the probability that $i = 0, 1, 2, \ldots$ substitutions occur in the time interval $(0, t)$. On average, μt substitutions with variance μt are expected. Note that the parameters μ (nucleotide substitutions per site per unit time) and t (the time) cannot be estimated separately, but only through their product μt (number of substitutions per site up to time t).

The nucleotide substitution process of DNA sequences described by the Poisson process can be generalized to a so-called Markov process that uses a rate matrix (typically called Q with elements Q_{xy}), which specifies the relative rates of change for each nucleotide. The most general form of the Q-matrix is shown in Figure 3. Rows follow the order A, C, G and T so that, for example, the second term of the first row is the instantaneous rate of change from base A to base C. This rate is given by the frequency of base C (π_C) times a relative rate parameter, describing (in this case) how often the substitution A to C occurs during evolution with respect to all other possible substitutions. Thus, each nondiagonal entry in the matrix represents the flow from nucleotide x to nucleotide y, while the diagonal elements are chosen to make the sum of each row equal to zero. They represent the total flow that leaves nucleotide x. Accordingly, we can write the total number of substitutions per unit time (i.e. the total substitution rate μ) as:

$$\mu = -\sum_x Q_{xx}\pi_x, x \in \{\mathrm{A}, \mathrm{C}, \mathrm{G}, \mathrm{T}\}. \tag{2}$$

Models like the one summarized in Figure 3 belong to the general class of time-homogenous time-continuous Markov models. When applied to modeling nucleotide substitutions, they share the following set of assumptions:

- The rate of change from x to y at any nucleotide position in a sequence is independent of the nucleotide that occupied this position prior to x (Markov property).
- Substitution rates do not change over time (homogeneity).
- The waiting time until the first substitution occurs follows a continuous distribution (time continuity).

$$Q = \begin{pmatrix} -(a\pi_{\mathrm{C}} + b\pi_{\mathrm{G}} + c\pi_{\mathrm{T}}) & a\pi_{\mathrm{C}} & b\pi_{\mathrm{G}} & c\pi_{\mathrm{T}} \\ g\pi_{\mathrm{A}} & -(g\pi_{\mathrm{A}} + d\pi_{\mathrm{G}} + e\pi_{\mathrm{T}}) & d\pi_{\mathrm{G}} & e\pi_{\mathrm{T}} \\ h\pi_{\mathrm{A}} & i\pi_{\mathrm{C}} & -(h\pi_{\mathrm{A}} + i\pi_{\mathrm{C}} + f\pi_{\mathrm{T}}) & f\pi_{\mathrm{T}} \\ j\pi_{\mathrm{A}} & k\pi_{\mathrm{C}} & l\pi_{\mathrm{G}} & -(j\pi_{\mathrm{A}} + k\pi_{\mathrm{C}} + l\pi_{\mathrm{G}}) \end{pmatrix}$$

Figure 3 Instantaneous rate matrix Q. Each entry in the matrix represents the instantaneous substitution rate from nucleotide x to nucleotide y (rows and columns follow the order A, C, G and T). a to l are rate parameters describing the relative rate one nucleotide is substituted by any other nucleotide. $\pi_{\mathrm{A}}, \pi_{\mathrm{C}}, \pi_{\mathrm{G}}, \pi_{\mathrm{T}}$ correspond to the nucleotide frequencies. Diagonal elements are chosen such that each row sums up to zero.

Once the evolutionary model (and thus the Q-matrix) is specified, the probabilities $P(t)$ of change from one nucleotide to any other during evolutionary time t is computed as follows:

$$P(t) = \exp(Qt) \ . \tag{3}$$

Each entry $P_{xy}(t)$ of the resulting probability matrix $P(t)$ specifies the probability to observe nucleotide y at time point t if the original nucleotide at this site was x.

2.1 Nucleotide Substitution Models

From the instantaneous substitution rate matrix Q in Figure 3 various submodels can be derived. Among these, the so-called stationary time-reversible models are the ones most commonly used. These models introduce the constraint that for any two nucleotides i and j the rate of change from i to j is the same as from j to i (thus, $a = g, b = h, c = j, d = i, e = l, f = l$ in Figure 3). Under these conditions the values of π_N ($N = \mathrm{A, G, C, T}$) correspond to the stationary frequencies of the four nucleotides, respectively (i.e. $\pi \cdot Q = 0$). If all eight parameters of a reversible Q-matrix are specified separately, the general time reversible model [92] is derived. The most simplest (fewest number of parameter) model assumes that the equilibrium frequencies of the four nucleotides are 0.25 each and that any nucleotide has the same rate to be replaced by any other. These assumptions correspond to a Q-matrix with $\pi_\mathrm{A} = \pi_\mathrm{C} = \pi_\mathrm{G} = \pi_\mathrm{T} = 1/4$, and $a = b = c = d = e = f = 1$. This resembles the well-known Jukes-Cantor model [82]. An overview of the hierarchy of the most common substitution models is shown in Figure 4.

2.2 Modeling Rate Heterogeneity

The nucleotide substitution models described so far implicitly assume that the rate of nucleotide substitution is the same for any position in the DNA sequence. However, it is well known that this is an oversimplification. For example, substitutions occur at an about 10 times higher frequency at C and G nucleotides when the C is followed by a G along the sequence [71]. Similarly, selective constraints maintaining functional DNA sequences result in varying substitution rates along a DNA sequence. To account for such site-dependent rate variations, a plausible model for the distribution of rates over sites is required. Most commonly, a continuous probability distribution, the Γ-distribution with expectation 1 and variance $1/\alpha$, is used [61]. By adjusting the shape parameter α, the Γ-distribution allows varying degrees of rate heterogeneity (Figure 5). For $\alpha > 1$, the distribution is bell-shaped and models weak rate heterogeneity among sites. For $\alpha < 1$, the Γ-distribution takes on

a characteristic L-shape, which describes strong rate heterogeneity, i.e. some sites have very high substitution rates, while the other sites are practically invariable.

2.3 Codon Models

Heterogeneous substitution rates become a particular issue for DNA that codes for proteins. Amino acid sites in a protein sequence are under different selective constraints, depending on their relevance for the protein func-

$$q_{xy} = \begin{cases} 0 & \text{if } x \text{ and } y \text{ differ at two or three nucleotide positions} \\ \pi_y & \text{if } x \text{ and } y \text{ differ by one synonymous transversion} \\ \kappa\pi_y & \text{if } x \text{ and } y \text{ differ by one synonymous transition} \\ \omega^{(h)}\pi_y & \text{if } x \text{ and } y \text{ differ by one nonsynonymous transversion} \\ \omega^{(h)}\kappa\pi_y & \text{if } x \text{ and } y \text{ differ by one nonsynonymous transition} \end{cases}$$

Figure 6 Instantaneous rate that codon x at site h is replaced by codon y. π_y represents the stationary marginal frequency of codon y, κ denotes the transition/transversion rate ratio and $\omega^{(h)}$ the nonsynonymous/synonymous substitution rate ratio at site h.

tion. Accordingly, nucleotide substitutions causing the encoded amino acid to change (replacement substitutions) will have fixation probabilities that depend on the selective constraint imposed on the encoded amino acid. In contrast, silent substitutions, i.e. a change in the DNA sequence has no effect on the encoded protein, are invisible to selective forces acting on the protein sequence. As a result, the ratio of nonsynonymous and synonymous substitution rates (ω) will vary among sites in a DNA sequence, with $\omega = 1$ indicating no selection, $\omega < 1$ representing purifying selection by removing replacement mutations and $\omega > 1$ representing diversifying positive selection/adaptive evolution. Codon models have been specifically designed to model the evolution of protein-coding DNA sequences [59]. An example is shown in Figure 6 based on an extension of the HKY85 model [65] (see Figure 4). Note that, in contrast to the conventional substitution models, codon models consider the replacement of one nucleotide triplet (codon) by another. Thus, we obtain $4^3 - 3 = 61$ possible character states at a site, the codon (the three stop codons are not taken into account). Obviously, the assignment of a distinct substitution rate ratio ω to each codon position would lead to a vast overparameterization of the model. Therefore, either a set of predefined ω-values or statistical distributions, both discrete and continuous, are used to account for varying ω-values among sites [104,156,157].

3 Tracing the Evolutionary Signal

Given a set of homologous DNA sequences whose phylogeny is known, inferences can be made about the evolutionary forces molding the contemporary DNA sequences from their shared ancestral sequence. Conversely, with a concept or a model at hand of how DNA sequences evolve one can aim to reconstruct the phylogenetic tree based on the DNA sequences. In either case, however, a meaningful sequence alignment is required. Thus, the sequences need to be aligned such that homologous nucleotides in different sequences form a column. To account for the insertion and deletion of nucleotides during evolution, gaps are introduced to achieve this positional homology. Chapter

3 deals with methods to compute sequence alignments. We will not dwell on further methodological details and take it for granted that an alignment is available. Based on this alignment, several criteria exist to compute the tree that best reflects the evolutionary relationships of the data. We will explain four principles for tree generation.

3.1 The Parsimony Principle of Evolution

Parsimony methods share as an optimality criterion that among various alternative hypotheses the one that requires the minimal number of assumptions should be chosen. In the context of DNA sequence evolution one searches for the tree(s) that explain the observed diversity in the contemporary sequences with the minimal number of nucleotide substitutions (Figure 7). Usually only a fraction of the differences in a sequence alignment determine the so-called parsimonious tree(s). They are called phylogenetically informative in a parsimony analysis. For instance, position 8 in the alignment (Figure 7) best supports a tree grouping sequences *W* and *X*, and *Y* and *Z*, respectively. In

	Position								
	1	2	3	4	5	6	7	8	9
Sequence W:	C	G	C	A	C	T	G	T	T
Sequence X:	C	G	C	A	C	T	G	T	T
Sequence Y:	T	G	A	A	C	T	G	C	T
Sequence Z:	C	G	G	A	C	T	G	C	T
	*		*					*	

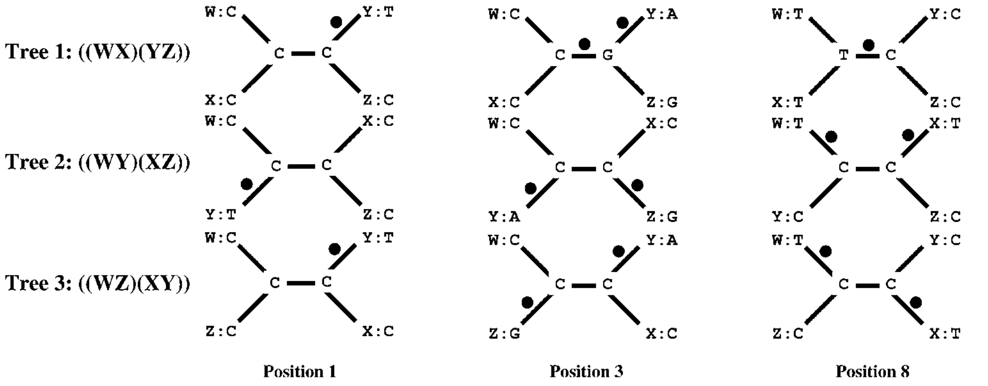

Figure 7 Maximum parsimony tree reconstruction from an alignment of four DNA sequences. For the alignment columns labeled with a "*" all three possible unrooted tree topologies are shown. Labels at the leafs denote the taxon and the represented nucleotide. Nucleotides at the inner nodes represent one parsimonious reconstruction. Nucleotide substitutions are represented by black dots. Position 8 is the only position that distinguishes the three trees with respect to the number of substitutions. Tree 1 requires only a single substitution compared to trees 2 and 3, which require two substitutions each.

contrast, to explain the sequence diversity at positions 1 and 3, two substitutions are necessary regardless of the tree structure. Such positions are called phylogenetically non-informative in a parsimony analysis. The tree that is supported best by the phylogenetically informative sites is then the maximum parsimony tree. Note, however, that no unique solution is guaranteed since more than one most parsimonious tree might exist.

3.1.1 Generalized Parsimony

To date, a vast number of modifications of the initial criterion of maximum parsimony exist [39,40,50,88]. Instead of referring to each and every modification separately, we would like to present the generalized idea of parsimony [128,129] from which the individual modifications can be easily derived. In a mathematical terminology, one aims to identify those trees in the space of all possible trees which minimize the following equation:

$$L(\tau) = \sum_{k=1}^{B} \sum_{j=1}^{L} \omega_j \cdot \mathrm{diff}(x_{k'j}, x_{k''j}) \ , \tag{4}$$

where $L(\tau)$ is called the length of the tree τ, B is the total number of branches in the tree, L is the number of nucleotide positions analyzed (alignment length), and k' and k'' are the two nodes connected by branch k displaying the nucleotides $x_{k'j}$ and $x_{k''j}$. These can be either the observed nucleotides present in the alignment or, in the case of internal nodes, the optimal nucleotide assignments. Finally, $\mathrm{diff}(x, y)$ represents the cost-matrix that specifies the cost of the transformation from nucleotide x to nucleotide y and ω_j is a specific weight for each alignment position. Thus, diff and $\omega = (\omega_1, \ldots, \omega_L)$ allow for specifying *a priori* some beliefs about the importance of positions and substitutions for the tree reconstruction, e.g. cost matrix **A** in Figure 8 reflects a Jukes–Cantor type of evolution, whereas cost matrix **B** down-weights transitions relative to transversions.

$$\mathbf{A} = \begin{array}{c|cccc} & A & C & G & T \\ \hline A & - & 1 & 1 & 1 \\ C & 1 & - & 1 & 1 \\ G & 1 & 1 & - & 1 \\ T & 1 & 1 & 1 & - \end{array} \qquad \mathbf{B} = \begin{array}{c|cccc} & A & C & G & T \\ \hline A & - & 5 & 1 & 5 \\ C & 5 & - & 5 & 1 \\ G & 1 & 5 & - & 5 \\ T & 5 & 1 & 5 & - \end{array}$$

Figure 8 Cost matrices for generalized parsimony. In matrix **A** substitutions between all four nucleotides invoke the same cost. Matrix **B** represents a slightly more sophisticated model. More weight is put on transversions than on transitions.

3.1.2 Multiple/Parallel Hits

Parsimony principles rely on the assumption that a group of related sequences share a certain nucleotide by descent. However, this only approximates the true evolutionary events if the overall amount of sequence changes is low. Thus, multiple changes at the same site in one taxon or parallel independent changes at the same site in different taxa are sufficiently infrequent not to be an issue. However, when considerably diverged sequences are used for tree reconstruction or marked substitution rate heterogeneity among sites exists, multiple/parallel hits can cause severe problems in both assessing the correct number of nucleotide substitutions along the phylogenetic tree and in inferring the correct tree topology.

3.2 Distance-based Methods

In contrast to parsimony methods with a biologically motivated approach to tree reconstruction, distance-based methods choose a mathematical route [43]. A phylogenetic tree is reconstructed for a set of taxa from their pairwise evolutionary distances. To this end, a distance matrix D is calculated from all possible pairwise sequence comparisons. Entry D_{ij} of this matrix represents the distance between sequence i and sequence j. In a simple approach D_{ij} is computed as the edit distance (Hamming distance), i.e. the minimum number of substitutions required to transform sequence i into j. However, multiple changes at the same position cannot be accounted for and therefore the Hamming distance will sometimes underestimate the true number of substitutions. To rectify this, models of sequence evolution are invoked that correct for multiple changes (see Section 2). Various methods were suggested for inferring a tree from a distance matrix. Common, although in fact not especially designed for phylogenetic tree reconstruction, are *clustering methods*. Clustering methods do not have an explicit objective function to be optimized. UPGMA, the most widespread clustering method, will serve as an example.

3.2.1 UPGMA

The "Unweighted Pair Group Method using Arithmetic means" groups those two taxa first whose evolutionary distance is minimal. Consider taxa A, B, C, and D with evolutionary distances as shown in Figure 9a. The taxa A and B with distance 6 are clustered first. Subsequently, A and B are treated as one compound taxon AB, and pairwise distances to the remaining taxa C and D are computed. $D_{(AB)C}$ is calculated as the arithmetic mean of the individual distances D_{AC} and D_{BC}, thus $D_{(AB)C} = (7 + 8)/2 = 7.5$. Likewise, we compute $D_{(AB)D} = (13 + 14)/2 = 13.5$. Now the cycle is repeated for the new 3×3 distance matrix. We obtain $((AB)C)$ and D as the two remaining

	A	B	C

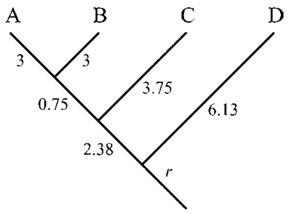
a)



b)

Figure 9 Reconstruction of a phylogenetic tree with the UPGMA method. From the matrix of pairwise sequence distances (a) the phylogenetic tree shown in (b) is reconstructed. Numbers in (b) represent the branch lengths inferred under the assumption of a molecular clock. r identifies the root of the tree.

taxa with $D_{((AB)C)D} = (13 + 14 + 11)/3 = 12.7$. Finally, D and $((AB)C)$ are merged to conclude the procedure. The full tree $(((AB)C)D)$ with branch lengths is displayed in Figure 9b. Thus, UPGMA reconstructs a rooted tree, where branch lengths are computed such that the distances from root r to the leaves A, B, C, and D are identical (6.13 in our example). More generally, such trees fulfill the so-called ultrametric inequality, i.e. for each triple of taxa X, Y and Z:

$$D_{XY} \leq \max[D_{XZ}, D_{YZ}]. \tag{5}$$

Equation 5 is equivalent to the statement that two of the three distances are the same and at least as large as the third distance. More interestingly, the reverse is also true. If for a distance matrix the ultrametric inequality is fulfilled, then the distance matrix is representable by a rooted tree such that the distances D_{ij} are identical to the sum of the branch lengths connecting the two taxa X and Y in the tree. In biological parlance, if the distances computed from a set of aligned sequences obey the ultrametric inequality then the sequences evolve according to a molecular clock, i.e. they accumulate substitutions at the same rate (see Section 2). Therefore, UPGMA can give misleading trees if the distances reflect a substantial departure from the molecular clock. To arrive at a correct tree topology nevertheless, the distance matrix can be corrected for unequal rates of evolution among the lineages under study (*transformed distance method* [87]). The such modified distance matrix can then be used to infer the tree topology using UPGMA.

3.2.2 **Neighbors-relation Methods**

To overcome the restriction of the molecular clock, the characterization of unrooted trees with branch lengths is helpful. If it is required, alternative routes can be taken at a later step in the tree reconstruction to located the

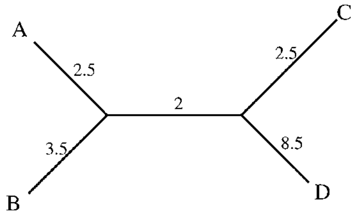


Figure 10 An unrooted quartet tree and its branch lengths reconstructed from the distance matrix in Figure 9(a).

position of the root (see Section 3.6). The celebrated *four-point condition* and its relaxations [5,20] state conditions when a distance matrix is representable as a tree. A distance matrix is representable as a tree if and only if for all quartets W, X, Y and Z in a taxon set the following holds:

$$D_{WX} + D_{YZ} \leq \max[D_{WY} + D_{XZ}, D_{WZ} + D_{XY}] \,. \tag{6}$$

The distance matrix in Figure 9(a) fulfills this criterion and the corresponding unrooted quartet tree is displayed in Figure 10. However, for real data the four-point condition is rarely met. Thus, one relaxes this condition by introducing the concept of *neighbors*. Two taxa are called neighbors in an unrooted tree if they are connected through a single internal node. For instance the taxa A and B in Figure 10 are neighbors, while the taxa A and C or B and D are not. This concept of neighborhood was generalized to distance matrices [5] and resulted in a series of tree reconstruction methods [5,51,131].

3.2.3 Neighbor-joining Method

A widely used method based on the neighbors-relation concept is the NJ method by Saitou and Nei [123]. NJ is a clustering algorithm. During each clustering step, two taxa or clusters of taxa are identified as neighbors in the tree, if their grouping results in a tree whose overall length is minimal, i.e. the sum of the lengths of all branches is minimal (minimum-evolution criterion [21]). To this end, one starts with a star-like tree. Subsequently, two taxa X and Y are identified that minimize:

$$S_{XY} = \frac{1}{2(N-2)} \sum_{k=3}^{N} (D_{Xk} + D_{Yk}) + \frac{1}{2} D_{XY} + \frac{1}{N-2} \sum_{3 \leq i \leq j \leq N} D_{ij} \,. \tag{7}$$

The cycle of calculating a new distance matrix and identifying the next neighbors is continued until the initially star-like tree is fully resolved (see also Section 12). For details of the NJ algorithm, see Ref. [147]. Since then, several weighted and improved versions of the NJ algorithm have been published [16,53].

3.2.4 **Least-squares Methods**

We have described the application of cluster methods to phylogeny reconstruction. However, another view of the reconstruction problem based on a distance matrix is the specification of an objective function we want to optimize. From a mathematical view, we want to find a tree together with its branch lengths such that the distance of two taxa X, Y in the tree, i.e. the sum of the branch lengths connecting the two taxa in the tree, is close to D_{XY}.

The least-squares method provides such a measure for the goodness of fit of the tree and its branch lengths to the data. The best tree (τ_{LS}) under this criterion minimizes the following equation:

$$R(\tau) = \sum_{XY} (T_{XY} - D_{XY})^2 \,, \tag{8}$$

where T_{XY} is the sum of the branch lengths along the unique path connecting sequences X and Y. Cavalli-Sforza and Edwards [21] and Fitch and Margoliash [49] were among the first to apply the least-squares theory to the tree-reconstruction problem. However, the big challenge is the determination of the tree topology.

3.3 The Criterion of Likelihood

The third method of tree reconstruction is based on the principle of ML [48] which was made popular in the field by Felsenstein in 1981 [42]. The general idea of ML is as simple as it is appealing: for a given model M and its parameters θ_M the probability or likelihood of observing data D can be calculated. Those parameters are chosen that maximize the likelihood of observing the data. For the particular problem of inferring a phylogenetic tree from biological sequence data the tree topology τ is introduced such that:

$$\tau_{\mathrm{ML}} = \underset{(\tau,\theta_M)}{\operatorname{argmax}} \, P(D|\tau, \theta_M). \tag{9}$$

Note the subtle, but far-reaching, difference to the principle of maximum parsimony. The general concept of sequence evolution inherent to maximum parsimony, i.e. that one sequence is transformed into another via the least number of changes, is replaced by an explicit model of sequence evolution to describe the substitution process. From this the most significant advantage of ML becomes apparent: it allows us to incorporate any model of biological sequence evolution into the tree reconstruction process. In this way, it opens access to the full use of statistical approaches to compare alternative phylogenetic hypotheses, as well as to test fit and robustness of individual models of sequence evolution. A further advantage compared to the previous two approaches is the possibility to make full use of the sequence information.

In a likelihood framework also constant alignment sites provide information about the tree topology and its branch lengths.

3.4 Calculating the Likelihood of a Tree

We have described in Section 2 how to calculate the probability of observing a difference at a given site in two sequences. We now extend this to compute the probability to find a certain nucleotide pattern (A_s) in column s of N aligned DNA sequences, e.g. the pattern `CCTC` at position 1 of the alignment shown in Figure 7. This probability depends on the model of DNA sequence evolution and on the tree relating the N nucleotides in the alignment column: $P(A_s|\tau, \theta_M)$. We assume that all positions in the alignment of length L evolve according to the same evolutionary model M and evolve independently from each other. Then, the probability of the alignment given a tree and a model is a function of the tree τ and θ_M. Thus:

$$P(A|\tau, \theta_M) = \prod_{s=1}^{L} P(A_s|\tau, \theta_M). \tag{10}$$

To avoid numerical problems caused by underflows and rounding errors during the calculation the likelihood of the data is usually calculated in log-scale, such that:

$$\log[P(A|\tau, \theta_M)] = \sum_{s=1}^{L} \log[P(A_s|\tau, \theta_M)]. \tag{11}$$

Equation (11) facilitates computation of the likelihood of an alignment, if θ_M, τ and its branch lengths are specified. In reality, however, we face the reverse situation. Starting from a given alignment, we aim to infer the underlying phylogenetic tree together with its branch lengths. In order to do so we regard these parameters as variables. Once we have decided on an evolutionary model and have specified its parameter values, we can adjust the tree topology and the branch lengths such that Eq. (11) is maximized. While straightforward and efficient ways exist to obtain ML branch lengths for a specific tree topology (e.g. Ref. [42]), it is a computationally demanding problem to obtain an optimal tree topology. Section 4 explains the details.

3.5 Bayesian Statistics in Phylogenetic Analysis

The likelihood approach outlined so far determines the quality of a tree by calculating the probability of observing the alignment A given the tree τ and the model of sequence evolution specified by θ_M (see Eq. 11). If we consider a particular combination of τ and θ_M as an evolutionary hypothesis, H, we have inferred $P(A|H)$, the probability of A given H. However, it might be interesting to address the reverse question: what is the probability that the evolutionary hypothesis H is correct given the data, i.e. $P(H|A)$ (see [37, p. 106])? Applying Bayes' theorem, we can calculate this posterior probability as:

$$P(H|A) = \frac{P(A|H)P(H)}{P(A)} . \tag{12}$$

Rewriting the equation for the problem of tree reconstruction we obtain:

$$P(\tau, \theta_M|A) = \frac{P(A|\tau, \theta_M)P(\tau, \theta_M)}{P(A)} , \tag{13}$$

where $P(\tau, \theta_M)$ is the prior probability to choose the tree τ and the model with its parameters. $P(A)$ is the total probability of the alignment A.

Equation (13) can be used in two ways for making phylogenetic inferences from a set of DNA sequences. If one is only interested in identifying the tree that is best supported by the data, one simply determines the tree and the θ_M that maximize Eq. 13. Because $P(A)$ is a constant it can be ignored during optimization. Alternatively, the posterior probability for every possible realizations of τ and θ_M (H_i) can be calculated. This identifies not only the H_i that is supported best by the data, but allows us also to assess how much better the support is compared to the alternative hypotheses [139]. However, it is easy to see that this is feasible for only a very limited number of sequences (see Section 4.1). Thus, Markov chain Monte Carlo (MCMC) simulations are used to estimate the posterior probabilities [105].

Imagine that the individual H_i comprise points in a landscape and $P(H_i|A)$ corresponds to their respective (unknown) altitude. A MCMC simulation is similar to a walk through this landscape that visits the individual points. This walk, however, is not totally random, but guided in a way that higher points are visited more often than lower ones. Thus, when the walk is finished an altitude profile of the landscape is generated from the number of times a particular point was visited. In practice, MCMC simulations work the following way. Starting from any H_i the transition to a new hypothesis H_j, e.g. a new tree topology, is proposed with a probability $q(H_i, H_j)$. This proposal is then accepted with probability:

$$\min\left(1, \frac{P(A|H_j)P(H_j)q(H_i, H_j)}{P(A|H_i)P(H_i)q(H_j, H_i)}\right) , \tag{14}$$

otherwise remaining at H_i. If H_j is supported better by the data than H_i, then H_j is always accepted. Otherwise, H_j is accepted with a probability that depends on how much worse the support of H_j is compared to H_i. The latter option ensures to escape from local optima (see Section 4). If the transition is accepted, H_j will be sampled and the chain moves on. Given that the chain could run for a sufficiently long time, the number of times H_i has been sampled reflects its posterior probability. However, in most cases it is not clear how long a chain should be run. To reduce potential biases of the Monte Carlo estimates, initial sample points are generally discarded [9]. This *burn-in* procedure has the effect that the chain samples only near-optimal hypotheses. Moreover, one samples only every 1000th hypothesis to generate more or less independent samples [46]

Today, more sophisticated MCMC simulations are performed that use several Markov chains whose "temperatures" differ [57, 77]. So-called "hot" chains have a high acceptance probability of inferior transition proposals. To stay in the above picture, they are used for a more global exploration of the landscape since their affinity to areas of high altitude is low. In contrast, "cold" chains with their low acceptance probability of inferior hypotheses are used for a thorough exploration of local areas in the landscape. Hypothesis sampling is done only from the cold chain. However, from time to time, the temperatures of the chains are swapped such that a hot chain is turned into a cold chain and *vice versa*. However, many more variants of MCMC sampling of phylogenies exist and the field is quickly evolving [33, 74–76, 95].

3.6 Rooting Trees/Molecular Clock

So far we have introduced various methods of inferring the relationships between sequences (or taxa). Unfortunately, most of the methods described above lack an inherent criterion for assigning directionality to the evolutionary process. As a consequence, they are unable to identify the root of a phylogenetic tree. To obtain a rooted tree, nevertheless, it is required (and possible) to add supplementary information into the tree reconstruction procedure.

3.6.1 **Outgroup Rooting**

Among the various methods for rooting a tree, it is most intuitive to divide the taxa into two subgroups: a monophyletic ingroup, i.e. taxa that share a common ancestor to the exclusion of all other taxa in the dataset, and an outgroup, whose more distant relationship to any member of the ingroup is either known or at least reasonable to assume (Figure 11a). It is then straightforward to conclude that the node that joins the outgroup to the ingroup represents the root of the ingroup subtree (r_{subtree} in Figure 11) [110, 140]. Though simple, this approach requires some considerations. Despite their clear position outside the ingroup, outgroup taxa should be as closely related to the ingroup taxa as possible. This will increase the probability of

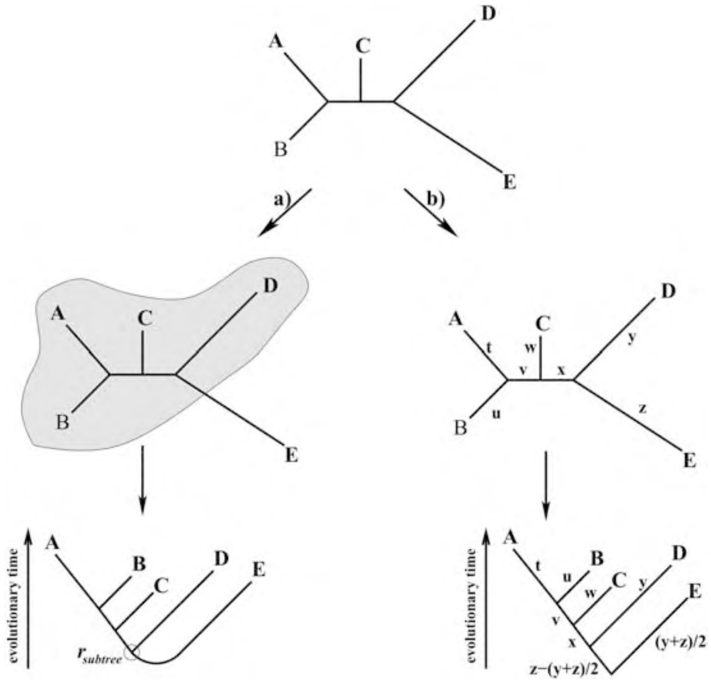

Figure 11 Two alternative principles for rooting phylogenetic trees. (a) Outgroup rooting. The set of taxa A–E is divided into an ingroup (shaded in grey) and the outgroup, taxon E. The node that joins the outgroup to the ingroup represents the root of the ingroup-subtree (r_{subtree}). The root of the entire tree, i.e. the common ancestor of all taxa, must be located somewhere on the outgroup branch. However, its exact position remains unknown. (b) Distance-based rooting. t to z denote the lengths of the individual branches in the tree. The root of the entire tree is identified as the midpoint of the path connecting the two taxa with the largest evolutionary distance.

reliably identifying homologous sequence positions using standard alignment procedures. Furthermore, it minimizes the risk of misplacing the outgroup due to its large evolutionary distance from the ingroup [99, 127, 154]. In addition to these more general requirements, some additional guidelines exist for rooting phylogenetic trees by an outgroup. First, more than one taxon should be included into the outgroup [100]. Furthermore, different outgroup taxa should be used to check whether the root placement depends on the choice of the outgroup [150].

3.6.2 **Midpoint Rooting and Molecular Clock**

As we have seen, the choice of a meaningful outgroup for rooting a phylogenetic tree can become a considerable problem. This is especially relevant when groups are analyzed whose phylogenetic relationships are unclear. In such cases additional assumptions about the evolutionary process are imposed that help rooting the tree.

Given that per unit of time any lineage accumulates the same amount of sequence changes (molecular clock) the point in the tree that is equally distant from all terminal taxa can be assigned as the root (see Section 3.2). In reality, however, the assumption of a molecular clock is frequently violated. If this is neglected rooting under the clock assumption tends to place the root in a part of the tree that is evolving at a high evolutionary rate. Midpoint rooting slightly relaxes the constraints imposed by the molecular clock assumption. It places the root on the midpoint of the path connecting the two most distantly related taxa in the phylogenetic tree (Figure 11b). Compared to the molecular clock scenario this retains only the postulation that the evolutionary rate has to be the same along the two most divergent lineages in the dataset. Midpoint rooting identifies the localization of the root correctly when this criterion is met [148].

4 Finding the Optimal Tree

So far we have outlined the principles to construct a phylogenetic tree from a set of aligned sequences. However, it still is unclear how to find the tree that reflects the relationships between the taxa best. We can differentiate between two general concepts of searching the tree space comprised by all possible tree topologies for the desired optimal tree: (i) *exhaustive* searches, which guarantee the identification of the optimal tree, and (ii) the computationally less-demanding *heuristic* searches that, however, do not necessarily obtain the globally optimal tree.

4.1 Exhaustive Search Methods

In the conceptually simplest approach, the exhaustive search, each and every possible bifurcating tree in the tree space is evaluated under the selected optimality criterion. The identification of the optimal tree(s) is then straightforward and the computational challenge is limited to exploring all of the tree space. To accomplish this, one starts with the (unique) unrooted tree that connects three randomly chosen taxa from the dataset. Subsequently, the remaining taxa are added in a step-wise fashion, such that the ith taxon is added separately to each of the $2i - 5$ branches of every possible tree for the $i - 1$ previous taxa. Obviously, the addition of every taxon increases the number of possible trees by the number of branches to which the new taxon can be connected [41]. Thus, the total number of unrooted trees for a set of n

taxa is:

$$B(n) = \prod_{k=3}^{n}(2k-5) = \frac{(2n-5)!}{2^{n-3}(n-3)!}. \tag{15}$$

The limitations of the exhaustive search are evident. Already a compilation of 20 taxa, a dataset that is nowadays easily exceeded, requires the evaluation of over 2×10^{20} different trees. This is, and presumably will remain, computationally infeasible.

Branch-and-bound methods [93] provide an alternative approach to finding a globally optimal solution without the need of evaluating all tree topologies. Instead, a guided search in the tree space is performed omitting those subspaces that cannot contain an optimal tree [67]. The rationale is simple and has the only prerequisite that the criterion of tree evaluation, i.e. the objective function F, is nondecreasing when new taxa are added to a particular subtree. If we want to minimize F, then we start with the computation of an upper bound F_{upper}, e.g., we evaluate any arbitrary n-taxon tree. Subsequently, using a three-taxon tree as a primer we recursively reconstruct the possible n-taxon trees. However, as we move along in our reconstruction procedure, i.e. with the addition of more and more taxa into the trees, we compare F of the resulting subtrees with F_{upper}. As soon as F_{subtree} exceeds F_{upper} we know that the search path leads to a subspace which contains trees where F is always larger that F_{upper}. Thus, no further reconstruction is required and another search path is evaluated. Alternatively, if we end up with a n-taxon tree, we store the new tree as candidate and update F_{upper} to the new value. The estimation of F_{upper} is crucial for the computational efficiency. Therefore, a number of improvements have been added to this basic scheme [67, 148]. These refinements are mainly designed to further reduce the exploration of tree space. They include methods for obtaining a near-optimal tree for an assessment of the initial upper bound, as well as schemes for generating a suitable order in which the taxa are added to the subtrees. For instance, by adding divergent taxa first, the length of the initial subtrees is increased, allowing for a quicker identification of subtrees that exceed the upper bound for the tree length.

Despite these improvements, exact searches eventually run into computational problems when data sets become large. For these cases, the considerably faster heuristic methods for tree reconstruction are required.

4.2 Heuristic Search Methods

Heuristic methods for tree reconstruction earn a substantial speed-up in computation time by jettisoning a guaranteed globally optimal solution to the tree search problem. With contemporary software it is possible to reconstruct trees from datasets of more than 1000 taxa (e.g. [63, 107, 141]). Thus, nowadays biological datasets hardly ever reach the computational limits of tree reconstruction software, provided that one is willing to abandon the guaranteed optimality.

4.2.1 Hill Climbing and the Problem of Local Optimization

The problem to find an optimal tree for a set of taxa can again be illustrated by the metaphor of exploring a landscape. A hiker aims to visit the point with the highest altitude in a hilly area. Due to the poor visibility, the highest peak cannot be identified *a priori*. Thus, the hiker remains with the only option to climb any slope he encounters first until he has reached its top. Up there he checks his altimeter and is either confident to have reached one of the highest points in this area and finishes his search or he invests more effort and climbs another hill. This kind of search strategy is called a local search.

Applying this approach to the tree search problem, we start off with any tree and modify it in a stepwise fashion, usually accepting only such modifications that result in an improved tree according to the chosen objective function. At a certain point no further improvement is possible and thus we have reached the top of the hill. At this point we have no means of deciding whether we have found the globally optimal tree or merely a local optimum and an optimization with a different initial tree would obtain better results. Consequently, tree searches based on a local search have to cope with three challenges: (i) the identification of a reasonable tree to start the search with, (ii) the implementation of a stepwise hill-climbing algorithm for the tree search and (iii) the avoidance of getting stuck in local optima that are highly suboptimal in terms of cost.

4.2.1.1 Identification of the Starting Tree

Reasonable starting trees are quickly obtained via so-called “greedy” strategies. The tree reconstruction is divided into several subproblems which are then sequentially solved by always choosing the solution that looks best given the current situation. In star decomposition methods (Figure 12), we begin with an assignment of all taxa to the terminal nodes of a star-like tree. Subsequently, all trees are evaluated that can be obtained by joining any two of the terminal taxa into a new group. The tree that scores best under the chosen optimality criterion forms the basis for the next step. The iteration of pairwise joining and tree evaluation continues until the tree is fully resolved.

Alternatively, we can directly construct a binary tree from scratch by inserting the taxa into a tree in a stepwise fashion (Figure 13) [38]. First, a set of three taxa is used to form a unique binary tree. Next, a fourth taxon is chosen for insertion into the initial tree. Since the taxon can be attached on any of the three branches of the initial tree, we have three possible topologies for the

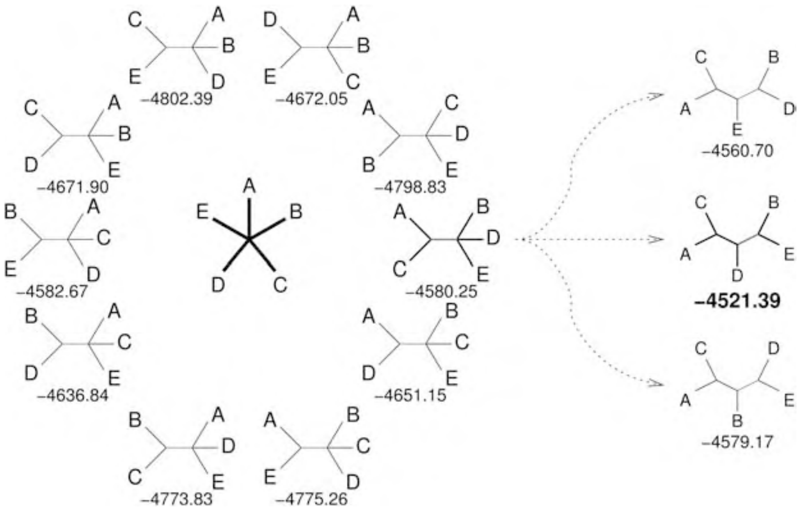

Figure 12 Star decomposition.

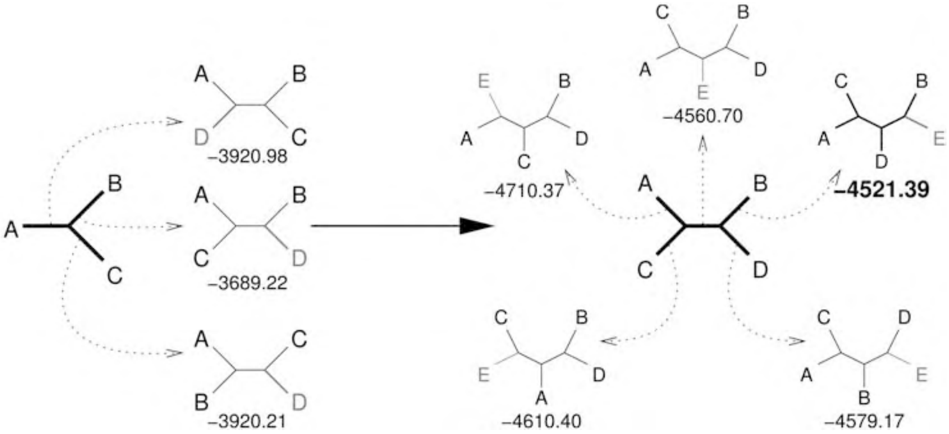

Figure 13 Stepwise insertion.

four-species tree. All of these will be evaluated and the best tree will be stored for insertion of the fifth taxon. The iteration continues until the tree includes all taxa in the dataset.

It is straightforward to see why both star decomposition methods as well as the stepwise insertion procedure are prone to obtaining only locally optimal trees. Any decision concerning the position of a taxon in the tree is fixed for the remaining part of the reconstruction procedure.

4.2.1.2 **Optimization Procedure and Avoidance of Local Optima**

In order to escape local optima, tree-rearrangement methods were suggested that override previous decisions concerning the placement of taxa in the tree. In brief, the initial "optimal" tree is modified such that a part of the tree is excised and re-inserted elsewhere. The trees resulting from such "branch swaps" are evaluated and subjected to one or more acceptance criteria. While a better tree is always accepted, trees inferior to the one already obtained can be accepted under certain conditions [77]. This deviation from the strict hill-climbing approach facilitates the transition to better trees that require more than one rearrangement of the current best tree. Note, the similarity to the MCMC approach (see Section 3.5). Currently, three branch-swapping methods are in use (Figure 14). Nearest neighbor interchange, the simplest approach, takes any internal branch of the tree and swaps two of the four connected subtrees. In this way, a total of $O(n)$ alternative trees are evaluated. (Note that only swapping two subtrees located on the opposite sides of the internal branch leads to the formation of a new tree!) Subtree pruning and regrafting ($O(n^2)$) excises a subtree and regrafts it with the cut surface at any branch on the tree. Tree bisection and reconnection is the most exhaustive way of swapping branches ($O(n^3)$). The tree is bisected along an internal branch and the resulting subtrees are rejoined at any pair of branches.

As noted, any of the branch-swapping methods is capable of guiding the tree-reconstruction procedure out of a local optimum. However, no guarantee is given that this does not simply lead into the next local optimum. Apparently, if the branch swapping is continued for a sufficient amount of time it becomes likely that sooner or later the global optimum will be found. However, how shall we recognize the globally optimal tree once we found it and for how long should we continue the tree search?

4.2.2 Modeling Tree Quality

It is inherent in the heuristic approach that, no matter how long we search, we can never be sure that we have found the globally optimal tree. Thus, we need a concept of tree quality, as we are continuing the search. In most cases it is essentially up to the user how long the search is continued. Either a predefined number of optimization steps or a lower limit by which new trees have to improve can be used as stopping criteria. However, both criteria are arbitrary and a well-founded basis for deciding when to end the search would be desirable. Recently, a method was suggested that is based on the rate of finding better trees during the search [152]. Let $F_1, F_2, \ldots, F_j$ denote the values of the objective function F for the trees found at iteration $1, 2, \ldots, j$. Then the sequence $r(k)$ of record times (i.e. number of iteration at which a better tree is found) is defined by:

$$r(1) = 1,\; r(k+1) = \min\{j | F_j > F_{r(k)}\}. \tag{16}$$

This sequence is used to estimate the point in time, r_{stop}, when to stop the search based on the probability of yet finding a better tree. Using the theory detailed in Refs. [23,120], one can estimate on the fly an upper 95% confidence limit $r_{95\%}$ of r_{stop}. Once $r_{95\%}$ iterations have been carried out and a better tree has not been detected the program will stop. It can then be concluded that with a probability of 95% no better tree will be found during this search. On the other hand, if a better tree is found before $r_{95\%}$ is hit, the $r_{95\%}$ is re-estimated on the basis of the new record time added to the sequence $r(k)$ and the search continues.

4.2.3 Heuristics for Large Datasets

The considerable ease with which DNA sequences are obtained nowadays results in ever-increasing datasets available for phylogeny reconstruction. As a consequence there is a demand for increasing the capacity of tree reconstruction software. One way to satisfy the needs is the development of parallelized versions of tree reconstruction programs, e.g. fastDNAml-based programs [111,141,142], TREE-PUZZLE [132], GAML [14] and MRBAYES [2].

The objectives for further improvements on the computational basis can be quickly summarized. (i) Finding in a shorter time a better starting tree for subsequent optimization. IQPNNI [152] accomplishes this by limiting the number of computation steps to place a new taxon during tree reconstruction. PhyNav [151], on the other hand, reduces the initial tree space by choosing for each group of closely related taxa one representative. From the resulting representative leaf set a scaffold is reconstructed, to which the initially deferred taxa are subsequently added such that an optimal tree is obtained. (ii) Improving the algorithms for tree optimization. For instance, PHYML [63] has implemented a fast algorithm for nearest-neighbor interchange, and RAxML [141] provides an improved version for subtree pruning and regrafting. (iii) The utilization of alternative approaches for tree reconstruction, such as a metapopulation genetic algorithm [96]. (iv) The dissection of the tree-reconstruction problem into a set of subproblems that can be solved on several CPUs in parallel. Some of these improvements are recent developments and it is not clear yet which combination will be optimal for tree reconstruction. In a sense an all-embracing optimal solution might be elusive since it is likely that different combinations will perform optimally on different data sets. Thus, it seems impossible to provide guidelines for when to use what program.

5 The Advent of Phylogenomics

A common problem for the accurate reconstruction of evolutionary relationships among taxa is the limited amount of phylogenetic signal in the data which, in addition, is frequently blanketed by noise. In view of the various genome sequencing efforts it seems trivial to enhance the signal-to-noise-ratio by the simple addition of more data [69]. However, even with the availability of whole-genome sequences, alignments remain limited to the level of individual genes in many cases. Both the rearrangement of genetic information in different taxa and the in part substantial sequence divergence of nonfunctional parts of the genome prevent the generation of meaningful longer sequence alignments. To extend the amount of information, nonetheless, disjoint datasets derived from multiple genomic loci can be combined for the analysis. This intersection of phylogenetics and genomics is referred to as phylogenomics.

5.1 Multilocus Datasets

Two approaches have been suggested for combining multilocus datasets from the same set of taxa for phylogenetics analysis. In supermatrix approaches [126] (also referred to as "total evidence" [89]) all individual sequence alignments are concatenated to form one large superalignment. The tree reconstruction is then based on this superalignment using standard methods. In

Combination level	Combination method	
early	*Supermatrix/ Total evidence*	late	*Consensus tree*	
Figure 15 Two alternative methods to reconstruct a single phylogenetic tree from a set of disjoint alignments. In the early-level combination, the individual alignments represented by the patterned boxes are concatenated first to form a single superalignment. Standard phylogeny reconstruction programs can then be applied to reconstruct a tree from the superalignment. In the late-level combination a phylogenetic tree is reconstructed first for each alignment separately. The individual trees are later combined into a single consensus tree.

this approach, the phylogenetic information present in the individual alignments is combined early in the phylogenetic analysis. Hence, we refer to them as *early-level combination* methods (Figure 15, "early"). Alternatively, the information present in the individual alignments can be combined late in the phylogenetic analysis. Trees are reconstructed first for each alignment separately. These individual trees are then combined at a later step to form a so-called *consensus tree* (Figure 15 "late"). However, in contrast to the concatenation of individual alignments, which is simple text-editing, the combination of trees requires some further considerations.

A frequently used method for computing a consensus from a compilation of trees is based on the principle of identifying the set of compatible splits among these trees. To this end, splits comprise bipartitions of the taxon set that are induced by cutting a tree at any edge. More formally, splits are represented by the symbol "|" (Figure 16). Note that cutting at an external edge creates only trivial splits present in all trees. These are usually discarded from the analysis. Thus, we can induce for any tree with taxon set $\mathcal{N}$ a split $\mathcal{A}|\mathcal{B}$, such that $\mathcal{A} \cup \mathcal{B} = \mathcal{N}$ and $\mathcal{A} \cap \mathcal{B} = \emptyset$.

From the tree in Figure 16 we deduce the splits $\{A, B\}|\{C, D, E\}$ and $\{A, B, C\}|\{D, E\}$ (or shorter $AB|CDE$ and $ABC|DE$) We note that taxon C has changed sides. Thus, if we compute all four possible intersections between the splits only one will be empty. More formally, two splits $\mathcal{A}|\mathcal{B}$ and $\mathcal{C}|\mathcal{D}$ are said to be compatible if one of the four possible intersections $\mathcal{A} \cap \mathcal{C}$, $\mathcal{A} \cap \mathcal{D}$, $\mathcal{B} \cap \mathcal{C}$, $\mathcal{B} \cap \mathcal{D}$ is empty. If two intersections are empty the splits are identical. It is

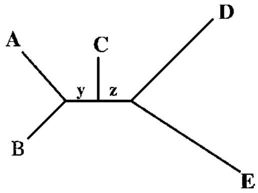

Figure 16 Two nontrivial splits can be derived from this tree. Cutting at the edge y induces the split $AB|CDE$. Cutting at edge z moves taxon C from the right-hand side of the split to the left-hand side and results in $ABC|DE$.

easy to see that splits derived from a tree are always pairwise compatible. On the other hand, a collection of splits that are pairwise compatible fit on a tree. Hence, collections of pairwise compatible splits are another way of encoding trees. For multilocus data the resulting trees are not necessarily the same and, thus, one needs approaches to summarize the results. The easiest form to summarize the result is simply counting the fraction ℓ at which a certain split occurs in a set of trees. If we collect only splits with $\ell > 50\%$, then the resulting system of splits is pairwise compatible and therefore representable as a tree [136] which we call M_{50} or majority rule consensus tree [102] (Figure 17). The cutoff value ℓ can of course be raised to construct more stringent majority consensus trees M_ℓ [102].

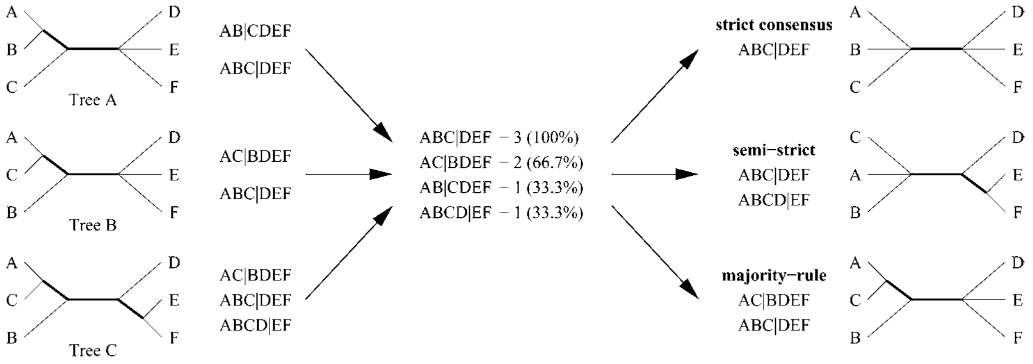

Figure 17 Examples for consensus methods to summarize a set of trees with identical taxon sets: strict (M_{strict}), semi-strict ($M_{\text{semi-strict}}$) and 50% majority rule consensus (M_{50}).

More restrictive cases of majority consensus are the strict consensus M_{strict} [122] that incorporates only splits present in all trees, and the semi-strict consensus $M_{\text{semi-strict}}$ [15] that contains all splits which are not contradicted by any split from the input trees (Figure 17). Many further methods exist for generating a consensus tree (e.g. Refs. [1,19,81,133]).

The application of consensus methods extends beyond the combination of trees from multilocus datasets. In principle, they can be used to summarize any set of trees, e.g., derived from Jackknife [106] or Bootstrap analysis [35, 44], sampled from MCMC simulations [77], or obtained by randomized input orders [144] to assess the reliability (or uncertainty) in the reconstructed trees.

5.2 Combining Incomplete Multilocus Datasets: Supertrees and their Methods

Consensus methods have one serious limitation – they are restricted to trees of equal size and taxon sets. The mutual coverage of currently available gene sequences and taxa is far from being satisfactory [32]. Thus, consensus methods are only applicable to very special and restricted multilocus data. This results in a trade-off between the number of taxa and the number of loci used in an analysis. Thus, one can study either many loci with only few taxa or vice versa. This situation will improve as more sequence data accumulate, especially in the wake of completely sequenced genomes. However, incomplete data will still remain simply because not all genes are present in the genomes of all taxa. Consequently, the question emerges of how to incorporate multiple incomplete datasets into phylogenetic analysis.

In principle, similar strategies are applicable as outlined in Section 5.1. Supermatrix methods use concatenated alignments. However, this requires that tree reconstruction methods must be able to handle the missing data. Simply discarding alignment positions with gaps would leave the user with only completely sampled loci or even no data at all.

When the data is combined at a late level in the analysis, several strategies are feasible. Methods have been proposed to combine separately reconstructed overlapping (typically rooted) trees of the different loci into one so-called supertree [11, 60] (Figure 18). Supertree approaches can be divided into two classes: agreement supertrees [12] and optimization supertrees [155].

5.2.1 Agreement Supertrees

Agreement supertree methods reconstruct a supertree based on those groupings that are shared or at least are uncontested among the set of rooted source trees [12]. This reflects the assumption that all source trees can in principle be obtained simply by pruning different sets of branches from one large tree, the parent tree, i.e. the source trees are compatible. It should, therefore, be straightforward to reconstruct the topology of the parent tree from the topologies of the source trees. Unfortunately, different parent trees may frequently lead to the same set of partial trees. In other words, agreement supertree reconstruction may result in different parent trees. The first supertree method available [60] was designed to find all possible parent trees

Combination level	Combination method	
early	*Supermatrix/ Total evidence*	 Alignment 1 Alignment 2 Alignment 3 Superalignment Tree
late	MinCut, ModMinCut	 Alignment 1 Alignment 2 Alignment 3 Rooted triplets Partial trees Supertree
late	*MRP, MRF*	 Alignment 1 Alignment 2 Alignment 3 Matrix representation Partial trees Supertree
late	*Quartet-based supertree*	 Alignment 1 Alignment 2 Alignment 3 Quartets Partial trees Supertree
medium	*Superquartet puzzling (SQP)*	 Alignment 1 Alignment 2 Alignment 3 Superquartets Ouartets Tree

Figure 18 A number of different methods to construct a single phylogenetic tree from a set of alignments with incomplete, but overlapping taxon sets. In early-level combination all alignments are concatenated into one large (super)alignment (or supermatrix, missing sequences are filled with gaps) from which the tree is reconstructed. In late-level combination the (typically rooted) trees are decomposed into sub-structures like rooted triplets (to obtain common nestings) or quartets, or are re-coded into a binary matrix representation (see Figure 19). These are then used to reconstruct a supertree. In medium-level combination with SQP the data is combined via quartets computed from each alignment. The resulting superquartets are then amalgamated into an overall tree.

for a set of partial trees and compute the strict consensus from the different parent (see Section 5.1). The resulting supertree, however, displays only those bipartitions that are supported in all parent trees, but some information about the structure present only in a fraction of the parent trees might be concealed.

Thus, subsequent approaches like OneTree [17] returned only a single possible parent tree as the supertree. Obviously, the strict requirement of the source trees being compatible severely limits the applicability of these supertree methods. Any real application leads to source trees that are incompatible for a variety of reasons, one of which is just by chance. Thus, subsequent agreement supertree methods, such as the MinCut Supertree algorithm [135] or the ModMinCut Supertree algorithm [112] aimed to overcome the requirement of compatibility. In brief, they introduced a weighting of the links between taxa (i.e. common occurrence in the same subtrees) during the reconstruction of supertrees, such that the weight of a link increases the more source trees display this link. Subsequently, if a subtree cannot be resolved further due to incompatible source trees, the subtree is resolved by pruning those links with the lowest weight (MinCut) greedily. Furthermore, the ModMinCut Supertree algorithm [112] aims to keep links that are uncontradicted, even if they are established only by a single input tree, which would cause the MinCut Supertree algorithm to discard it. Further agreement supertree methods have been suggested recently and a comprehensive overview is given in Refs. [10,12].

5.2.2 **Optimization Supertrees**

Here, the set of input trees is decomposed into smaller entities. These entities serve as input to reconstruct an overall tree based on an objective function.

Matrix representation methods are one example. Prior to constructing the supertree, the rooted input trees are encoded into a binary matrix. Typically each internal node in the (rooted) input trees is encoded either by its adjacent subtree (Ragan/Baum scheme [7, 119], Figure 19a) by assigning "1" to taxa within the subtree and "0" otherwise, or its adjacent sister groups (Purvis' scheme [118], Figure 19b) assigning "0" to the taxa in one sister group and "1" to the other. All other and missing taxa of the tree are assigned "?". The obtained matrix representation of the input trees is then used as input alignment to reconstruct a supertree (Figure 18). For this purpose, various optimizing algorithms can be applied, such as (i) parsimony (MRP [7, 119]), which is to date the by far most common method, (ii) distance-based methods (MRD or average consensus method [94]), and (iii) finding the optimal tree which requires the least changes between ones and zeros (flips) to be congruent with the matrix (MRF [22]).

As an alternative to the matrix representation method, quartet-based supertree methods make direct use of the topological information in the input trees. To this end, the source trees are decomposed into quartet trees, which then serve as building blocks to reconstruct of the supertree [115, 121] (Figure 18).

Figure 19 For matrix representation methods like MRP a set of rooted input trees are encoded into a binary matrix. Each internal node (here 1–6) forms a column in a "binary" matrix. In the coding scheme of (a) Baum and Ragan a taxon that is located in the subtree associated to the current internal node is assigned "1", and a "0" otherwise. Missing taxa get the character "?". (b) In Purvis' scheme only adjacent sister groups are encoded to compensate for different tree sizes. Taxa connected to one subtree are assigned "1", those of the sister subtree "0". Missing taxa and those located root-wards are assigned the character "?".

5.2.3 **The Supertrees/Consensus versus Total Evidence Debate**

Alternative approaches to reconstruct trees from incomplete multilocus data ultimately invoke the debate whether supertree/consensus methods are superior to a supermatrix approach [10,13,24,108], or *vice versa* [34,55,89,90]. Meanwhile a number of points of critique have been raised against either approach, as have advantages. The predominant critique on the supermatrix (total evidence) approach addresses the issue of choosing an evolutionary model and its parameters such that the various evolutionary constraints imposed on the different concatenated datasets are reflected. On the other hand, supertree methods are criticized for their careless treatment of information provided by the data. Usually, the underlying sequence data is discarded prior to combining the input trees. Thus any information not represented by the tree topology is inevitably lost. Furthermore, supertrees carry the risk of possible unwanted data duplication and weighting [54,56], especially if tree topologies have been collected from the literature.

5.2.4 **Medium-level Combination**

Based on the above criticisms, a third level of dataset combination has been proposed recently [133], which takes an intermediate position between the (late) supertree and the (early) supermatrix approaches. Thus, we call it medium-level combination. The so-called superquartet puzzling algorithm (SQP [133]) combines the data on the level of four-taxon (quartet) trees. These so-called superquartets are then used as building blocks in the reconstruction using a voting scheme and a construction algorithm that is aware of missing data. SQP allows the application of evolutionary models fitted to each locus separately. Furthermore, it uses the phylogenetic information in the sequences both for combining the data and in the reconstruction of the final tree. Thus, SQP tries to combine known advantages of supermatrix and supertree methods. In addition, SQP can use datasets without defined outgroups or other information where the root has to be placed, which is generally required by most other supertree methods.

6 Phylogenetic Network Methods

By the nature of the biological data, the tree-reconstruction methods presented so far are only approximate methods. For any sufficiently large dataset, the four-point condition (Eq. 6) introduced in Section 3.2 is frequently not fulfilled. In such cases either the assumption of the underlying data evolving according to a (single) tree is not valid or methodological shortcomings disguise the tree-like evolution of the data. A number of reasons why the evolutionary relationships of DNA sequences might not resemble a tree (both methodological and biological) have been outlined earlier in this chapter (see Sections 1.2.1 and 5.1). Irrespective of the cause for the nontree-likeness of the phylogenetic signal in the data, it is obvious that coming up with a single tree is a feature of tree-reconstruction methods that might not be always desirable.

In the case of conflicting evolutionary signals in the data, a tree might not be the appropriate form to representing the phylogenetic relationships for a set of sequences. Thus, a series of algorithms have been proposed that are useful additions a to tree-based analysis. These methods can visualize to some extent conflicting alternative taxon groupings that cannot be represented by a single tree [6]. Nowadays, such algorithms are subsumed under the notion of (phylogenetic) network methods [116].

6.1 From Trees to Split Networks

6.1.1 Split Systems and their Visualization

Recall the idea of representing a tree by a set of *splits* introduced in Section 5.1. By definition, splits derived from a single tree are always compatible and, in turn, a tree can be reconstructed from a set of compatible splits. In order to combine phylogenetic information present in a set of trees based on sequences from various genetic loci the collection of splits observed in the individual trees can be collected and analyzed. Usually, not all splits are compatible and thus *strict* or *majority-rule consensus* trees are applied to filter the set of splits prior to tree reconstruction.

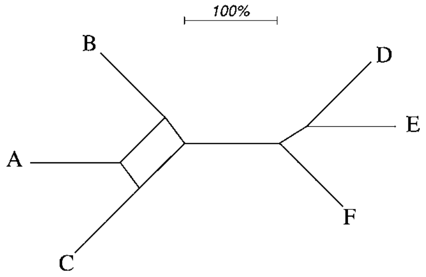

Figure 20 Consensus network representing all four splits collected from the three input trees in Figure 17. Branch lengths are drawn relative to the percent occurrence in the input trees. The compatible splits $ABC|DEF$ and $ABCF|DE$ form the tree-like branches in the right part of the graph, while the pairwise incompatible splits $AB|CDEF$ and $AC|BDEF$ form the net structure on the left. Note that the contraction of one set of parallel branches each obtains the corresponding tree responsible for the incompatible split.

One way to visualize incompatible splits present in the data goes along the lines with these consensus methods. Instead of stopping at the 50% cutoff which guarantees that the outcome is, in fact, a tree, one keeps adding less frequent splits obtained from a set of input trees to the split system, i.e. the set of splits. More generally, the application of a cutoff value r (analogous to ℓ in consensus trees) allows the selection of any split system S_r that is present in at least a portion r of all input trees. Pushing r below 50% ($r \leq 0.5$) may lead to a splits system that no longer conforms to a tree. Visualizing such incompatible splits systems provides insights into the extent and pattern of heterogeneity of the phylogenetic signal in the data. In such a network, one split is represented either by a single branch or by parallel branches, indicating incompatible splits as in Figure 20, where $AC|BDEF$ and $AB|CDEF$ are incompatible.

It has been shown (see Ref. [73]), that a split system S_r with cutoff fraction r does contain any subset larger than $\lfloor 1/r \rfloor$ splits which are all pairwise incompatible. S_r is said to be $(\lfloor 1/r \rfloor)$-compatible. The split system in Figure 20, for example, is 2-compatible, containing the subset of two pairwise incompatible splits $AC|BDEF$ and $AB|CDEF$. All split systems S_r with $r > 0.5$ are 1-compatible, which means that there are no incompatible splits and, hence, the resulting topology would again be a tree.

The amount of pairwise incompatible splits obviously determines the complexity of the network containing them. Median networks [4, 72] can contain cubes of dimension up to $\lfloor 1/r \rfloor$, and might thus be utterly complex. For example, a split system $S_{0.25}$ can be 4-compatible and, hence, needs four dimensions to be visualized.

Median networks are a very general type of network which can be reconstructed from the binary encoding of a split system. To this end, for each split taxa on one side of the split are assigned ones, those on the other side zeros. Then, intermediate states (representing the inner nodes in the median network) are computed from the binary sequences in a parsimonious fashion (see Section 3.1). It has been shown [4,72] that by pruning branches from a median network one can extract all the most parsimonious trees for the split system. Due to the fact that median networks can grow arbitrarily incomprehensible, less-complex approximations are often applied. Split graphs [6, 30, 31], for example, attempt to filter the splits and branches drawn, to derive a planar graph, i.e. a graph without intersecting edges. Refer to Ref. [72] for a more detailed overview.

6.1.2 Constructing Split Systems from Trees

Commonly, split systems are collected from a set of input trees with equal taxon sets as they are obtained, for example, from Bootstrap analysis or MCMC sampling (see Section 3.5). Similar to consensus trees (see Section 5.1), such split systems are visualized as so-called *consensus networks* [70]. Such consensus networks (see Figure 20) visualize the area and the extent of contradiction of the phylogenetic signal found in the input trees. However, like supertrees (Section 5.2), network reconstruction is not restricted to trees with equal taxon set, but can also be done from overlapping trees using the Z-closure method [78]. In accordance to the amalgamation of trees to supertrees, such networks are then called “super-networks” (Note, that the “super” prefix in super-networks does not follow the same notation as in supertrees, super-alignments, or superquartets, since is not network constructed from networks, but from trees.)

6.1.3 Constructing Split Systems from Sequence Data

Although applications such as consensus networks and super-networks were suggested quite recently, one should note that the basic idea of representing evolutionary processes by networks rather than trees is not new.

In contrast to approaches for network reconstruction based on collections of splits derived from trees, distance-based methods including split decomposition [6] or Neighbor-Net [18] have been suggested for constructing split systems directly from the data.

Applied to viral sequences from Ref. [124], methods like split decomposition and Neighbor-Net can easily identify the presence of the three recombinant HIV strains SE7812_2, UG266 and VI1310-1.7 (Figure 21b and c). These would have been wrongly classified based on the result of a tree reconstruction method like BioNJ (Figure 21a). To avoid such missinterpretation of the data, phylogenetic networks should be taken into account at early stages of the analysis.

Programs like SplitsTree [80], T-REX [101] NETWORK [3] and Spectronet [72] provide easy to use means that can be readily applied to a phylogenetic

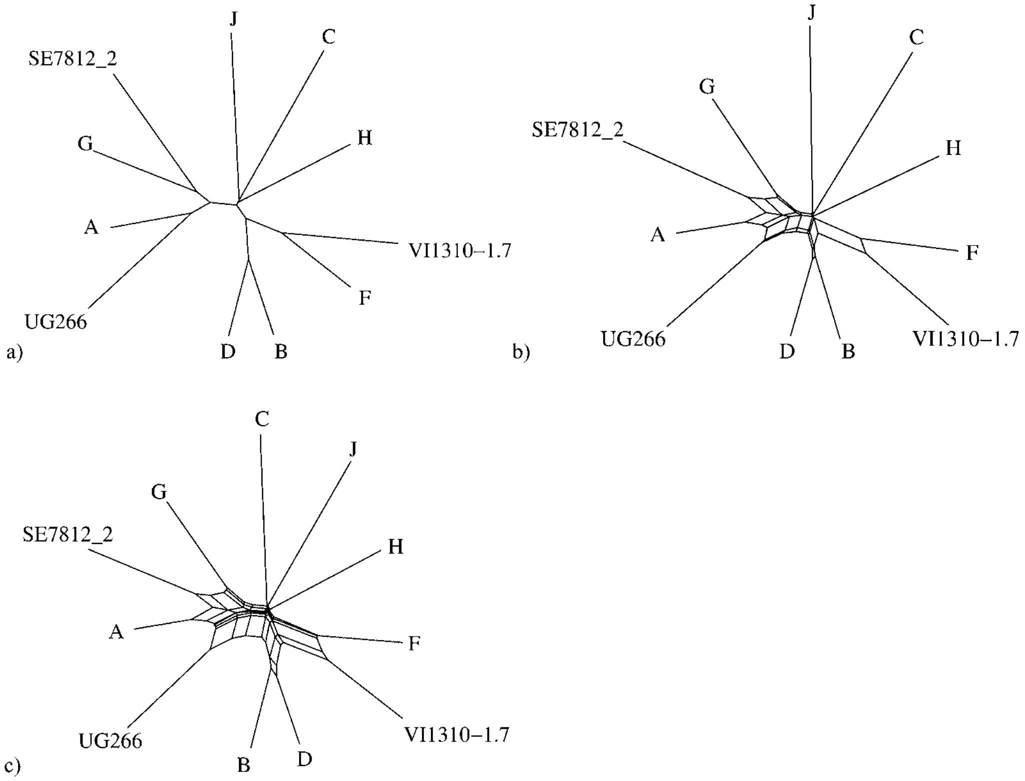

Figure 21 Results for a set of HIV dataset from Ref. [124] containing reference strains (A, B, C, D, F, G, H and J) together with three recombinants (SE7812_2, UG266 and VI1310-1.7). (a) BioNJ tree (eight splits), (b) split decomposition (14 splits) and (c) Neighbor-Net (19 splits).

analysis. These packages were used to analyze viral data [29, 124], hybridization events [98] and intra-specific data [4], respectively.

It should be noted that such split-based networks provide only a visualization of ambiguities in the data and do not qualify as methods to infer the reasons for the net-like structure [18].

6.2 Reconstructing Reticulate Evolution and Further Analyses

As mentioned above, in the case that different methods, different loci or even just different parts of the very same gene show conflicting phylogenetic signals, various causes might account for the observed conflicts.

One would certainly first check whether the conflicting evolutionary hypotheses are really significantly different [58, 66, 138]. If so, we can envi-

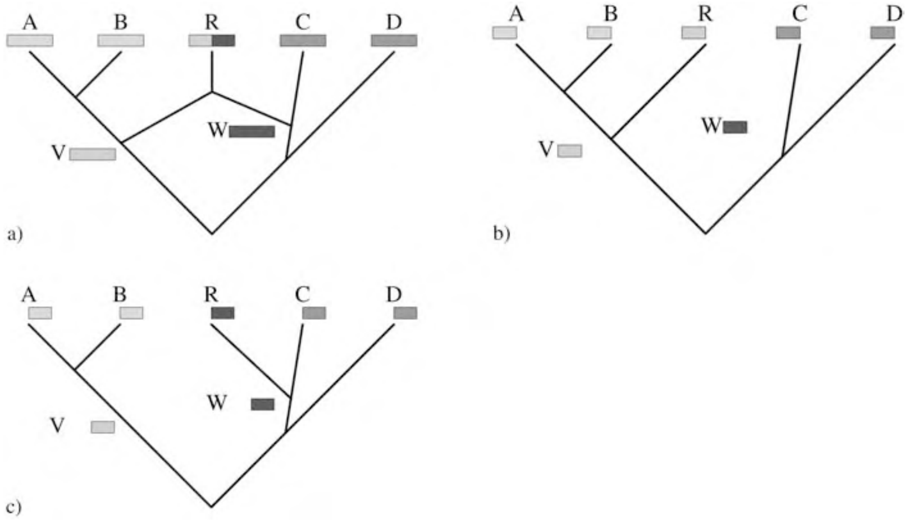

Figure 22 A case of reticulate evolution. (a) The recombination between strain V and W forms the recombinant strain R. The two parts of the sequence reflect different evolutionary histories (b) and (c) of the reticulation.

sion several biological mechanisms to produce reticulations, i.e. network-like evolution. In the particular example of virus evolution, reassortment, i.e. the mixture of viral chromosomes within a cell co-infected by different viral lineages [86], and recombination, i.e. the reciprocal exchange of genomic regions among chromosomes [113, 117] both of which are highly abundant in viruses [52, 125], are two examples. Horizontal gene transfer [8, 25, 62] and genome hybridization or fusion [28, 103, 158] constitute other possibilities. Sometimes reticulations may be simply due to parallel substitutions in different organisms. In such a situation the loops in the network indicate the occurrence of reverse or parallel mutations.

In general, purely split-based networks are not sufficient to illustrate an event of reticulate evolution like the recombination shown in Figure 22, because one cannot represent this evolutionary history as a set of splits, although one could map the separate gene trees. Hence, recently network methods like hybridization networks, recombination networks or galled trees [64, 79] have been suggested to reconstruct reticulate evolution.

The pros and cons of the different algorithms still need to be evaluated. However, the comparison of different phylogenetic networking strategies is not easy. From Figure 21 it is apparent that Neighbor-Net is more liberal in introducing noncompatible splits (19 splits in the Neighbor-Net compared to 14 splits in the split decomposition network and eight splits in a fully resolved tree.) Simulation studies, successfully applied in phylogenetic inference, might be one way to evaluate accuracy and robustness of phylogenetic network methods. To this end a carefully designed experimental setup is required. An alternative approach is the introduction of optimality criteria (least-squares, likelihood) in the network construction process. Unfortunately, the development of phylogenetic networks in a likelihood framework is still in its infancy [143, 146, 153]. Only with such methods is one able to decide whether the nontree-like signals are biologically plausible or are merely an artifact of the reconstruction procedure.

In this chapter, we have only touched upon some phylogenetic network methods. Space limitations do not allow a full account of all existing methods. The pyramidal clustering technique [26] is, like Neighbor-Net, an agglomerative approach. Statistical geometry in sequence space [36] and its descendants [109, 145] are alternative approaches to summarize the extent of tree-likeness in the data without reconstructing phylogenetic networks.

The field of phylogenetic networks will certainly profit from the data produced in whole-genome projects. As independently evolving DNA segments of eukaryotic genomes may display different evolutionary histories, the correct history of the taxa, as carriers of these segments, is probably more adequate. However, before we can reliably do this, we need to distinguish true loops in a network from artificial loops generated by too simple assumptions about the evolutionary process.

5
Finding Protein-coding Genes

David C. Kulp

1 Introduction

Gene finding in genomic DNA sequences is a critical step in the functional annotation of genomes. Over the past approximately quarter century increasingly sophisticated methods have been developed to better understand and catalog the mechanisms of transcription, splicing and translation, and to predict the gene products, be they peptide sequences or RNA genes. With the advent of large-scale sequencing, software programs were developed to automate gene prediction.

In this chapter the common techniques for computational gene finding are introduced. Basic concepts and terminology are given in Section 2. Sections 3–5 discuss feature prediction for both content and signal features, and Section 6 introduces the standard dynamic programming formalism for incorporating multiple features into complete gene structure predictions. Some performance results for *ab initio* gene finding are given in Section 7. Practical gene finding must also consider available experimental mRNA, protein and genomic sequence data. Some of these homology methods as well as other integrative approaches are described in Section 8. Finally, the chapter concludes with some caveats about the practical limitations of automated gene prediction.

2 Basic DNA Terminology

Since one DNA strand is the complement of the other, in DNA analysis only one strand is stored in the databases. Which strand is represented is generally arbitrary and unimportant, but in this chapter the represented sequence is called the forward strand and the implicit complement is the reverse. A DNA sequence is always represented, by convention, in the direction of DNA replication. The left end of the sequence is referred to as upstream or 5′ and the right end is downstream or 3′.

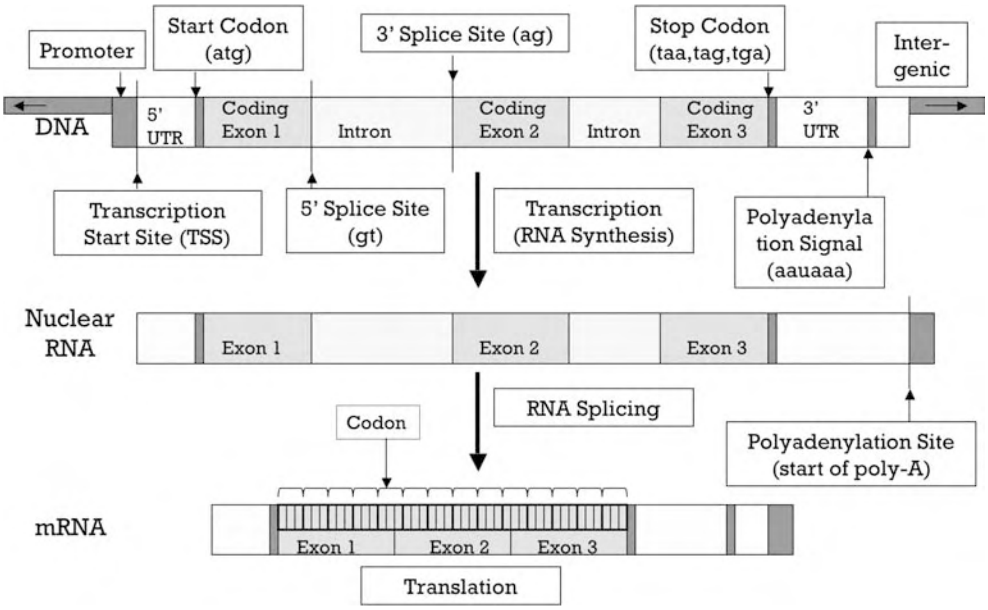

Figure 1 The central dogma of molecular biology in eukaryotes. A primary transcript region starting at the promoter is copied into pre-mRNA. The transcript is then spliced in eukaryotes to produce the mature cytoplasmic message. The message is translated into peptides. Note that codons may span splice boundaries. Although not shown in this diagram, splicing is possible in the untranslated regions.

For the purposes of this discussion, a gene is defined as the subsequence of genomic DNA that is transcribed by RNA polymerase – usually Pol II when referring to eukaryotic transcription. The gene structure further includes those features on the mRNA involved with splicing and translation, i.e. the splice and translation start and stop sites. For convenience, all of these features are usually annotated with respect to the original DNA sequence as shown in Figure 1. Transcription occurs on single-stranded DNA, on either the forward or reverse strand. By convention the gene structure is annotated on the informational or sense strand (not the template or antisense strand).

Although transcription has been observed to occur at the same physical genomic position on both strands, we usually assume for simplicity that there are no overlapping transcripts. Automatic gene finders must evaluate both the explicitly represented sequence and the implicit reverse complement – this is usually performed simultaneously.

Predicting genes in eukaryotes is considerably more challenging than in prokaryotes because of splicing. Most transcribed mRNA (pre-mRNA) in eukaryotes is spliced into smaller sequences called processed or mature mRNA through the excision of introns by the spliceosome complex, leaving a set of concatenated exons to be passed to the ribosome. The introns are located between the 5′ and 3′ splice sites, also called donor and acceptor sites. At least 99% of 5′ splice sites begin with "GT" and 3′ splice sites end with "AG", called the consensus dinucleotides.

The spliceosome concatenates exons separated by often long introns. Each exon can be as short as a few nucleotides. Thus, while gene finding in prokaryotes involves indentifying a single contiguous coding sequence, gene finding in eukaryotes requires a combinatorial search of many different possible exons.

3 Detecting Coding Sequences

Identification of the protein-coding domain sequence (CDS) between the start and stop codons is of great interest because the translated peptide product can be directly inferred from the CDS. The ribosome, after binding to the mRNA, begins translation at an AUG triplet (ATG in DNA). The ribosome matches these triplets, called codons, consecutively with tRNAs adding deterministically one of the 20 amino acids to a polypeptide sequence for each codon according to the genetic code (Table 1). The translation process is terminated when one of three stop codons (UAA, UAG or UGA) is encountered. Thus, the CDS on the DNA sequence is composed of a sequence of codons that code for

Table 1 The standard genetic code showing codon and amino acid single- and three-letter abbreviations

TTT	F	Phe	TCT	S	Ser	TAT	Y	Tyr	TGT	C	Cys

GTG	V	Val	GCG	A	Ala	GAG	E	Glu	GGG	G	Gly

Prokaryotes also use an additional GTG initiation codon. There are other rare genetic codes as well. See http://www.ncbi.nlm.nih.gov/Taxonomy/Utils/wprintgc.cgi.

the corresponding protein, beginning with the start codon and ending with a stop codon.

Note that the notions CDS and exon are not synonymous, although frequently exchanged in gene-finding literature. Exons refer to those DNA segments that are not excised by splicing, i.e. all of the sequence corresponding to the mature mRNA. Exonic sequences can be either coding (CDS) or untranslated regions (UTRs). A CDS typically begins and ends in the middle of an exon. Introns are possible upstream and (rarely) downstream of a CDS. Splicing need not occur on codon boundaries.

3.1 Reading Frames

There are six possible reading frames along double-stranded DNA – three on each strand. A CDS beginning translation at position i is in reading frame $f = i$ modulo 3. Reading frames on the opposite strand are conventionally labeled as $-f$. We say that a codon is in frame if its position modulo 3 is the same as the CDS in question. In particular, an in-frame stop codon terminates a CDS, but out-of-frame stop codons have no effect. A sequence of consecutive codons between a start and stop codon is called an open reading frame (ORF).

Genes in prokaryotes are relatively easy to identify by searching for ORFs of a minimum length, say 300 nucleotides. In random DNA, an in-frame stop codon is expected about every 21 codons (63 nucleotides) and the chance of an ORF longer than this becomes increasingly unlikely. Small ORFs can truly be coding, especially in eukaryotes, due to splicing and asymmetric nucleotide distributions can easily allow for long ORFs, requiring more sophisticated pattern recognition methods, as described below.

3.2 Coding Potential

The distribution of codons is subject to evolutionary and biophysical constraints. The G + C content (fraction of G and C nucleotides) among genomes varies, which affects codon frequencies for different organisms. Amino acid frequencies are not uniform and arrangements of amino acids in polypeptides are, of course, also not random. These effects, as well as other DNA and mRNA structural and processing constraints, lead to biases in the frequency and ordering of codons, called codon bias. Moreover, basal expression levels have been observed to relate to the levels of available tRNAs, so codons in higher expressed genes are more significantly biased towards the abundant tRNAs [27]. Synonymous codon bias, closely related to codon bias, describes the differing frequencies of codons coding for the same amino acid.

Codon usage tables that list codon frequencies have been compiled for many organisms (http://www.kazusa.or.jp/codon). To test for coding potential is to assess whether the frequencies of codons in a candidate ORF are statistically similar to the codon usage for the organism and these measures are typically the heart of all gene-finding programs. For example, about 2.1% of human codons are "ATC" and among its class of synonymous codons that encode isoleucine ("ATC", "ATT" and "ATA"), "ATC" is used about 47% of the time.

A representative method of this class of coding potential measures is the Gribskov codon preference statistic [26]. The relative frequency of a codon, C, among its class of synonymous codons, $f_{\text{class}(C)}(C)$, is computed using a codon-usage table derived from highly expressed genes and compared to the relative frequency of the codon, $g_{\text{class}(C)}(C)$, in a background model according to position-independent nucleotide composition:

$$S(C) = \log\left[f_{\text{class}(C)}(C)/g_{\text{class}(C)}(C)\right] \ .$$

For example, suppose the codon, C, is "ATC", and its codon usage is as above and the frequencies of A, T, C and G in the query sequence are (0.21, 0.21, 0.29, 0.29). Then $S(C = \text{ATC}) = \log(0.47/0.41) = 0.14$. The normalized sum of log-likelihood ratios over a window w (of, say, 25 codons) provides an indication of relative coding potential and expression. By convention, the normalized sum is exponentiated to generate the final Gribskov statistic. Such methods are often used in plots for preliminary visualization of a novel genomic sequence and are sometimes sufficient to support manual gene prediction in prokaryotes (Figure 2).

Measures such as the Gribskov codon preference statistic lack consideration for the positions of codons relative to each other. Observed dependencies among adjacent codons led to the proposal of several measures based on pairs of codons (dicodons). In an important benchmark paper, Fickett and Tung [22], assessed most of the extant methods and their conclusion was that dicodon (or hexamer, more generally) measurements were superior to all other methods.

The three-periodic fifth-order Markov model is a particularly appealing formulation of hexamer statistics that is widely used in modern gene finders. Proposed by Borodovsky [7], such Markov models are used to represent the probability distributions of the four possible nucleotides at each of the three base positions in a codon. Suppose we are interested in a codon beginning at position i composed of individual nucleotides b_i, b_{i+1} and b_{i+2}. Three separate Markov models are defined: $P_0(b_i|b_{i-5}\dots b_{i-1})$, $P_1(b_{i+1}|b_{i-4}\dots b_i)$ and $P_2(b_{i+2}|b_{i-3}\dots b_{i+1})$. Each probability distribution is generated from simple frequency counts of each possible nucleotide in the context of the previous five nucleotides. Training sets of millions of codons are available from annotated

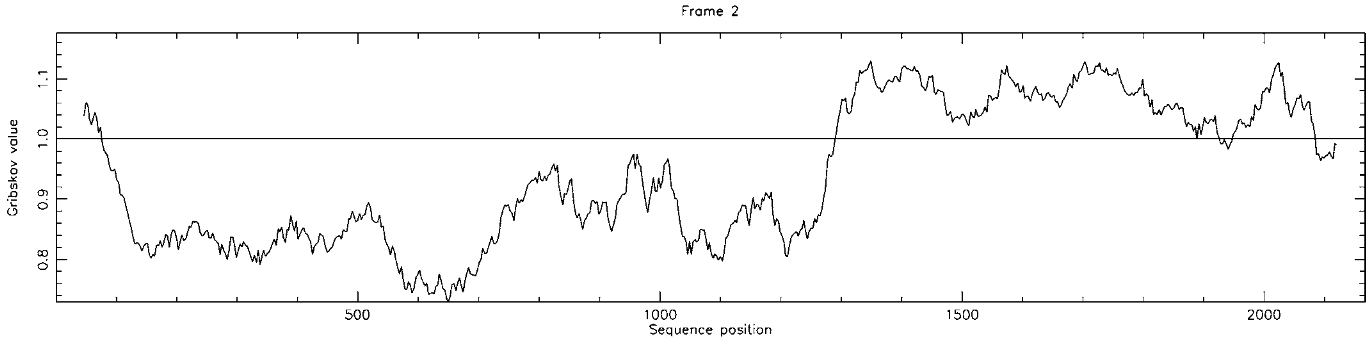

Figure 2 Codon bias computed by the Gribskov codon preference statistic. Frame 2 of the *Pseudomonas amiC* gene as generated by the program syco from the EMBOSS software collection. The region starting around position 1300 has consistently high coding potential, suggesting a coding region.

GenBank sequences. Assuming conditional independence, the probability of a codon is just the product of the probabilities of the individual bases b_i, b_{i+1}, and b_{i+2}. A separate null model is defined for noncoding bases, $P_{\mathrm{nc}}(b_i|b_{i-5}\dots b_{i-1})$. A log-likelihood ratio score for a codon starting at i is then:

$$\sum_{f=0..2}\left[\log P_f(b_{i+f}|b_{i+f-5}\dots b_{i+f-1}) - \log P_{\mathrm{nc}}(b_{i+f}|b_{i+f-5}\dots b_{i+f-1})\right] .$$

These scores can be accumulated over a window as with the Gribskov measure.

To obtain accurate estimates, a fifth-order Markov model requires sufficiently large numbers of observations in each context. This is not always available and, in some cases, even longer contexts may be plentiful. Salzberg describes a variant that uses different context length depending on the available data [66].

The fact that statistics related to codon usage aid in the identification of CDS and also in the estimation of expression levels indicates an inherent classification weakness in the use of codon statistics, i.e. that genes with low expression levels are more difficult to find because their statistics are weaker. Low expressors are more difficult to detect experimentally as well, further biasing the codon statistics gathered regarding known genes.

4 Gene Contents

In addition to the statistical regularities in CDS, other discriminating properties of coding exons and introns have been observed. These features of variable-length DNA sequences are sometimes referred to as content.

For example, noncoding DNA is expected to have a relatively neutral distribution of nucleotides with exceptions such as physical–chemical constraints and the presence of repeats. Thus, models of noncoding DNA have been devised similar to coding potential measures. A simple and common implementation is the use of Markov models for intron and intergenic DNA analagous to the three fifth-order Markov models for coding DNA. The log probabilities of different models can then be compared. Figure 3 shows the distribution of probabilities from fifth-order coding and intron models, and the distribution of the difference in log probabilities.

Guigo and Fickett [29] showed that all content measures are highly correlated with G + C bias. Thus, it is common to compute Markov distributions by partitioning the training data into discrete isochores (extended regions of G + C bias in the genome) based on windowed-G + C content [9].

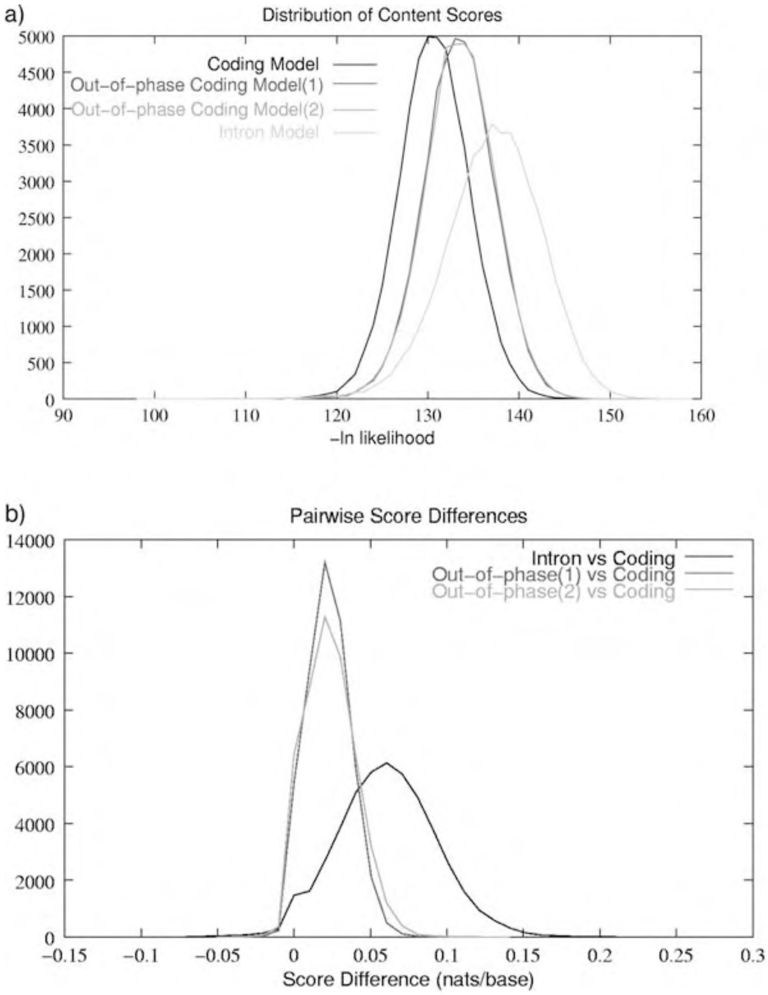

Figure 3 Score distributions for Markov chain models of coding and intronic DNA. Three Markov chains were trained on 53 183 460 coding bases and one Markov chain was trained on 16 149 264 intronic bases from the well-annotated protein-coding exons of *Caenorhabdtis elegans*. For each of 48 124 exons, a 99-nucleotide in-frame coding region was scored using the coding model, two out-of-phase coding models and the intron model. (a) The distribution of log-likelihoods for fifth-order Markov chains. (b) The distribution of differences in log-likelihoods per base of the fifth-order coding model versus the intron and out-of-phase fifth-order models for each coding exon. (Pairwise comparisons with likelihoods from out-of-phase models were only made if there were no in-frame stop codons in the alternative frame.) The implication here is that although the overall distributions for the coding and noncoding models are very similar, a comparison of scores for individual exons shows good separation (i.e. most model score differences are greater than zero). This simply shows that the fifth-order Markov models are reasonably good at classifying coding regions.

The lengths of exons and introns differ – often significantly [32]. Exons follow an approximately log-normal distribution with a mean length of about 140 bases in most eukaryotes, but the typical length of introns varies significantly by organism. Many of the model organisms such as fly and worm have intron lengths within a relatively tight range of about 70 bases – the minimal required intron length for efficient splicing. Mammalian introns are typically much longer than exons due to prolific insertions of repetitive elements; they are rarely less than 100 bases and have a long exponential distribution to 10^6 bases.

5 Gene Signals

Gene structure is defined by the start and stop positions in DNA of exons and CDS. Through laboratory experimentation, molecular biologists have shown that for each of these sites there are necessary, conserved motifs that govern the transcription and translational machinery. With respect to gene finding, Staden [75] distinguished these control sites as signals as compared to variable length content. Signal features loosely correspond to binding sites or special functional patterns recognized by the polymerase, spliceosome or ribosome.

If it were possible to automatically detect all signals independently, then the gene-finding solution would be complete. For the most part, however, no one signal can reliably be detected on its own. Later in this chapter we will learn how to combine these measures along with coding potential to achieve superior gene finding performance. First, we explore a few of the methods for independent signal detection.

5.1 Splice Sites

Degenerate matches to a motif can be detected using a position-specific weight matrix [74]. Weight matrices are commonly used in many biosequence approximate matching problems. A weight matrix is a (2-D) array $W(1 \leq i \leq m, 1 \leq j \leq 4)$ such that $W(i, j)$ is the probability of nucleotide j at position i in a motif of length m. Frequencies can be used to generate these probabilities, priors can be introduced when data is sparse or more sophisticated contexts can be represented such as dinucleotide frequencies (e.g. an order-1 Markov weight matrix at each position resulting in a $m \times 16$ matrix). For example, almost all introns begin with the consensus dinucleotide “GT” and end with “AG”, but the regions around the beginning and end of the intron (the splice sites) have less specific nucleotide patterns. Figure 4 shows examples of weight matrices for splice sites in *C. elegans*.

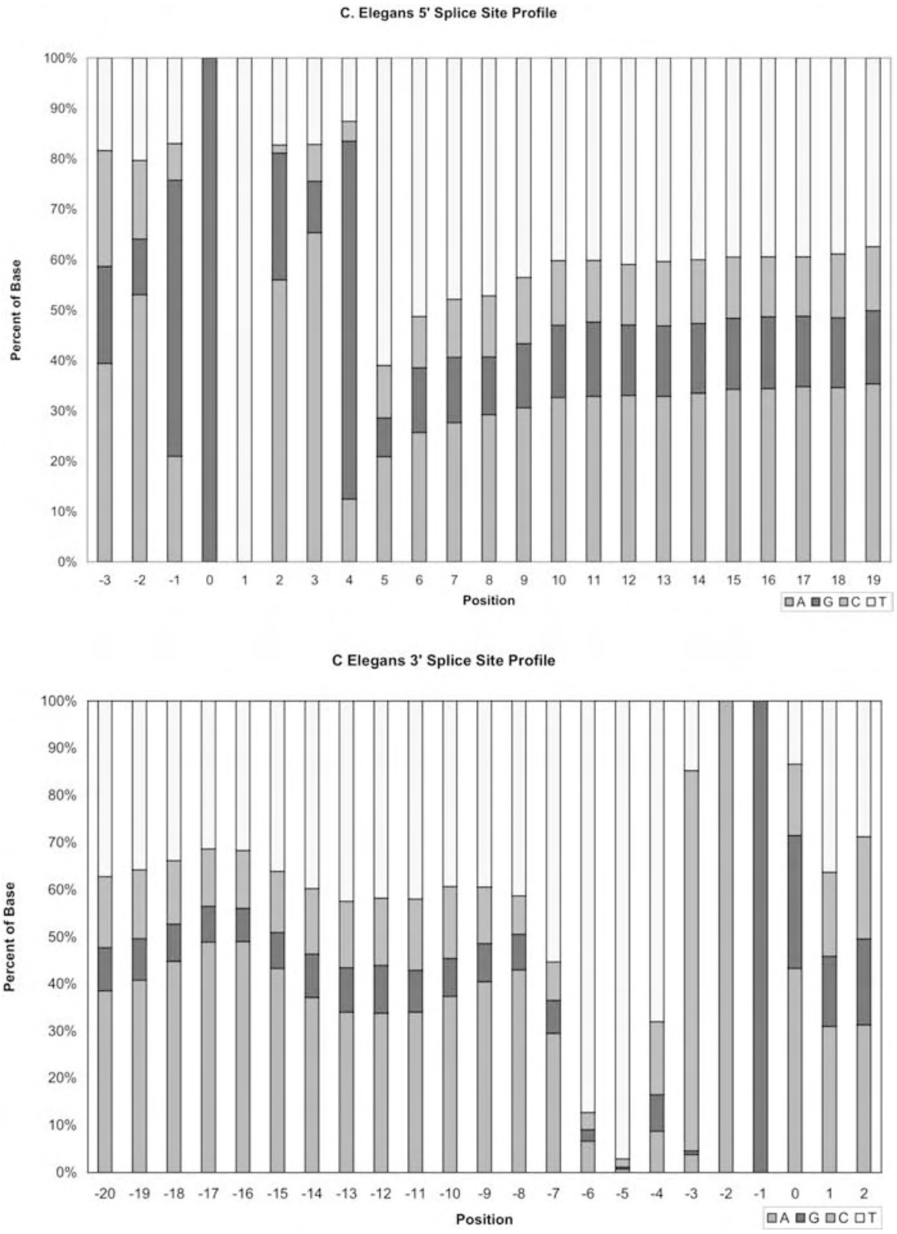

Figure 4 *C. elegans* splice site weight matrices. Windows of 20 bases downstream of the $5'$ exon junction ("GT", the beginning of the intron, is positions 0 and 1) and 20 bases upstream of the $3'$ exon junction ("AG", the end of the intron, is positions -1 and -2) were selected from curated gene sequences [16].

Given any test sequence represented as a 2-D matrix $S(1 \le i \le m, 1 \le j \le 4)$, where $S_{i,j} = 1$ for the nucleotide *j* found at position *i* and 0 elsewhere, then the likelihood of the feature can be defined simple as $\prod_{i=1...m} \prod_{j=1...4} W_{i,j}^{S_{i,j}}$. Stormo presented thermodynamic, likelihood, and information theoretic justifications for the use of weight matrices [76].

Moving beyond the simple weight matrix is the maximal dependence decomposition decision tree (MDD) method that captures local, but nonadjacent dependencies [9]. The MDD method evaluates a set of rules to determine which weight matrix to use to score the sequence. The rules are based on the dependencies between positions in the motif. For example, in eukaryotic $5'$ splice sites, it can be shown that the distribution of nucleotides in the conserved columns $-3 \cdots + 6$ around the consensus GT are most correlated to the nucleotide G in position $+5$. Thus, the training set is partitioned according to the "+5" value into two sets such that the score function for each set is conditionally independent of that nonadjacent position. This leaves only adjacent dependencies or independent positions, which can be easily modeled using conventional weight matrices as above. (Other approaches have been proposed to detect dependencies among nonadjacent bases with similar performance characteristics, e.g. a Bayesian Network structure inference method was proposed by Cai and coworkers [13].)

The primary limitation of weight matrices is the inability to model insertions and deletions. To handle more complex motifs, profile hidden Markov models (HMMs) (see also Chapter 3) and related probabilistic state machine models can be employed in a similar manner as for protein sequences [20,42].

The $3'$ splice site is slightly more complicated because the upstream pyrimidine-rich branch site contributes to its recognition. However, the branch site is variable and so not amenible to fixed-width matrix methods. As a result, many recognition methods have been proposed for splice site recognition that allow for the incorporation of multiple distinct sequence features as inputs (branch site, splice site, intron content, exon content). One of the more effective techniques for combining different sequence features is discriminant analysis in which weights for different features are fitted to maximize the discrimination between true and decoy sites [72,82].

Probably the current leading method for splice site prediction is GeneSplicer – an extension of the MDD metric [59]. Other techniques include neural networks, boolean logic rules, decision trees, support vector machines (SVMs) and many others (e.g. Refs. [8,9,61,73]).

In addition to the conventional splice site recognition, about 1% of splice sites have non-canonical dinucleotides. This is largely ignored in gene finding, but is addressed by Burset and coworkers [11].

In general, recent methods achieve reasonable performance in splice site detection, but are unavoidably burdened by large numbers of decoy sites, resulting in false-positive rates around 5% when recognizing about 90% true splice sites.

5.2 Translation Initiation

Identifying the beginning of translation is perhaps surprisingly challenging. Part of the difficulty is that the database is rife with experimentally unconfirmed start sites. In addition, the signal for start sites tends to be rather weak. In prokaryotes, the Shine–Delgarno motif serves as a binding site for the ribosome preceding the first codon. The consensus motif is AGGAGG, but it can take on short and degenerate forms. Kozak observed that in higher eukaryotes translation usually begins at the first start codon after the transcription start site [41]. However, for the purposes of *ab initio* gene finding, this is usually of little help since the beginning of the transcript is also unknown and cannot be reliably predicted in large DNA sequences without a high false-positive rate [21] (and even the annotated transcription start sites are often wrong due to truncated mRNAs). In vertebrates, a consensus of `gccaccATGg` (start codon in caps) is observed and weight matrices have been developed from reliable start sites using first and second order models similar to approaches for splice sites [2, 40], but these methods are subject to high false-positive rates.

Like with splice site detection, many of the conventional machine learning techniques have been successfully applied including neural networks, linear and quadratic discriminant analysis and SVMs [58, 64, 67, 85]. The most successful independent predictor of translation initiation is an SVM classifier that remarkably identifies almost 100% of start sites with well less than 1% false positives on a standard test set [48].

5.3 Translation and Transcription Termination

Recognizing one of the stop codons (TAA, TAG or TGA) is trivial assuming that the reading frame is known. Conversely, more probable stops are those with high coding potential upstream of the site and low coding potential downstream. The transcript following the stop codon is typically one long exon. Splicing after the stop codon is rare.

Finally, transcription is terminated by a polyadenylation signal with a consensus of `AATAAA` although there are many variants. The motif is small, is not located predictably near other contextual features, is frequently unannotated in the databases and may not even be present. Moreover, it is estimated that in human about half of all transcripts have multiple $3'$ termination sites and these are often imprecisely cleaved [80]. Graber [25] describes a pseudo-probabilistic model for detecting termination in yeast. Again, standard weight matrix and discriminant analysis methods have shown moderate success for detecting the termination site [47,77]. In practice, transcription termination is largely ignored in *ab initio* prediction. Instead, it is often considered sufficient to detect just the gene structure from the start to stop codons.

6 Integrating Gene Features

So far, we have learned that there are different gene features (signals and contents) each with statistically significant discriminative power. There are numerous scoring methods for different features assessed independently, yet we intuit that combining these features is likely to yield better results. However, there is an exponential combination of possible labelings of exons, introns and intergenic regions (i.e. any segment can begin or end at any position). Thus, the gene finder is faced with two major problems: how to effectively combine features and how to efficiently explore the possible gene structures. The solution for both of these problems is using dynamic programming. In some implementations, logical adjacent features are combined into a single score and then a dynamic program is applied.

6.1 Combining Local Features

In the same way that multiple features were used as input to the long list of machine learning classifiers in splice site recognition (Section 5), so too can multiple features be combined to recognize larger functional units. Zhang is a major proponent of this strategy of recognizing exons based on combined information from the flanking signals and content, noting that the *in vivo* recognition of exons in transcription is believed to largely be driven by the interactions of DNA-binding complexes that straddle the exons, according to the exon definition model [5,30]. Zhang has produced a suite of methods for recognizing the $5'$ and $3'$ UTR exons, initial coding exon, internal coding exons and last coding exon using quadratic discriminant analysis, each recognition module combining multiple, different features, with excellent performance [77,83].

The choice of the fundamental functional units of gene recognition differ among gene finding programs. For example, the nucleotide is the basic unit in HMMGene, Genie treats splice sites and coding exons separately, and MZEF combines these local features into a single functional unit. However, in all cases, the same dynamic programming technique can be used to combine these functional units into complete gene structure predictions.

6.2 Dynamic Programming

Snyder and Stormo [71] showed how the optimal combination of features could be obtained using dynamic programming. Let us define the states of our gene finder as the different types of functional units in our gene model, $Q = q_1 \dots q_m$. We say that the sequence, $X = x_1 \dots x_n$ is labeled by a corresponding sequence of states, $\Phi = \phi_1 \dots \phi_n$, called the "parse", where $\phi_i \in Q$. Quite simply, a parse formally describes the gene structure, e.g. intergenic DNA from position 0 to 100, $5'$ UTR from 101 to 150, initial CDS exon from 151 to 200, etc.

The key idea behind dynamic programming is the assumption that the score of a parse can be decomposed into independent segments or, at least, segments that are only locally dependent. This independence assumption is clearly violated in some cases. For example, tertiary protein structure obviously implies specific long-range interactions among codons. Nevertheless, this is a reasonable approximation for gene finding that offers significant computational advantage.

If every possible segment can be scored independently, then the parse with the best score can be computed recursively. Given an input DNA sequence X and possible states Q, then define a score matrix $S(j,k)$ that holds the score of the best parse of the subsequence $x_1 \dots x_j$ ending with a segment at x_j in state q_k. Define $s(i,j,k)$ as the independent score of a segment from $x_i \dots x_j$ of state k. [These $s(i,j,k)$ terms are based on feature scores from one of the many methods discussed and alluded to in the previous sections, such as coding potential, splice site scores, etc.] If we assume for simplicity in this formulation that any segment of any length can follow any other segment (we will improve on this momentarily), then $S(j,k)$ is defined as the best score from all positions $i < j$ in any possible state in Q plus the score of a segment in state k from $i \dots j$. For example, the best score for labeling a DNA sequence such that that an initial exon ends at position 200 is computed by considering the score for an initial exon starting from every position less than 200 following any of the other possible states ($5'$ UTR, intron, intergenic, etc.):

$$S(j,k) = \max_{i<j, l \in Q} \left(S(i,l) + s(i,j,k) \right) . \tag{1}$$

The general form of this dynamic program is usually called the Viterbi algorithm and the process of predicting a parse is often called decoding [23]. While $S(\dot{;})$ holds only the best score, it is straightforward to also simultaneously compute a trace-back describing the parse that achieved the best score.

The formulation here is different from the conventional presentation of dynamic programming for biosequence analysis (Chapter 3) because segments can take on arbitrary length. As a result, running time is quadratic in the length of the sequence and number of states – prohibitively expensive except for very small sequences, but at least not exponential.

6.3 Gene Grammars

In order to ensure that the evaluation of all reasonable gene structures for long DNA sequences can be achieved in acceptable running time we add grammatical constraints that ensure only legal and sensible parses are considered. Dong and Searls [18, 68] were the first major proponents for describing gene structure in linguistic terms. (For a thorough treatment in a modern gene finding system, see also Ref. [46].) The key idea behind grammatical constraints is that different segment states can only appear within specific contexts. For example, an intron can only following an exon. The grammatical constraints for genes can be expressed in a so-called regular grammar and can be visualized as a finite state machine. Figure 5 shows such a state diagram for a simplified gene model.

We call neighboring pairs of states transitions (e.g. intron following exon). In addition to strict contextual constraints on state transitions, we observe that some state transitions are allowed, but are less likely than others. For example, it is less likely that an intron will be followed by a terminal exon than an internal exon. We define $t(l,k)$ as the score for a transition from state l to state k. These are usually assigned based on frequencies of observed transitions in training data. In addition, we define a function $T(k)$ that returns a set of allowable previous states for k.

One specific type of transition constraint in $T(\cdot)$ is especially important, i.e. the frame constraint. In order to ensure that the total number of bases in the CDS is a multiple of 3, states must be created to ensure that introns split codons in a frame consistent manner. For example, if one base precedes an intron then two bases must follow it before the next full codon (see Figure 5.)

In Section 4 we observed that exons and introns had predictable length distributions as well as maximum and minimum lengths that are rarely or never exceeded, e.g. coding exons are rarely larger than a few thousand bases and introns are almost never smaller than about 50 bases. Therefore, we restrict the allowable length segments considered in our dynamic program by introducing $\min(k)$ and $\max(k)$ values for each state k.

From this, we have an improved method for scoring possible parses that extends Eq. (1) as:

$$S(j,k) = \max_{\substack{i<j,\ l \in T(k) \\ j-i>\min(k) \\ j-i<\max(k)\ .}} S(i,l) + s(i,j,k) + t(l,k) \tag{2}$$

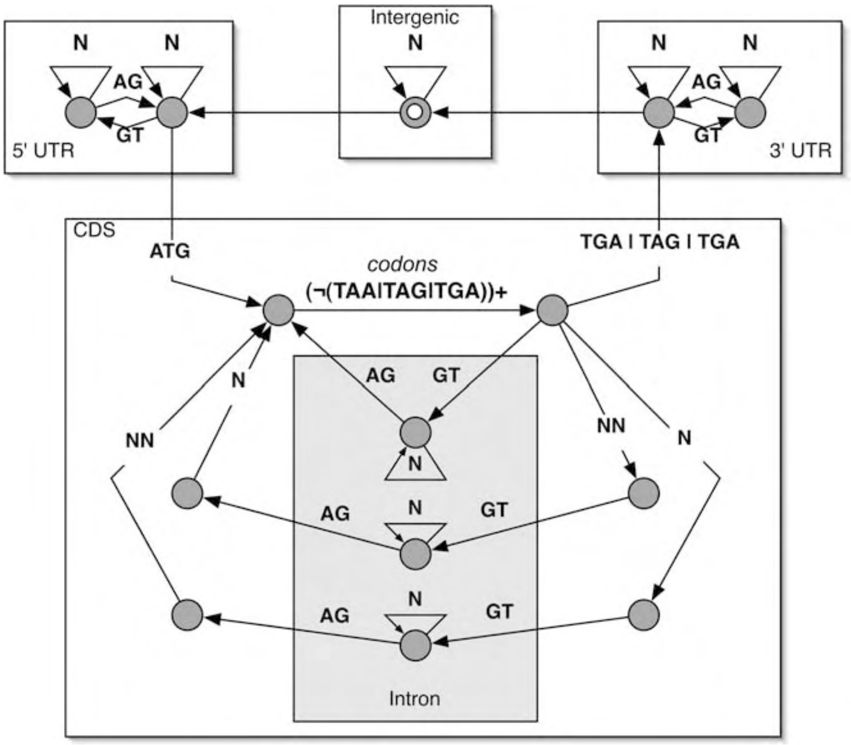

Figure 5 A finite state automaton (FSA) that recognizes gene structures. This simplified FSA recognizes legal protein-coding gene structures such that the total CDS length is a multiple of 3. Nucleotides are matched along the arcs and states are associated with nodes. N represents any base. "¬" indicates negation and "+" indicates one or more repeated times. The score functions $s(i, j, k)$ provide scores for sequences along the arcs. $l \in T(k)$ if there is a directed edge from k to l. $t(l, k)$ map to the possible outward arcs for node k. In this model, a single variable length codon state is used. In more sophisticated models there might be elaborate splice site states, states for initial, internal and final coding exons, promoter and polyadenylation sites, and reverse strand genes. The double circle is the start and end state.

The addition of length and state transition restrictions significantly improves running time, while ensuring that only meaningful parses are considered. In addition, software engineers for different systems have employed other tricks to improve the speed of gene prediction to approximately linear in the length of the input DNA sequence [9,46,55].

When the segment scores and transition scores are defined as log probabilities, which is easily derived from feature scoring methods such as weight matrices and Markov models, then we say that such a model of gene structure is a stochastic regular grammar or equivalently a HMM. (Note that sometimes the inclusion of variable length segments in the model is called a generalized HMM (GHMM) [44] or a state-duration HMM [60].) The dynamic program is then a maximum likelihood optimization:

$$\arg\max_{\Phi}(-\log P(X,\Phi)) \ .$$

Such models are called generative models because the score functions are decomposed into conditional probability terms of the form $-\log P(x_i \dots x_j|q_k)$, corresponding to the $s(i,j,k)$ score function, and $-\log P(q_l|q_k)$, the $t(l,k)$ transition score. It is sometimes convenient to describe HMMs as generating the sequence X via a random walk through the finite state machine. The decoding step is, then, the prediction of the most likely random path, Φ, that generated the observed data (see also Chapter 3).

Almost all of the successful, modern gene finders are based on this HMM framework including the most widely used *ab initio* gene finders GENSCAN [9] and FGENES [65]. Furthermore, we will shortly see that improvements to gene finders with respect to the inclusion of homologous protein, aligned cDNA and orthologous DNA are all extensions of this basic HMM framework.

An additional advantage of the probabilistic framework is that the score functions can be learned systematically using standard learning procedures, i.e. a maximum likelihood optimization using the forward–backward algorithm [60]. In practice, the parameters for the different score functions are trained independently in most gene-finding programs, but HMMGene [43] is a notable exception that achieves good performance. In addition, using the same algorithm for a test sequence it is possible to obtain the score of any single feature (such as an internal coding exon) in the context of all possible parses that might contain it. Studies have shown that these scores are meaningful metrics for ranking the confidence of different segments of a prediction [9,46,63].

7 Performance Comparisons

Performance of different gene finders has been assessed by several researchers including studies by Reese and coworkers [62] on *Drosophila* and Rogic and coworkers [63] on mammalian sequences. First, in Reese and coworkers, a 2.9-Mb contiguous DNA sequence was subjected to automated analysis by a battery of gene-finding programs and compared with the gene structures from a careful manual curation. Assessing false-positive rate (over-prediction) in this test was problematic because full-length gene structures were known with certainty for only a fraction of genes, full-length cDNAs were rejected if they did not meet certain automatic criteria such as having a good splice site score and for those uncertain genes there was a serious bias because automated gene finder predictions had been used by the manual curators to guide their annotations. Five *ab initio* gene finders were tested and standard evaluation statistics were collected (using the same metrics as in Ref. [12]). Table 2 presents the performance predicting individual exons and the entire CDS from start to stop codon. The only strong conclusion that can be made is that HMM-based gene finders (FGENES, Genie and HMMGene) perform comparably and superior to the other methods. We also know from these tests and others that gene finders naturally perform better when trained with examples from the organism being tested or related species [78].

Table 2 *Ab initio* performance for the *Adh* locus in *Drosophila*

	FGENES (v1/v2/v3)			GeneID (v1/v2)		Genie	HMMGene	Grail
Exon								
Sn	0.65	0.44	0.75	0.27	0.58	0.70	0.68	0.42
Sp	0.49	0.68	0.24	0.29	0.34	0.57	0.53	0.41
Missing	0.11	0.46	0.06	0.54	0.21	0.08	0.05	0.24
Wrong	0.32	0.17	0.53	0.48	0.47	0.17	0.20	0.29
CDS								
Sn	0.30	0.09	0.37	0.02	0.26	0.40	0.35	0.14
Sp	0.27	0.18	0.10	0.05	0.10	0.29	0.30	0.12
Missing	0.09	0.35	0.09	0.44	0.14	0.05	0.07	0.16
Wrong	0.24	0.25	0.52	0.22	0.30	0.11	0.15	0.24

Sn refers to the fraction of known genes that were predicted exactly correct. Sp is the fraction of predicted genes that were exactly correct. Missing is the fraction of known genes with no overlapping prediction. Wrong is the fraction of predictions that do not overlap annotated genes. High Sn and Sp and low Missing and Wrong values are better. Sn and Missing were determined from a different test set than Sp and Wrong. FGENES and GeneID were run under multiple parameter settings to produce different sensitivity/specificity trade-offs. See Ref. [62] for details. Importantly, different versions of these programs have typically been developed since these tests, so conclusions should be qualitative regarding methodology only.

Recognizing that biases could exist in gene prediction programs if testing data included gene structures used in training, Rogic and coworkers assessed the performance of seven *ab initio* gene finders on 195 mammalian gene structures that were submitted to GenBank after the programs were released. In the overall results shown in Table 3, the ranges of performance measures is comparable to that for invertebrates and the gene finder HMMGene shows a

Table 3 *Ab initio* performance for mammalian genes [63]

	FGENES	GeneMark	Genie	GENSCAN	HMMGene	Morgan	MZEF
Exon							
Sn	0.67	0.53	0.71	0.70	0.76	0.46	0.58
Sp	0.67	0.54	0.70	0.70	0.77	0.41	0.59
Missing	0.12	0.13	0.19	0.08	0.12	0.20	0.32
Wrong	0.09	0.11	0.11	0.09	0.07	0.28	0.23

Measures are interpreted as in Table 2.

significant advantage over other methods. However, to complicate matters, Rogic and coworkers also found that gene finder performance was frequently highly dependent on gene or genome characteristics such as type of CDS exon (initial, internal or terminal) and G + C content.

A third study, by Guigo and coworkers, has shown that gene finders perform notably worse on long DNA sequences than for the short test sequences that contain only one gene found in assessment studies [28], so mammalian performance shown here is probably an upper bound and should be evaluated only relatively.

8 Using Homology

A second class of gene finders is those that take advantage of homologous sequences from databases of cDNA, DNA and protein sequences. Alignments of cDNA indicate the exon–intron structure. Conserved sequences between orthologous chromosomes indicates functional DNA, i.e. regulatory and protein-coding sequences, and protein–DNA similarity identifies putative CDS.

8.1 cDNA Clustering and Alignments

The gold standard for gene structures are derived from the alignment of cDNAs (complementary DNA from mRNA) to DNA. A full-length cDNA requires only the identification of the CDS, which is typically assumed to be the largest ORF. However, full-length cDNAs are rare. Instead, tens of millions of cDNA fragments called expressed sequence tags (ESTs) with lengths of several hundred bases have been deposited in GenBank. These sequences are typically random sequencing reads from the $3'$ or $5'$ ends of libraries of cloned full-length or partial mRNAs. The primary difficulties with ESTs are the relatively short size, the frequent sequencing errors and the sheer number of such sequences.

Occasionally ESTs are analyzed individually in the hope of identifying fragments of coding regions. For this purpose, specialized HMMs similar to profile HMMs (see Chapter 3) have been developed to identify the reading frame with the highest coding potential while allowing for frame shifts that interrupt the CDS [35]. The methods employ similar, but simpler, Markov model scoring metrics and state machines than those used for gene finders in DNA (Figure 6).

Most EST analysis is based on assembling multiple EST sequences to form longer cDNA sequences. If no genome sequence is available, then rapid clustering methods are often employed to generate groups of homologous

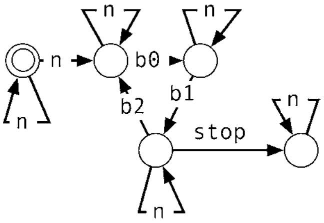

Figure 6 A finite state automaton for labeling the CDS (codons of "b0 b1 b2") in EST sequences allowing for frameshifts. A function such as the fifth-order Markov model is used for the scoring of the b0, b1 and b2 arcs.

ESTs [10]. These groups are then input to a conventional fragment assembler (see Chapter 2). This approach typically generates undesirable chimeric or partial assemblies and alternative isoforms can cause havoc.

In the conventional assembly approach, each EST contributes to just one assembled cDNA, but if multiple isoforms exist, then an EST should naturally be a part of multiple cDNA assemblies. A splice graph captures all of the possible isoforms implied by a set of ESTs [33]. In the splice graph, a virtual genome sequence is deduced, nodes are positions in the genome, and arcs connect positions that are adjacent in aligned ESTs. Figure 7 shows an example visualization of a splice graph. The splice graph makes clear that the number of possible isoforms can, in the worst case, be exponential to the number of exons.

With a completed genome sequence, cDNAs can be aligned to the DNA, which serves as a template, and the gene structure can be delineated by the connected set of overlapping, aligned ESTs. This is superior to the previous cluster-based transcript assembly because (i) errors in ESTs can be corrected by comparison with DNA, (ii) chimeras are less likely and (iii) the genome is directly annotated providing exon–intron structure.

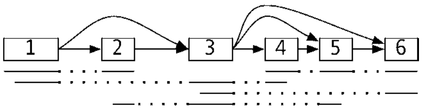

Figure 7 Splice graph. Nodes are positions along the horizontal axis, representing a DNA sequence. (When no genome sequence is available, the DNA sequence is virtual and ambiguous, i.e. implied exclusively by the differences between homologous ESTs.) Nodes are connected based on EST evidence. Those nodes adjacent on the DNA are merged into exons (numbered boxes). Arcs between boxes are introns. Assembled ESTs are shown below the splice graph. Dotted lines show where an EST spans across a DNA gap. Note that the genomic DNA is not necessary to build a splice graph. However, errors in the EST sequences can easily introduce false variants. To address this, multiple ESTs are usually required to confirm alternative splicings.

Highly accurate programs for cDNA–DNA alignment that include special handling for small exons, accurate splice site definition and EST errors are now available, most notably GMAP [79] or BLAT [38]. Imposing strict alignment criteria is usually advisable such as requiring that at least 90% of the EST be aligned with 95% identity in the aligned region. Even stricter alignment criteria are common, such as requiring that all intron gaps in an alignment conform to consensus dinucleotide splice sites and span a minimal number of genomic bases.

EST sequences are obtained from the $3'$ and $5'$ ends of cDNA clone inserts (and sometimes random internal positions). Due to the construction of the vector sequence containing the cDNA insert, sequencing of the two ends occurs on opposite strands of the insert. By convention these sequences are deposited in GenBank without reverse complementing and so usually a $5'$ EST sequence is of the sense strand and a $3'$ EST is of the anti-sense strand. Therefore, the orientation of a gene on the DNA can be inferred by comparing the EST read direction and the orientation of the sequence in the EST–DNA alignment. However, the labeling of the read direction and the strand that is submitted to the database is only a convention and there are frequent errors in the EST database, mostly among older database entries due to lane shifts from gel-based sequencing machines [1]. Other characteristics can be used to infer orientation of the EST including comparisons to other aligned sequences, presence of a poly-A tail (or poly-T prefix), presence of a polyadenylation signal and, most effectively, the consensus dinucleotides in the splice sites, if the EST splices. Shendure and Church [69] describe one laboratory's orientation procedure although no single software program currently exists to perform this orientation. (A lingering problem remains that EST–DNA alignments may indicate anti-sense transcription – a phenomenon that has been increasingly documented [81]; however, conventional gene modeling and genome annotation prohibit overlapping transcripts.)

Once individual ESTs are oriented and aligned, longer transcripts can be derived by merging gene structures implied by overlapping ESTs. As with EST analysis without a genome sequence, conflicting alignments can imply a large number of putative alternative splice forms. The PASA program is one of several programs that can be used to generate a a set of such putative transcripts from EST–DNA alignments [31,37]. In PASA, a dynamic program, is employed to assemble a minimal set of unique transcripts from compatible EST alignments, i.e. those ESTs that agree in all of their inferred splicings.

Not all genes will be present in EST libraries because differentially expressed genes may be absent or expressed at low levels in the sampled tissues. Furthermore, due to limitations in full-length cDNA cloning and the long lengths of some transcripts, many genes are not fully covered by EST sequences. Thus, assembly of ESTs tends to result in fragmented, partial transcripts.

One method that has been used to specifically deal with the incomplete EST information is Genie [46]. The method assumes that assembled transcripts from EST–DNA alignments define true, but incomplete, gene structures and so the *ab initio* gene-finding algorithm described in Section 6.3 is employed only in the breaks between alignments. This can be achieved in a straightforward manner by modifying the $t(\dot{;})$ transcription score function to prohibit transitioning into some states at specific positions within the sequence depending on the EST–DNA alignment evidence (e.g. transitioning into an exon state in the middle of an EST-defined intron is prohibited in the dynamic program).

Lastly, it is possible to leverage the EST data to infer gene bounds even when only incomplete EST alignments exist using EST mate pairs. For some cDNA inserts both the $5'$ and $3'$ ends have been sequenced. When both ESTs are aligned to the same chromosome, within a reasonable genomic distance, and compatibly ordered and oriented, then one can infer that the entire region between the mate pairs corresponds to a single primary transcript. In a similar way as above, an *ab initio* gene finder can be constrained to predict exactly one primary transcript in the defined region.

8.2 Orthologous DNA

When two organisms are sufficiently similar to identify and align orthologous genomic sequence, but sufficiently distant so that nonfunctional DNA has mutated, then the comparative analysis of the two genomes can be directly applied to gene finding (see also Chapter 37). Organisms such as chicken and mouse are of a reasonable evolutionary distance from human to support this sort of comparison. The key assumptions are that the number and approximate content of CDS regions between the two species are well conserved, while introns, UTRs and intergenic DNA have drifted significantly from the common ancestor. Thus, if the conserved regions can be identified, then they are most likely coding regions and so the gene-finding problem is to combine these conserved CDS segments into a more complete gene structure.

There are two main approaches to the problem: *ad hoc* weighting schemes and principled pair HMMs. Twinscan [39] and SGP2 [56] are examples of the former method. For example, in Twinscan, the dynamic program corresponding to the gene grammar described in Section 6.3 is augmented with scores from BLAST sequence similarity matches between the two genomes. In other words, for any candidate region $x_i \dots x_j$ in a CDS state, q_k, the score function $s(i, j, k)$ is improved according to the quality of the genome–genome

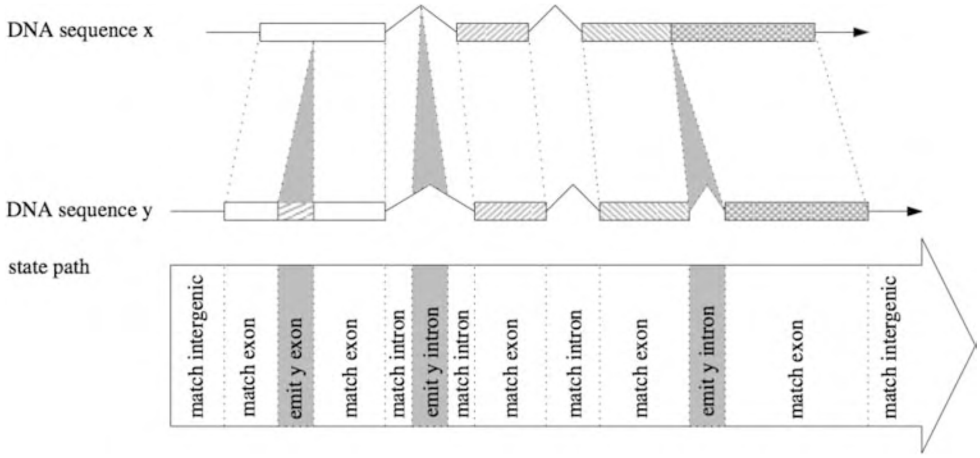

Figure 8 Pair HMM. Two DNA sequences are generated simultaneously from left to right. At each step, a subsequence (possibly of length zero) is emitted for each genome. The score for the pairs of subsequences is based on the local statistics like a conventional *ab initio* gene finder as well as the similarity of the two subsequences. (From Meyer and Durbin [51].)

alignment in that region. Thus, the method performs gene finding on one genome sequence using the second genome as evidence.

The second, more elegant, approach is to simultaneously align and label both genome sequences according to a probabilistic model. DoubleScan [51] and SLAM [3] embody this class of gene finders. The approach, called a pair HMM, is a generalization of the *ab initio* method and is best understood by considering an HMM-based gene finder as a generative model that produces labeled sequences of DNA, as previously described in Section 6.3. In a conventional HMM, one or more nucleotides are emitted for each state; in a pair HMM two sequences of nucleotides are emitted for each state. To address asymmetries such as inserts in one genome additional states must be added to allow for null string emissions in one genome. Figure 8 shows a diagram of the generative process.

Our score function $s(i, j, k)$ is extended to consider the scores of pairs of segments, i.e. $s(i, j, m, n, k)$ is the score for simultaneously emitting DNA sequences $x_i \ldots x_j$ and $y_m \ldots y_n$ in state q_k. The dynamic program for a pair HMM is not much different from the conventional single sequence HMM although the pair HMM must consider, theoretically, all possible segments $x_i \ldots x_j$ and $y_m \ldots y_n$ in every possible state, which adds a very significant computational burden. In practice this computational burden may not be worth the investment since the *ad hoc* score enhancement methods are fast and have been shown to perform well.

Conserved noncoding sequences (CNS), which are usually regulatory sequences, are often a problem for comparative modeling methods because they are interpreted as coding. In some implementations special CNS states are introduced and, in theory, if the CNS sequences lack sufficient coding potential, then they will be labeled CNS instead of CDS. In practice, mispredicting CNS remains a challenge, particularly for highly conserved genes.

The comparative method has also been extended to model the proper phylogenetic distance among three or more genomes in a phylo-HMM [70] and also to successfully annotate very closely related species such as among primates [50].

8.3 Protein Homology

The simplest application of protein homology is the identification of putative CDS subsequences from sequence alignment. For example, BLASTX [24] performs six-frame translation of a DNA query sequence and rapidly identifies those regions that are similar to known proteins. The user must assemble the fragmentary evidence.

The most elegant and specific use of protein homology is employed by the GeneWise [6] program, which merges the profile HMM used in protein remote homology searching (see Chapter 11) and the gene finding HMM model described in Section 6.3 into a unified DNA–protein alignment. The method is a pair HMM, similar to those used in comparative genomic analysis, but in this case the model is more complex because the two generated sequences use different alphabets, and additional constraints must be included to ensure proper pairing of amino acids and codons according to the genetic code. The model also includes a basic set of splice site recognition states to allow for the alignment of the protein sequence across introns (similar to cDNA–DNA alignment) as well as nucleotide insertion and deletion states to allow for errors and frame shifts.

GeneWise produces only partial gene structures corresponding to the region of protein alignment on the DNA. However, importantly, such alignments provide highly accurate predictions when a sufficiently close homolog is available. Moreover, the prediction of splice sites is particularly good due to the constraint of the alignment of the protein across introns.

HMM gene-finding programs such as FGENES++ [65] and Genie [45] employ a more *ad hoc* approach in which scores for coding features are artificially inflated when database similarities are found, in a similar manner as the comparative genome program Twinscan [39]. As a protein–DNA alignment improves, the score for labeling the DNA region as coding improves. In this way, a complete gene structure is predicted with protein homology evidence contributing, but it is not used exclusively nor is it required. Such an approach requires careful tuning of the contribution of protein homology to avoid overprediction or over extension of coding exons.

8.4 Integrative Methods

There has been much work on integrative methods of combining multiple gene finders and homology evidence, both principled and *ad hoc*, for whole genome analysis, but we do not review them in detail here. Several programs have attempted to integrate the predictions of multiple gene finders within a probabilistic model (e.g. Refs. [4, 53, 57]). Other programs provide an abstract framework of an HMM gene finder that allows a software developer to incorporate arbitrary feature scoring methods [34]. Most genome centers and informatics sites maintain "pipelines" for automated annotation. Many of these are not portable or are tightly bound to other institutional software infrastructure. Two noteworthy examples are the annotation pipelines of the NCBI (http://www.ncbi.nlm.nih.gov/genome/guide/build.html) and Ensembl [17]. Both include sophisticated and comprehensive methods for reliable whole genome gene prediction.

9 Pitfalls: Pseudogenes, Splice Variants and the Cruel Biological Reality

As this chapter concludes its tour of gene-finding methods, it is worth a brief mention of some of the unfortunate difficulties that make gene prediction a hard problem that is unlikely to be satisfactorily solved in the near term. The challenges almost all lie in the complexity of genome organization that is not (and often cannot be) modeled by the various gene-finding techniques [52]. Here are several issues:

- Exons can be extremely small – only a few nucleotides, which is insufficient to detect coding potential. Worse, re-splicing has been observed in which an exon is entirely removed.
- Noncanonical splice sites are expected to occur, on average, about once every 10 genes in the genome; however, with few exceptions, methods assume GT/AG splice sites.
- Pseudogenes are numerous in many organisms including the human. There are specialized programs to detect retrotranscribed and nonfunctional genes (e.g. Ref. [15]), but young pseudogenes are often quite difficult to distinguish by sequence statistics.

- Alternative splicing is prolific in higher eukaryotes. It is estimated that 60% of human genes have multiple isoforms. We saw in Section 8.1 that cDNA methods can be used to enumerate possible splice variants. HMM-based methods like those we learned here can be used to generate suboptimal parses that sometimes represent alternative isoforms [14]. Recent predictive methods have been developed for detecting alternative splice sites [19]. Nevertheless, alternative splicing remains a serious impediment to automated genome annotation.
- Untranslated exons make up a large fraction of the typical gene, yet there is very little, if any, signal differentiating UTRs from intergenic DNA.
- The size of most genomes implies that gene-like patterns are likely to occur frequently in intergenic DNA. In order to control false-positive rates, gene-finding programs must also sacrifice true positives. Studies of gene finders in large DNA sequences reveal frequent overprediction [28].
- Anti-sense transcription [81], high rates of transcription outside of known protein-coding genes [36] and large classes of small noncoding RNAs have been observed [54]. Besides causing difficulties in the use of cDNA–DNA alignment evidence for gene finding, these findings emphasize that important, functional, nonprotein-coding genes are being transcribed at high rates and that new classes of genes may yet be discovered. Alternatively, the high rates of transcription observed by Kampa and coworkers [36] also suggests that the genome is less of a programmed machine and more of a stochastic process in which nonfunctional transcription may be occurring at high levels. Such "noise" in the system is insurmountable using sequence analysis alone.

As a result of these and other complications, manual genome annotation is expected to remain the definitive source for gene structures for a long time. An excellent source of manual curations is the VEGA system [49].

10 Further Reading

Chapter 3 of this book introduces HMMs. Further background on HMMs and probabilistic modeling of gene sequences – the techniques that dominate gene finding – is best found in the book *Biological Sequence Analysis* [20] and Rabiner's oft-cited tutorial [60]. An excellent gene-finding bibliography is maintained by Wentian Li (http://www.nslij-genetics.org/gene/). The primary literature for generalized HMMs (e.g. GENSCAN [9] and Genie [44,46]) and comparative gene finders (e.g. DoubleScan [51], SLAM [3], and Shadower

[50]) is particularly good for new readers. There are many reviews of gene-finding techniques and Zhang's [84] is a relatively recent good one. The website www.genefinding.org is also a useful resource for developers.

Analyzing Regulatory Regions in Genomes

Thomas Werner

1 General Features of Regulatory Regions in Eukaryotic Genomes

Regulatory regions share several common features despite their obvious divergence in sequence. Most of these common features are not evident directly from the nucleotide sequence, but result from the restraints imposed by functional requirements. Therefore, understanding of the major components and events during the formation of regulatory DNA–protein complexes is crucial for the design and evaluation of algorithms for the analysis of regulatory regions. Transcription initiation from polymerase II (Pol II) is the best understood example so far and will be a major focus of this chapter. However, the mechanisms and principles revealed from promoters are mostly valid for other regulatory regions as well.

Algorithms for the analysis and recognition of regulatory regions draw from the underlying biological principles, to some extent, in order to generate suitable computational models. Therefore, a brief overview over the biological requirements and mechanisms is necessary to understand what are the strengths and weaknesses of the individual algorithms. The choice of parameters and implementation of the algorithms largely control the sensitivity and speed of a program. The specificity of software recognizing regulatory regions in DNA is determined, to a large extent, by how closely the algorithm follows what will be called the biological model from hereon. Several overviews of this topic have been published [27, 96].

1.1 General Functions of Regulatory Regions

The biological functionality of regulatory regions is generally not a property evenly spread over the regulatory region in total. Functional units usually are defined by a combination of defined stretches that can be delimited and possess an intrinsic functional property (e.g. binding of a protein or a curved DNA structure). Several functionally similar types of these stretches of DNA are already known and will be referred to as *elements*. Those elements are

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

neither restricted to regulatory regions nor individually sufficient for the regulatory function of a promoter or enhancer. The function of the complete regulatory region is composed from the functions of the individual elements either in an additive manner (independent elements) or by synergistic effects (modules).

1.2 Most Important Elements in Regulatory Regions

Transcriptional regulation depends on sequence elements that are directly accessible from the genomic DNA sequence such as transcription factor (TF)-binding sites (TFBSs), repeats and hairpins (repeats that can form hairpin-like structures by self-complementarity). In addition, various elements not easily detectable in the sequence are important. Most of these affect chromatin structure and accessibility such as histone acetylation and methylation status as well as DNA methylation status. Such phenomena not directly linked to the local DNA sequence are usually summarized under epigenetic effects.

1.3 TFBSs

Binding sites for specific proteins are most important among the sequence elements. They consist of about 10–30 nucleotides, not all of which are equally important for protein binding. As a consequence, individual protein-binding sites vary in sequence, even if they bind to the same protein. There are nucleotides contacted by the protein in a sequence-specific manner, which are usually the best-conserved parts of a binding site. Different nucleotides are involved in DNA backbone contacts, i.e. contacting the sugar-phosphate framework of the DNA helix (not sequence specific as they do not involve the bases A, G, C or T). There are also internal “spacers” not contacted by the protein at all. In general, protein-binding sites exhibit enough sequence conservation to allow for the detection of candidates by a variety of sequence similarity-based approaches. Potential binding sites can be found almost all over the genome and are not restricted to regulatory regions. Quite a number of binding sites outside regulatory regions are also known to bind their respective binding proteins [57]. Therefore, the abundance of predicted binding sites is not just a shortcoming of the detection algorithms, but reflects biological reality. Often it is not possible either to identify individual binding proteins as they might bind as part of multi-protein complexes [68]. This illustrates another important point: TF binding *in vivo* is usually context dependent. The isolated TF will bind to a cognate site quite differently if brought together in a reaction tube as naked protein and oligonucleotide probe than *in vivo* where adaptive DNA structure and a host of other proteins are present. As became evident from several chromatin immunoprecipitation

(ChIP) studies, even *in vivo* binding of a TF does not automatically imply a function in transcription control as was found in a genome-wide study which identified many more cAMP response element-binding protein (CREB)-binding sites than CREB-regulated genes [45].

1.4 Sequence Features

Regulatory DNA also contains several features not directly resulting in recognizable sequence conservation. For example, two copies of a direct repeat (approximate or exact) are conserved in sequence with respect to each other, but different direct repeats are not similar in sequence at all. Nevertheless, direct repeats are quite common within regulatory DNA regions. They consist either of short sequences, which are repeated twice or more frequently within a short region, or they can be complex repeats, which repeat a pattern of two or more elements. (More details on sequence repeats and how to detect them can be found in Chapter 7.) Repeat structures are often associated with enhancers. Enhancers are DNA structures that enhance transcription over a distance without being promoters themselves. One example of a highly structured enhancer is the interleukin-2 enhancer [74]. Other sequence features that are hard to detect by computer methods include the relatively weak nucleosomal positioning signals [46], DNA stretches with intrinsic three-dimensional (3-D) structures (like curved DNA, e.g. Ref. Ref. [81]), methylation signals (if there are definite signals for methylation at all) and other structural elements.

1.5 Structural Elements

Currently, secondary structures are the most useful structural elements with respect to computer analysis. Secondary structures are mostly known for RNAs (see Chapter 14) and proteins (see Chapter 9), but they also play important roles in DNA. DNA can form double hairpins called cruciform DNA representing the hairpin structures of RNA and can be important for transcriptional regulation [59]. Potential secondary structures can be easily determined and even scored via the negative enthalpy that should be associated with the actual formation of the hairpin (single-strand) or cruciform (double-strand) structure. Secondary structures are also not necessarily conserved in the primary nucleotide sequence, but are subject to strong positional correlation within the 3-D structure, i.e. the orientation of the double helix in space. Without any doubt 3-D aspects of DNA sequences are very important for the functionality of such regions. However, existing attempts to calculate such structures in reasonable time have met with mixed success and cannot be used for a routine sequence analysis at present. Part of that difficulty is that DNA structure can be quite flexible and structural changes are readily induced by interacting proteins [68].

1.6 Organizational Principles of Regulatory Regions

This section will mainly concentrate on eukaryotic polymerase II promoters, as they are currently the best-studied regulatory regions.

1.6.1 Overall Structure of Pol II Promoters

Promoters are DNA regions capable of specific initiation of transcription (start of RNA synthesis) and consist of three basic regions (see Section 1.6.3). The part determining the exact nucleotide for transcriptional initiation is called the core promoter, and is the stretch of DNA sequence where the RNA polymerase and its cofactors assemble on the promoter.

The region immediately upstream of the core promoter is called the proximal promoter and usually contains a number of TFBSs responsible for the assembly of an activation complex. This complex in turn recruits the polymerase complex. It is generally accepted that most proximal promoter elements are located within a stretch of about 250–500 nucleotides upstream of the actual transcription start site (TSS).

The third part of the promoter is located even further upstream and is called the distal promoter. This region usually regulates the activity of the core and the proximal promoter, and also contains TFBSs. However, distal promoter regions and enhancers exhibit no principal differences. If a distal promoter region acts position and orientation independent it is called an enhancer.

1.6.2 TFBS in Promoters

The TFBSs within promoters (and likewise most other regulatory sequences) do not show any general patterns with respect to location and orientation within the promoter sequences, although particular functionality may be associated with a specific location or association within the promoter [89].

Even functionally important binding sites for a specific TF may occur almost anywhere within a promoter. For example, functional activating protein 1 (AP-1, a complex of two TFs: one from the Fos and one from the Jun family)-binding sites can be located far upstream, as in the rat bone sialoprotein gene where an AP-1 site located about 900 nucleotides upstream of the TSS inhibits expression [97]. An AP-1 site located close to the TSS is important for the expression of Moloney murine leukemia virus [75]. Moreover, functional AP-1 sites have also been found inside exon 1 (downstream of the TSS) of the proopiomelanocortin gene [11] as well as within the first intron of the *fra-1* gene [6], both locations outside the promoter. Similar examples can be found for several other TF sites, illustrating why no general correlation of TF sites within specific promoter regions can be defined. TFBSs can be found virtually everywhere in promoters, but in individual promoters possible locations are much more restricted. A closer look reveals that the function of an AP-1-binding site often depends on the relative location and, especially, on the sequence context of the binding site. The AP-1 site in the above-mentioned rat bone sialoprotein gene overlaps with a set of glucocorticoid-responsive element (GRE, the DNA sequence that is bound by the glucocorticoid receptor which is a TF) half-sites (nuclear factor-binding sites are often composed of two almost identical half-sites separated by a spacer of a few nucleotides), which are crucial for the suppressive function.

The context of a TF site is one of the major determinants of its role in transcription control. As a consequence of context requirements, often TF sites are grouped together and such functional groups have been described in many cases. A systematic attempt at collecting synergistic or antagonistic pairs of TFBSs has been made with the COMPEL database [51]. In many cases, a specific promoter function (e.g. a tissue-specific silencer) will require more than two sites. Promoter subunits consisting of groups of TFBSs that carry a specific function independent of the promoter will be referred to as *promoter modules*. Arnone and Davidson originally gave a more detailed definition of promoter modules [1]. In summary, promoter modules contain several TFBSs which act together to convey a common function like tissue-specific expression. The organization of binding sites (and probably also of other elements) of a promoter module appears to be much more restricted than the apparent variety of TF sites and their distribution in the whole promoter suggests. Within a promoter module both sequential order and distance can be crucial for function, indicating that these modules may be the critical determinants of a promoter rather than individual binding sites. Promoter modules are always constituted by more than one binding site. Since promoters can contain several modules that may use overlapping sets of binding sites, the conserved context of a particular binding site cannot be determined from the primary sequence. The corresponding modules must be detectable separately before the functional modular structure of a promoter or any other regulatory DNA region can be revealed by computer analysis. One well-known general promoter module is the core promoter, which will be discussed in more detail below. However, the basic principles of modular organization are also true for most, if not all, other regulatory regions and are neither peculiar nor restricted to promoters.

1.6.3 Module Properties of the Core Promoter

The core promoter module can be defined functionally by its capability to assemble the transcription initiation complex and orient it specifically towards the TSS of the promoter [100], defining the exact location of the TSS. Various combinations of about four distinguishable core promoter elements that constitute a general core promoter can achieve this. This module includes the TATA box, the initiator region (INR), an upstream activating element and a downstream element (Figure 1). The TATA box is a basic transcription element, which is located about 20–30 nucleotides upstream of the actual TSS and is known to bind to the TATA box-binding protein (TBP). However, this is also where the straightforward definition of a core promoter module ends because not all four elements are required or some elements can be too variable to be recognizable by current computer tools.

The first group is made up of TATA box-containing promoters without a known initiator. Successful positioning of the initiation complex can start at the TATA box-containing promoters by the TFIID complex, which contains the TBP as well as several other factors. Together with another complex of general TFs, termed TFIIB, this leads to the assembly of an initiation complex [22]. If an appropriate upstream TFBS cooperates with the TATA box, no special initiator or downstream sequences might be required, which allows for the assembly of a functional core promoter module from just two of the four elements. This represents one type of a distinct core promoter that contains a TATA box, common among cellular genes in general.

The second group is TATA-less promoters with a functional initiator. As is known from a host of TATA-less promoters, however, the TATA box is by no means an essential element of a functional core promoter. An INR combined with a single upstream element has also been shown to be capable of specifically initiating transcription [41], although initiators cannot be clearly defined at the sequence level so far. Generally, a region of 10–20 nucleotides around the TSS is thought to represent the initiator. A remarkable array of four different upstream TF sites (SP1, AP-1, ATF or TEF1) was shown to confer inducibility by T-antigen to this very simple promoter, i.e. mediated transcriptional activation upon binding of T-antigen. T-antigen is a potent activating protein from a (simian) virus called SV40. This is an example of a TATA-less distinct promoter that can be found in several genes from the hematopoietic lineage (generating blood cells).

The third group is made up of a composite promoter consisting of both a TATA box and an initiator. This combination can be found in several viral promoters and it has been shown that an additional upstream TFBS can influence whether the TATA box or the initiator element will determine the promoter properties [21]. The authors showed that upstream elements can significantly increase the efficiency of the INR in this combination; in particular, SP-1 sites made the TATA box almost obsolete in their example. The combination of TATA box with an INR had the general effect of inducing resistance against the detrimental effects of a TFIIB mutant, which interfered

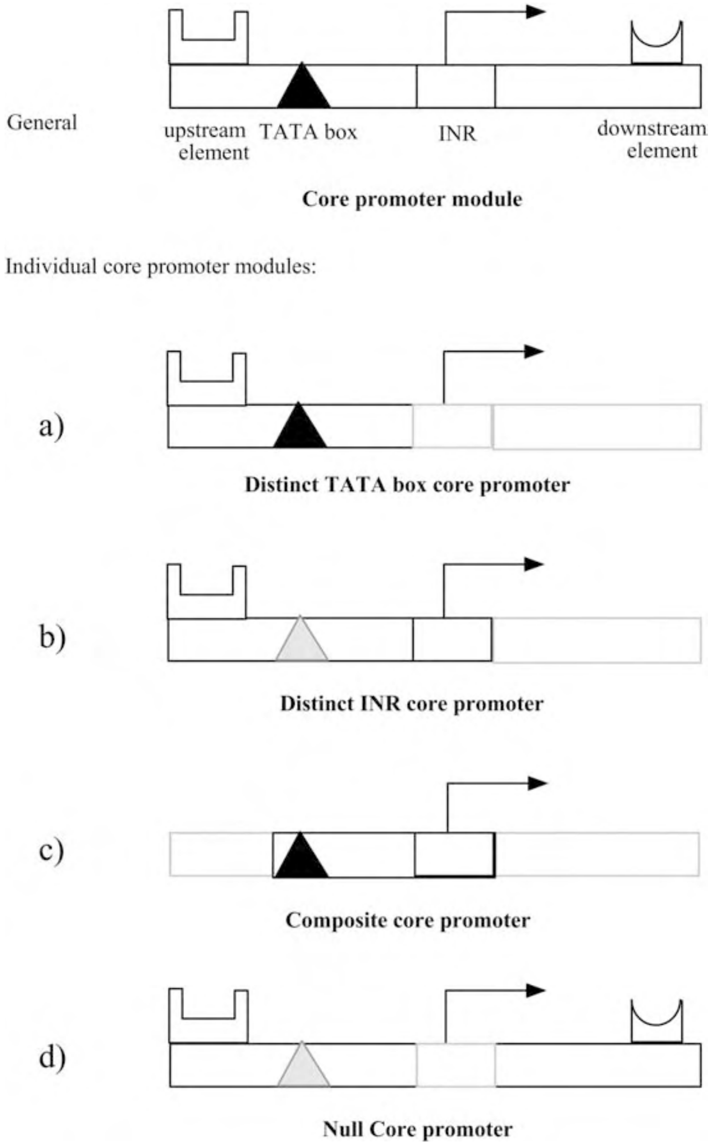

Figure 1 General structure of a Pol II core promoter and four different setups (a–d) of a Pol II core promoter. Simultaneous presence of all four elements is not always essential. The shapes above the bar symbolize additional protein-binding sites and the arrow indicates the TSS.

with expression from TATA-only promoters. This is also an example for of more indirect effects of specific arrangements in promoters that may not be apparent unless special conditions occur.

The last group consists of so-called null-promoters, which have neither a TATA box nor an initiator, and rely exclusively on upstream and downstream elements [66].

Basically, at least the four different core promoter types detailed above have been identified so far, all of which represent valid combinations of core promoter sites (reviewed in Ref. [66]). If the combinations involving upstream and downstream elements are also considered, seven core promoter modules are possible (most of which can be actually found in genes and consist of the four variants in Figure 1(a–d) adding upstream or downstream elements or both).

The only apparent common denominator of transcription initiation within a promoter would be that there must be at least one core promoter element anywhere within a certain region. This assumption is wrong. Both the spacing and/or sequential order of elements within the core promoter module are of utmost importance regardless of the presence or absence of individual elements (as a rule; however, there appear to be some exceptions). Moreover, many distinct promoters have requirements for specific upstream or downstream elements and will only function with their specific TF. Moving around the initiator, the TATA box and, to some extent, also upstream elements can have profound effects on promoter functions. For example, insertion of just a few nucleotides between the TATA box and an upstream TFBS (TF MyoD) in the desmin gene promoter cuts the expression levels by more than half [62]. Moreover, the promoter structure can affect later stages of gene expression like splicing [23]. It was also shown for the rat β-actin promoter that a few mutations around the TSS (i.e. within the initiator) could render that gene subject to translational control [7].

As a final note, the mere concept of one general TATA box and one general INR is an oversimplification. There are several clearly distinguishable TATA boxes in different promoter classes [35] and the same is true for the INR region, which also has several functionally distinct implementations as the glucocorticoid-responsive INR in the murine thymidine kinase gene [73], the C/EBP-binding INR in the hepatic growth factor gene promoter [48] or the YY-1-binding INR [90].

Most of the principles of variability and restrictions detailed above for the core promoter modules are also true for other promoter modules that modify transcriptional efficiency rather that determining the start point of transcription as the core promoter does. The bottom line is that the vast majority of alternative combinatorial arrangements of the elements that can be derived from a particular promoter might not contribute to the function of the promoter. Module-induced restrictions are not necessarily obvious from the primary sequences. Figure 2 shows a schematic Pol II promoter with the initiation complex assembled that illustrates that it matters where a specific

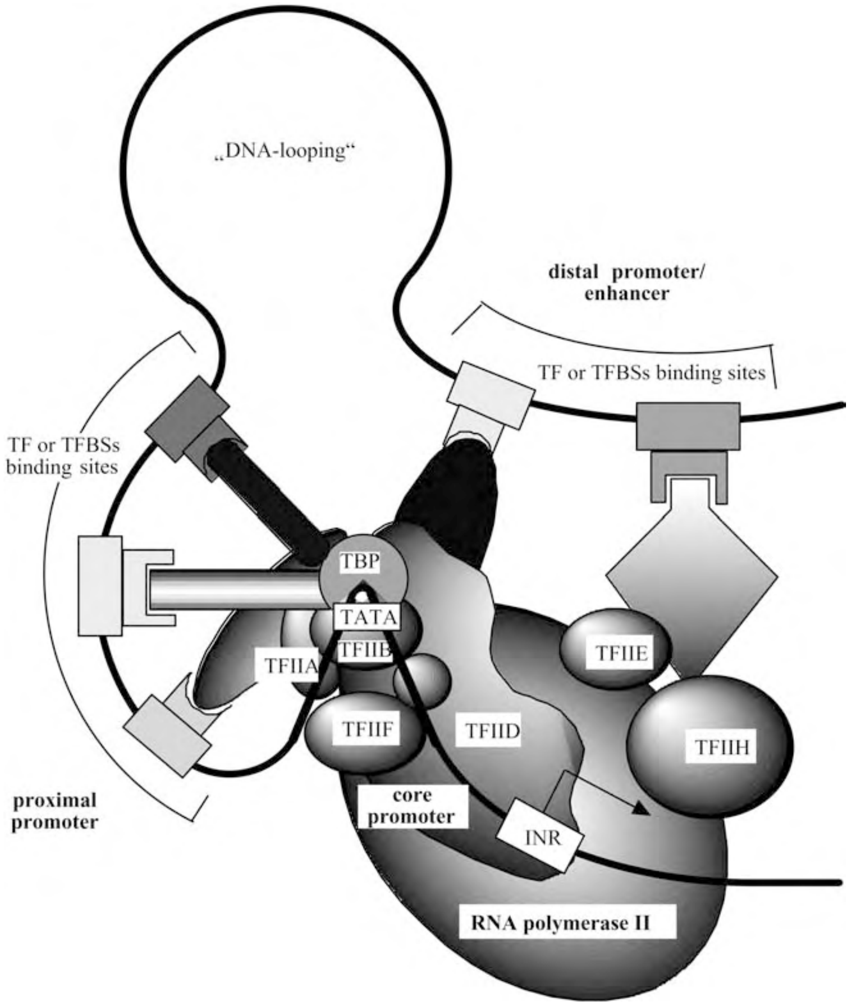

Figure 2 Transcription initiation complex bound to a schematic promoter.

protein is bound to the DNA in order to allow for proper assembly of the molecular jigsaw puzzle of the initiation complex. This is not immediately obvious from inspection of promoter sequences because there exist several (but a strictly limited set of) alternative solutions to the assembly problem. As complicated as Figure 2 may appear, it still ignores all aspects of chromatin rearrangements and nucleosomal positions, which also play an important role in transcription regulation. Stein and coworkers, initially in 1995 and in a 2001 follow-up paper, have detailed an example of the profound influence of these effects on promoter–protein complex assembly and function for the osteocalcin promoter [63, 84]. However, chromatin-related effects are not yet considered in any of the promoter prediction methods. Therefore, we do not go into any more details here.

1.7 Bioinformatics Models for the Analysis and Detection of Regulatory Regions

Algorithms used to analyze and detect regulatory regions are necessarily based on some kind of usually simplified model of what a regulatory region should look like. All of these models inevitably compromise between accuracy with respect to the biological model (the standard of truth) and computational feasibility of the model. For example, a computational model based on *a priori* 3-D structure prediction derived from molecular dynamics using sophisticated force fields may be the most accurate model for a region, but cannot be used for the analysis of real data due to excessive demand on computational resources. On the other hand, a model based on simple sequence similarities detected by IUPAC consensus (see also Section 2.1) sequences can be easily used on a PC, but results will usually not match the biological truth in an acceptable manner.

1.8 Statistical Models

It was noted several years ago that promoters and most likely also other regulatory regions like enhancers contain more TFBSs that nonregulatory sequences. Therefore, an analysis of the relative frequencies of such sites within a sliding window can yield some information on the potential regulatory character of a stretch of DNA, which is the prototype of simple statistical models. Several programs exist that rely to some extent on this type of statistics. Another set of statistical models calculates local GC content bias and uses this feature to discriminate potential promoters from other sequences. Such nucleotide bias statistics are only used in combination with other features (see Section 1.8.1) as they do not exhibit sufficient discriminatory power on their own.

A new breed of statistical models has been successfully introduced into promoter analysis more recently. These models focus on statistical analysis based on identification of promoter-associated words (not predefined such as TFBSs) using methods coming from other fields such as speech recognition. These methods are currently the best performers in promoter finding.

1.8.1 Mixed Models

It is clear from Section 1.6 that a binding site description-based pure statistical model is an oversimplification that will adversely affect the accuracy of prediction despite its attractive ease of implementation. Therefore, mixed models are also used that take at least some regional information into consideration and can be seen as statistical models split into compartments. Within the compartments solely statistical features are considered, but promoter organization is somewhat reflected by the arrangement of the compartments, which represent different promoter regions.

1.8.2 Organizational Models

The last category consists of models that try to closely follow the organizational principles of real regulatory regions. In order to accomplish this, individual promoter elements like TFBSs as well as their relative order and distances are encoded in a formal model, which reflects the setup of a single promoter or a small group of functionally similar promoters. Although they match the biological situation best, their widespread application requires an enormous amount of automation and background logistics such as high-quality promoter databases, automatic methods to derive the computational models as well as means of evaluating the resulting models. In the meantime, most of the basic requirements have been met, but real-life application is just picking up as this book is written.

However, such approaches are well suited for elucidating the molecular basis of coregulation of genes in a particular coexpressed cluster of genes from microarray experiments. So far this has been shown mainly for a simple eukaryote, *Saccharomyces cerevisiae* (yeast) [69]. Considerable progress has been made already in applying combinatorial TFBS models to higher eukaryotes such as mammalian systems, mostly based on experimental evidence [14, 40].

2 Methods for Element Detection

2.1 Detection of TFBSs

TFBSs are the most important elements within regulatory DNA regions like promoters or enhancers. The majority of the known TFs recognize short DNA stretches of about 10–15 nucleotides in length that show different degrees of internal variation. Successful detection of protein-binding sites in DNA sequences always relies on precompiled descriptions of individual binding sites. Such descriptions are usually derived from a training set of four or more authentic binding sites. However, the criteria applied for the decision whether a site is authentic or not vary considerably among authors of different publications. One of the first approaches to define protein-binding sites used IUPAC consensus sequences, which indicate the predominant nucleotide or nucleotide combination at each position in a set of example sequences (e.g.

SIGNAL SCAN [70]). The IUPAC string `TGASTCA` indicates that the first three positions are most frequently T, G and A, while the fourth position may be C or G, followed by T, C and A in most cases. IUPAC consensus sequences became very popular as they are extremely easy to define from even a small set of sequences, and their definition does not require more than a pencil and a sheet of paper.

However, IUPAC consensus sequences strongly depend on the sequence set used for definition because IUPAC consensus findings are based on majority rules. Adding or removing a single sequence can change the assigned nucleotide at a position while it would have little effect in a corresponding weight matrix. Cavener defined some rules that we have used for several years now and, in our experience, IUPAC consensus sequences defined that way can be useful [16]. However, IUPAC consensus sequences may reject biologically functional binding sites due to a single mismatch (or an ill-defined IUPAC sequence).

The concept of nucleotide weight matrix (NWM) descriptions was developed in the 1980s as an alternative to IUPAC strings (e.g. Refs. [83, 86]). Basically, weight matrices use an alignment of sequences to first generate a nucleotide distribution matrix representing the complete nucleotide distribution at each position of the alignment. Then some sort of weighting algorithm is used to adjust the matrix to the biological situation (also detailed in Section 5.3.1). However, although weight matrices proved to be generally superior to IUPAC strings, their greatest disadvantage is the absolute requirement for predefined matrices, which are more complicated to construct than IUPAC strings and require specific software. This delayed widespread use of weight matrices for almost a decade, although the methods were principally available. They remained mostly unused because only a few special matrices had been defined (e.g. Ref. [12]). The situation changed when in 1995 two (overlapping) matrix libraries for TF sites were compiled and became widely available almost simultaneously [17, 72]. MATRIX SEARCH [17] transformed the TRANSFAC database as completely as possible (starting at two binding sites for one factor) into matrices using a log-odds scoring approach. The MatInspector library [72] was originally largely based on a stringent selection from the matrix table of the TRANSFAC database, including the matrices derived from the ConsInspector library [32, 33] and several genuine matrices. The Information Matrix Database was compiled from the TRANSFAC matrix table and the TFD. In the meantime, the MatInspector library became independent from TRANSFAC and is updated regularly by Genomatix Software (Munich; currently more than 600 matrices), whereas IMD (another weight matrix database) has not been updated recently.

2.2 Detection of Novel TFBS Motifs

All the above covers the various approaches used to describe and find known TFBS motifs, i.e. there is always evidence that a known TF binds to such regions. There is another group of methods that join knowledge about evolutionary relationship of promoters with pattern-finding algorithms to detect phylogenetically conserved TFBSs. Examples of publications in this field include comparison of conserved human mouse patterns with [64] or without [61] direct sequence alignment, as well as approaches no longer restricted to two sequences such as FootPrinter [8] or PhyME, which includes overrepresentation into the probabilistic score of its findings [80].

A completely different set of methods deals with the detection of potential TFBS patterns solely based on their occurrence in a set of sequences without any biological knowledge about the particular TF binding to such regions. I separate such methods from the TFBS recognition methods as an unknown proportion of significant motifs detected this way may in fact not be TFBSs at all, but may be conserved for other reasons. Nevertheless, these methods do contribute to the generation of hypotheses about hitherto unknown TFBS patterns. Available matrix detection programs were reviewed some time ago [34] and a comparison of these methods by application to a test set of sequences has been published [36] (see Ref. [85] for a more recent review of the topic). A very recent study focused on matrix generation programs with no real emphasis on search programs [88]. For convenience, Table 1 summarizes some methods for the detection of TFBSs that are available in the internet with emphasis on programs featuring a WWW interface.

Various newer approaches have been published in the meantime, ranging from excellent purely mathematically motivated pattern detection (e.g. from Pevzner's group [50] or using self-organizing maps [65]) to strong connection

between biological [71] and experimental data with pattern detection [13]. This list only represents an arbitrary collection of very few papers in the field and the selection was purely driven by the desire to cite at least one method for each basic approach. I will not discuss *de novo* detection methods in any more detail here, as the major scope of this chapter is not *de novo* detection of patterns, but regulatory sequences analysis, which is usually based on precompiled pattern collections.

2.3 Detection of Structural Elements

Regulatory sequences are associated with a couple of other individual elements or sequence properties in addition to the factor-binding sites. Among these are secondary structure elements like the HIV-1 TAR region (*trans*-activating region, which constitutes an RNA enhancer, e.g. Ref. [10]), cruciform DNA structures (symmetric double hairpins of both strands in DNA, e.g. Ref. [92]) or simple direct repeats (e.g. Ref. [5]). Three-dimensional structures like curved DNA [54] also influence promoter function. Most of these elements can be detected by computer-assisted sequence analysis [20, 43], but none of them is really promoter specific and all such elements can be found frequently outside of promoters. The promoter or enhancer function arises from the combination of several elements that need to cooperate to exert transcription control which none of them can achieve alone. This also illustrates the main problem of promoter recognition. It is necessary to compile several individually weak signals into a composite signal, which then indicates a potential promoter without being overwhelmed by the combinatorial complexity of potential element combinations.

2.4 Assessment of Other Elements

Several methods employ statistical measures of sequence composition to include features of regulatory sequences, which cannot be described by the three types discussed above. These includes frequencies of oligonucleotides (dinucleotides, trinucleotides and hexamers are used most frequently), CpG islands (CG dinucleotides are usually underrepresented in mammalian genomes except in part of coding and regulatory sequences; CpG islands are regions where the dinucleotide is NOT underrepresented [38]) and periodicity of weak sequence patterns (`AA`, `TT`, etc.). Definitions of such elements are usually too weak to make any significant contribution to current prediction programs. However, this situation might well change due to the unprecedented amounts of continuous genomic sequences that become available in the course of the current genome-sequencing projects.

3 Analysis of Regulatory Regions

Basically, two different tasks can be distinguished in the analysis of regulatory regions. The first task is analysis aimed at the definition of common features based on sets of known regulatory sequences. This is a prerequisite for the definition of descriptions suitable for large-scale application for prediction of potential regulatory regions within new anonymous sequences, which can be seen as the second task.

3.1 Comparative Sequence Analysis

Comparative sequence analysis is one of the most powerful methods to deduce regulatory features and organization. Two main types of comparative analysis can be distinguished. The first approach compares regulatory regions, e.g. promoters within one species such as promoters coexpressed under particular conditions, or simply all (known) promoters within a genome to deduce general features. The second approach compares only orthologous regulatory sequences (again promoters are the most prominent representatives) in order to elucidate which features and elements have remained conserved in evolution. Such features should be closely associated with conserved functions of the corresponding regulatory regions. While comparative analysis within species affords no distinction between pure statistical findings and functional conservation, phylogenetic analysis of orthologous regulatory sequences should indicate predominantly functionally conserved features. However, intragenomic comparison may differentiate between individual functions, whereas phylogenetic analysis will always yield a summary over all conserved functions. Thus, very often a combination of both approaches is the best way to go [25].

3.2 Training Set Selection

One of the most important steps in comparative sequence analysis is the selection of suitable training sets of sequences. If a training set of promoters consists only of constitutively expressed sequences (constant level of expression, no or little regulation), little can be learned about any kind of tissue-specific expression regardless of the methods applied. Inclusion of too many wrong sequences (e.g. that are not promoters at all or promoters not involved in the regulation under investigation, see alternative promoters below) may also prevent any meaningful analysis. Although this observation appears trivial at first, it becomes a real issue when data are scarce and less well-characterized sequences have to be used.

Control sets known not to be functionally similar to the training sets are about as important as the training sets. However, true negative regions are even scarcer than known regulatory regions. Negative often means just "no positive functions found", which can also be due to failures or simply means that the sequences have not been tested at all. Therefore, statistical negative control sequences are often required. Random sequences can be generated easily, but often are of limited use, as they do not represent several important features of natural DNA correctly. This includes underrepresented features (e.g. CpG islands), asymmetric features (e.g. strand specificity), local changes in GC content or repetitive DNA elements. Selection of appropriate control sequences can be a major effort, but is also crucial for the validity of the evaluation of any method. Common problems with controls are either known or unknown biases in the control set or circularity problems, i.e. the training and the test sets of sequences are related or overlap. The availability of large continuous stretches of genomic DNA from the genome-sequencing projects constantly improves this situation. Genomic sequences should always be the first choice for controls as they reflect the natural situation.

3.3 Statistical and Biological Significance

The quality of sequence pattern recognition is often optimized to improve the correlation of the methods with the data (positive and negative training sets). However, in most cases it is not possible to collect sufficient data to perform a rigorous correlation analysis. Therefore, bioinformatics methods often rely on statistical analysis of their training sequences and optimize for the statistically most significant features. Unfortunately, this kind of optimization does not always reflect the evolutionary optimization of regulatory sequences that is always optimizing several features at once. This problem is different from overfitting of data as it is more about optimization criteria than parameter fitting *per se*.

The dynamics of biological function often necessitates suboptimal solutions. For example, real sequences usually do not contain binding sites with the highest affinity for their cognate protein because binding *and* dissociation of the protein is required for proper function. The perfect binding site with the highest binding affinity would interfere with the dissociation and is therefore strongly selected against.

3.4 Context Dependency

The biological significance of any sequence element is defined by the regulatory function it can elicit. This is usually dependent on a functional context rather than being a property of individual elements. Therefore, statistical significance of the features or scores of individual elements is neither necessary nor sufficient to indicate biological significance. Recognition of the functional context in an essentially linear molecule like DNA can be achieved by correlation analysis of individual elements, which became an important part of all semi-statistical or specific modeling approaches discussed below. The context is also an important parameter in statistical analysis. For example, an element frequently found all over the genome could become even statistically significant if only the immediate vicinity of a binding partner's binding sites is analyzed such as in case of transcriptional modules. Therefore, lack of statistical significance may just indicate that the wrong context was chosen for the analysis.

4 Methods for Detection of Regulatory Regions

There are several methods available for the prediction of regulatory DNA regions in new sequence data. Table 2 lists methods available with a special focus on programs that provide a WWW interface. Unfortunately, there is no "one-does-it-all" method, and all methods have their individual strong and weak points. There was a fairly recent review on the subject including most relevant programs, with one exception [4]. The program PromoterInspector

Table 2 Internet-accessible promoter/promoter region prediction tools

Program	Availability	Comments
Promoter prediction *Ab initio* promoter finding (large-scale sequences)

[77] was not included as it predicts promoter regions and neither strand orientation nor the TSS.

A program doing an excellent job in one case might be a complete failure in another case in which other methods are successful. Therefore, we will describe a number of methods without intending any rank by order of discussion. We will rather follow the functional hierarchy that appears to apply to the different regulatory regions. However, the apparent best application range will be indicated.

4.1 Scaffold/Matrix Attachment Regions (S/MARs)

A chromatin loop is the region of chromosomal DNA located between two contact points of the DNA with the nuclear matrix marked by so-called S/MARs. The nuclear matrix is a mesh of proteins filling the interdomain space inside the nucleus where S/MARs form highly flexible structures that are necessary, but not sufficient, for anchoring at chromosomal DNA to the matrix [42].

Transcriptional regulation requires the association of DNA with this nuclear matrix, which retains a variety of regulatory proteins. S/MARs are composed of several elements, including TFBSs, AT-rich stretches, potential cruciform DNA and DNA-unwinding regions, to name a few of the most important S/MAR elements. There is an excellent recent review on chromatin domains and S/MAR functions [9]. Singh and coworkers published a method to detect potential S/MAR elements in sequences and made the method available via WWW (http://www.ncgr.org/MAR-search/) [79]. Their method is based on a statistical compilation of the occurrence of a variety of S/MAR features (called rules). Accumulation of sufficient matches to these rules will be predicted as potential S/MAR regions. The specificity of the method depends critically on the sequence context of the potential S/MAR sequences. Another approach utilizes a single S/MAR associated sequence element to locate potential S/MARs [91]. Therefore, results are difficult to evaluate by comparisons. We developed another approach to define especially AT-rich MARs called SMARTest, which is available on the web at http://www.genomatix.de. SMARTest is based on a library of MAR-associated nucleotide weight matrices and determines S/MARs independent of any larger sequence context [37]. Therefore, the method is suitable for testing isolated S/MAR fragments. MARFinder and SMARTest are complementary, and should be seen in combination rather than as alternatives.

4.2 Enhancers/Silencers

Enhancers are regulatory regions that can significantly boost the level of transcription from a responsive promoter regardless of their orientation and distance with respect to the promoter as long as they are located within the same chromatin loop. Silencers are basically identical to enhancers and follow the same requirements, but exert a negative effect on promoter activities. Both regulatory regions are also relevant in disease processes, as detailed in a recent review [55]. At present there are no specific programs to detect enhancers and silencers. However, programs designed to detect the internal organization of promoters are probably also suitable to detect at least some enhancers and silencers since these regions often also show a similar internal organization as promoters.

4.3 Promoters

Promoters were described in detail above – they are just mentioned here again to place them into context.

4.4 Programs for Recognition of Regulatory Sequences

There are several ways promoter recognition tools can be categorized. We will focus on the main principles and intended usage of the programs rather than technical details. Two generally distinct approaches have been used so far in order to achieve *in silico* promoter recognition. The majority of programs focus on *general promoter recognition*, which represents the first category.

The second category of tools aims at *specific promoter recognition* relying on more detailed features of promoter subsets like combinations of individual elements. The beauty of this approach is its excellent specificity, which is extremely helpful if only promoters of a certain class are of interest or megabases of sequences have to be analyzed. The bad news here is limited applicability, i.e. each promoter group or class requires a specifically predefined model before sequences can be analyzed for these promoters. This may result in a huge number of false negatives in large-scale analysis.

We will briefly discuss individual methods in these two categories with emphasis on the implementation of the biological principles of promoter features. Recently, a practical comparison of the majority of available tools based on general promoter models has been carried out [4], which was the first large-scale update since the original comparison carried out by Fickett and Hatzigeorgiou in 1997 [29]. There was another review in between those two studies by Ohler and Niemann [67]. Therefore, we will not go into details on the performance of the methods.

4.4.1 Programs Based on Statistical Models (General Promoter Prediction)

These programs aim at the detection of Pol II promoters by a precompiled general promoter model that is part of the method. Learning methods range from supervised artificial neuronal networks over statistical analyses to simple counting of features to a threshold. One group of programs in this category (see below) concentrates on recognition of core promoter properties and infers promoter location solely on that basis, whereas the other group consists of programs that take into account also the proximal promoter region of about 250–300 nucleotides upstream of the TSS. General recognition models were usually based on training sets derived from the Eukaryotic Promoter Database (EPD) and various sets of sequences without known promoter activities. The EPD originally was an excellent collection of DNA sequences that fulfill two conditions: they have been shown experimentally to function as promoters and the TSS is known. Recently, EPD also started to incorporate promoters not fulfilling these stringent conditions [78].

The beauty of the above approaches is their generality, which does not require any specific knowledge about a particular promoter in order to make a prediction. This appears ideal for the analysis of anonymous sequences for which no *a priori* knowledge is available. The bad news was that the specificity of all such general approaches implemented was very limited for quite some time. However, the development of PromoterInspector [77] heralded a new era of promoter prediction, combining acceptable sensitivity with high specificity. Other programs that followed performed comparably [3]. These general promoter prediction approaches were the first to provide acceptable *a priori* promoter prediction on a whole chromosome and now genome scale [76]. Specificities were originally reported just below 50%, but in the meantime many of the orphan predictions (in the middle of unannotated sequence) have found their genes and transcripts boosting specificity to between 80 and 90%. Only a really complete annotation of the genomes will tell the true specificity of those methods. Nevertheless, it is clear that the goal of highly specific promoter prediction in whole mammalian genomes has been achieved.

Some general promoter model-based programs employ methods already described for identification of individual promoter elements (usually TBFBS IUPAC or weight matrix descriptions), but try to derive more general features from a collection of such elements rather than emphasizing individual elements. These methods may be called *statistical element analyses* and treat the proximal promoter as a purely statistical problem of TFBS accumulations, sometimes fine-tuned by some sort of weighting based on occurrence frequencies of TFBSs in promoters as compared to a negative sequence set. Despite the complicated modular structure of promoters outlined above there is a solid rational basis for this general model. All promoters must have a functional core promoter module often containing a TATA box, which is the prime target of the majority of the general promoter prediction tools. This is also one of the reasons that some programs confine their analysis to the core promoter region, which avoids problems with the much more diverse proximal regions. Biological knowledge is solely used to select the training sets and a variety of methods is used to learn the distinctive patterns.

Without exception, TFBS-based statistical element analysis suffers from a huge number of false-positive predictions (typically about one prediction in 10 000–30 000 nucleotides).

4.4.2 Programs Utilizing Mixed Models

These programs also rely on statistical promoter models, but include directly or indirectly some organizational features of promoters, placing them in between the pure statistical models and attempts to approximate the biologically important structured organization of promoters. Again, the first-generation methods will only be summarized. FunSiteP [53] as well as the approach taken by Audic and Claverie [2] fall into this category.

4.4.3 Programs Based on Specific Promoter Recognition

The second, more recent and far more successful concept should be called *functional element analysis*, as it relies heavily on biological knowledge about the relative importance of individual elements and derives discriminative features on that basis. These methods carry out a sophisticated compositional analysis of the proximal promoter analysis to detect unique features within that region that can be used to distinguish promoters from nonpromoters without understanding the details, but using any pre-existing knowledge for feature selection.

This category of methods introduces the functional context in the form of heuristic rules or tries to learn the context from comparative sequence analysis. These methods emphasize specific modeling of promoters or promoter substructures rather than general recognition. Therefore, it is not possible to directly assess the promoter prediction capabilities of these methods. However, in many cases recognizing a common substructure between promoters can be very helpful, especially for experimental design. Although these programs were also published during the time the first-generation general promoter prediction programs appeared, they are still useful in whole-genome scans due to their very high specificity, warranting a more detailed discussion here.

The method FastM was derived from the program ModelGenerator [31] and takes advantage of the existence of NWM libraries. It can be accessed via a WWW interface (http://genomatix.gsf.de part of GEMS launcher) and allows for a straightforward definition of any modules of two TFBSs by simple selection from the MatInspector Library [72]. This now enables definition and detection of wide variety of synergistic TFBS pairs. These pairs are often functional promoter modules conferring a specific transcriptional function to a promoter as shown in Refs. [52, 56]. FastM models of two binding sites can successfully identify promoters sharing such composite elements, but are not promoter specific. Composite elements can also be located in enhancers or similar structures. The latest version of FastM enables definition of complete, highly specific promoter class models including up to 10 individual elements, also including IUPAC strings, repeats and hairpin structures.

The program FrameWorker [15] automates several of the steps taken manually in FastM in order to ground specific promoter modeling on as much an algorithmic basis as possible. FastM requires crucial parameters such as strand orientation, distance ranges, order of elements, as well as the individual nature of the elements (e.g. which weight matrix to use) to be determined by the user. FrameWorker, in contrast, automatically determines theses parameters from a comparison of an (still manually selected) set of input sequences within user-defined ranges. However, determination of the individual weight matrices to be used, as well as their number, distances and relative order, does not require previous knowledge.

Another approach aimed at modeling promoter substructures consisting of two distinct elements is TargetFinder [58]. This method combines TFBSs with features extracted from the annotation of a database sequence to afford selective identification of sequences containing both features within a defined length. The advantage is that TargetFinder basically also follows the module-based philosophy, but allows inclusion of features that have been annotated by experimental work for which no search algorithm exists. Naturally, this excludes analysis of new anonymous sequences. The program is accessible via a WWW interface (http://gcg.tigem.it/TargetFinder.html).

It should be mentioned here that Fickett also employed the idea of a two-TFBS module to successfully detect a subclass of muscle-specific regulatory sequences governed by a combination of MEF2 and MyoD [28]. However, this was also a very specific approach and no general tool resulted from that work. The MEF2/MyoD model can be used to define a corresponding module with FastM. Wasserman and Fickett also published a modeling approach based on clustering of a preselected set of NWM (defined in the same study) correlated with muscle-specific gene expression [93]. They were able to detect about 25% of the muscle-specific regulatory regions in sequences outside their training set and more than 60% in their training set. They classify their method as regulatory module detection. However, their results suggest that they probably detect a collection of different, more specific modules with respect to the definition given above. Although the method is not promoter specific and the specificity is moderate, it is a very interesting approach that has potential

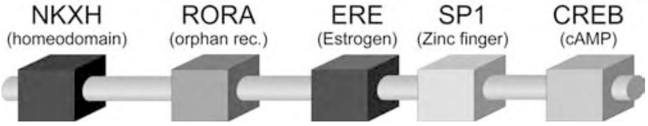

Figure 3 GFAP promoter model conserved in human mouse and rat promoter. The boxes indicate the individual TFBSs found and the bar indicates the genomic DNA.

for further development, as also became evident from follow-up publications of the same authors [30,94].

Generally, this group of methods achieves much higher specificity than the first-generation programs following general models. However, the price for this increase in specificity is usually restriction of the promoter models to a small subset (class) of promoters.

The model of the glial fibrillary acidic protein (GFAP) promoter shown in Figure 3 was derived from a comparison of the human, mouse and rat GFAP promoters. This model contains five different TFBSs and was derived from the set of three sequences using GEMS Launcher (Genomatix). This model recognizes a single sequence, the GFAP promoter, when searched against more than 36 000 human promoter sequences and thus is absolutely gene specific. Interestingly, if the search is carried out with relaxed stringency (allowing for less-perfect matches) only a second sequence comes up, the DGAT2 gene, which is the diacylglycerol *O*-acetyltransferase homolog 2 (homolog to mouse). From the literature it becomes immediately evident that both genes are brain-expressed (GFAP is brain/astrocyte specific) and both are genes associated with insulin signaling. Thus the promoter model-based search found biologically linked genes.

4.4.4 **Early Attempts at Promoter Prediction**

There are various programs that might be called first-generation programs for promoter prediction, some of which were absolutely instrumental in paving the way towards the newer developments, but are no longer of practical use. For that reason they will only be summarized here and not discussed in detail. The first exception to this rule will be Promoter Scan, as this was really the first program ever published for promoter prediction in mammalian sequences and served as a role model for a number of other developments.

Several of the general promoter prediction programs followed the basic design of Prestridge who used the EPD by Bucher's group [78] to train his software for promoter recognition. His program Promoter Scan was the first published method to tackle this problem [70]. He utilized primate nonpromoter sequences from GenBank as a negative training set and included the proximal promoter region in the prediction. The program uses individual profiles for the TFBSs indicative of their relative frequency in promoters to accumulate scores for DNA sequences analyzed. Promoter Scan employs the SIGNAL SCAN IUPAC library of TFBSs [70], introducing a good deal of biological knowledge into the method, although modular organization of the proximal region is necessarily ignored. Results of the first version were combined with the Bucher NWM for the TATA box, which served as a representation of the core promoter module [12].

Other methods following a similar design will not be discussed in detail, but should be mentioned. These include PromFD by Chen and coworkers [18], and the programs TSSG/TSSW from Solovyev's group, which are basically gene prediction methods that include promoter prediction [82]. Other programs in that category are XLandscape [60] and PromFind [44]. Michael Zhang published a new method to detect TATA-box containing core promoters by discrimination analysis.

5 Annotation of Large Genomic Sequences

Many of the methods discussed above were developed before the databases started to be filled with sequence contigs exceeding 100 000 nucleotides in length. The complete human genome draft now contains more than 3 billion nucleotides and many more genomic sequences of similar size are entering the databases. This changes the paradigm for sequence annotation. While complete annotation remains an important goal, specific annotation becomes mandatory when even individual sequences exceed the capabilities of researchers for manual inspection. Annotation of genomic sequences has to be fully automatic in order to keep pace with the rate of generation of new sequences. Simultaneously, annotations are embedded into a large natural context rather than residing within relatively short isolated stretches of DNA. This has several quite important consequences.

5.1 Balance between Sensitivity and Specificity

We will confine the discussion here to regulatory regions, but the problems are general. A very sensitive approach will minimize the amount of false-negative predictions and thus is oriented towards a complete annotation. However, this inevitably requires accepting large numbers of false-positive hits, which easily outnumber the true-positive predictions by an order of magnitude.

In order to avoid this problem methods can be designed to yield the utmost specificity (e.g. specific promoter modeling as discussed above). Here, the catch is inevitably a high number of false-negative results, which also may obscure 70–90% of the true-positive regions. The newer developments of general, but still specific, promoter finding (especially Refs. [3, 77]) may provide a way out of the dilemma. Once a rough annotation has been achieved, other methods can come in to locate promoters reliably in more restricted search spaces such as the FirstExon Finder [24] and Eponym [26]. There was a recent survey of promoter finding in genomic sequences emphasizing that suitability of methods for analysis of large genomic sequences cannot be inferred from limited tests with short samples, which could be referred to analysis in a "sheltered environment" [4].

Gene (or gene group)-specific methods were shown to produce more that 50% true-positive matches in their total output (e.g. Ref. [35]), but recognize just a small fraction of all promoters, which is inevitable for a function-specific model. A single specific model like the phylogenetically conserved GFAP promoter model (Figure 3) matched only once in the human genome, indicating that it is absolutely specific for the GFAP gene.

Definition of the required number of specific models based on current technologies was not a feasible task until recently. However, new developments have already been initiated to overcome the current obstacles and Genomatix is actually working on a genome-wide library of evolutionarily conserved organizational promoter models.

It is quite evident that functional promoter analysis in laboratories is capable of dealing specifically with several hundred or even thousand predicted regions, whereas predicting several hundred thousand or even millions of regions remains out of reach. However, recent improvements of laboratory high-throughput technologies such as location of the TSS by the so-called oligo-capping method [87] have provided an unprecedented amount of verified TSSs (which by definition are located within the promoters). Nevertheless, enhancements of the specificity of promoter recognition *in silico* will also be required as the oligo-capping method has an inherent error rate of 20–30%. Both developments will meet sometime in the future to close the gap in our knowledge about the location of promoters in the genome. More elaborative approaches will be required both in the laboratory as well as in bioinformatics in order to also understand the functionality hidden within these regulatory sequences. It is clear from the past and present developments that bioinformatics will probably cover significantly more than half of that path.

5.2 Genes – Transcripts – Promoters

Originally, the notion was that one gene would represent one function. We learned in the early days of molecular biology during the 1980s that this is not quite true and that one gene may very well have several functions. However, it did not become clear how this is realized until the large-scale

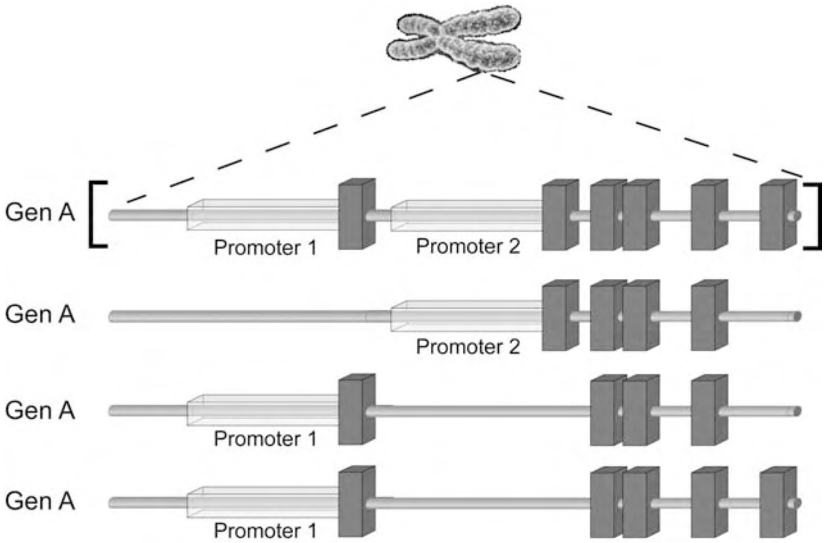

Figure 4 Genomic organization of genes, promoters and transcripts. The transparent boxes indicate promoters, the grey boxes indicate exons and the grey bars indicate the genomic sequence. The brackets delineate the locus of the gene.

mapping and sequencing effort provided us with a better insight into genomic organization. This knowledge has changed our perception of a gene. A gene is no longer an entity, but rather a container with individual transcripts representing the entities. Figure 4 illustrates this new notion schematically. The area in brackets indicates the genomic locus of the gene. This region can be larger than a million base pairs in some cases, providing the space for the complex inner organization. The line with the brackets indicates the genomic structure, such that both promoters and all exons are in a linear arrangement with no clue about the functional links between the individual elements. The lines below refer to individual transcripts, with two transcripts exhibiting alternative splicing originating from promoter 1, while another transcript originates from promoter 2. The important consequence is that this gene may behave like two independent genes with respect to regulation, and the transcript originating from promoter 2 can be completely independent in terms of regulation and function from the other transcripts. They may even encode quite different proteins.

From this it is immediately evident why the paradox of humans having only a moderate amount of genes in excess to *Drosophila* or *Caenorhabditis elegans* is not a real paradox. The inner complexity of transcript and regulatory combinations more than compensates for the apparent lack in total gene numbers. If we count transcripts rather than genes, mammalians do have close to or even above 100 000 – a number earlier pondered for genes as required for the observed complexity. It just turns out that within regulatory sequences as well as within the whole genome, complex hierarchical organization prevails over simple numbers of elements. This is not surprising as the hierarchical principle allows a much more economic utilization of genomic sequences.

5.3 Sources for Finding Alternative Transcripts and Promoters

Of course, once we realized that alternative transcripts as well as alternative promoters are important in general, the question arises how to cope with this extra level of complexity. There are several consequences that need to be taken into account. First, many expressed sequence tags (ESTs) sequences so far simply dismissed as "genomic contamination" may in fact indicate alternative transcripts, as what is an exon in one transcript can be an intron in another. The same is true for a predicted or experimentally verified promoter. If such a promoter was located inside a well-known gene, it was readily dismissed as a false positive, because we already "knew" that the promoter was further upstream. We have seen many cases in which the "false" promoter has found its own transcript in the meantime and was promoted from false to alternative. However, this has blurred the line between "true" and "false" considerably. What is apparently true for one condition (e.g. in one tissue) may be "false" for another condition (e.g. in another tissue). This dilemma is far from being finally solved, but as a practical approach we have adopted a policy of "multiple-evidence" support. The idea is very simple – both theoretical as well as laboratory-based approaches may yield false results. However, if two or more *independent* methods suggest the same conclusion, it is much more likely to be true than that both methods made exactly the same mistake. For example, if oligo-capping indicates a TSS, which happens to be located right inside a predicted promoter, we take this as evidence for a real promoter. Both methods are totally independent of each other and the chance of a result converging by chance is absolutely minimal. Based on this concept, ElDorado (Genomatix) has accumulated more than 150 000 primary transcripts as well as promoters for five mammalian species so far and we are quite confident that we have not yet seen the end of the story.

5.4 Comparative Genomics of Promoters

We have alluded to the "multiple-evidence" approach already in the previous section. However, there is very powerful line of evidence that has not yet been mentioned – the evolutionary conservation of gene regulation. This is one of the most direct lines of evidence towards the functional conservation of promoters as functional regions or elements are far better conserved that the sequence in general. We took advantage of this fact and developed a complete strategy affording the identification and subsequent mapping and analysis of orthologous promoters (Genomatix, patent pending). On top of identification of promoters of orthologous genes, this also includes finding the individual promoters within each species that correspond to each other, which we termed orthologous promoter sets. This is very important for subsequent analysis as functional elements, because functional element conservation is only detectable within orthologous promoter sets. Of course, this approach becomes stronger and stronger as the number of available genomes rises. As of 2004, this enabled us to detect or confirm more than 10 000 promoters in the human genome, making comparative genomics of promoters a major source of promoter annotation (as taken from the ElDorado statistics; Genomatix).

6 Genome-wide Analysis of Transcription Control

If the focus is broadened from individual genes or small gene groups towards looking at the whole genome it is no longer sufficient to just take promoters into consideration. On a genome-wide scale the hierarchy of gene regulation comes into the picture in full force. First, expression of genes on the mRNA level by transcription requires the locus of the gene to be accessible. Regulation of gene expression at the DNA level effected not by TFs, but by other factors elsewhere in the genome, is generally termed epigenetic regulation. This includes regulation by alternation of the chromatin structure, where DNA and histone modifications (e.g. DNA methylation or histone acetylation) play a role and the S/MAR elements discussed above become important. Whether the chromatin structure is open or closed determines whether a promoter becomes available for transcription or not. Thus, a gene with the perfect setup within its promoter(s) can be silent even if all the required TFs are present, provided the chromatin is closed, thus blocking access of these factors to the promoter. Let us assume that the chromatin is in an open, i.e. accessible, state. Even this does no guarantee active transcription of the embedded genes. Local DNA methylation can interfere, an active silencer can specifically block individual genes or one crucial factor may be missing or sequestered (e.g. the nuclear factor NFκB can be blocked by its inhibitor IκB, rendering it nonfunctional the despite presence of the protein). Active transcription is only observed when all conditions are right: the chromatin is open, no repressor is active, and all crucial factors can actually access their respective binding sites on the promoter and enhancer, if one is required. There is also a very old mechanism that seems to gain importance in the regulation of gene expression again – antisense transcription [98]. This means that the same region is transcribed in both directions, resulting in complementary RNAs that can form dimers and thus cancel each other out, as RNA dimers are prone to be destructed immediately. This very complex situation is a formidable safeguard against spurious expression of genes, which could be disastrous for a cell.

6.1 Context-specific Transcripts and Pathways

The many conditions that have to be met to enable the expression of a gene are also behind the differential expression of individual transcripts often coupled to particular pathways. Transcripts can be cell/tissue specific, pathway specific (or better associated as complete specificity is rare) or tied to a particular developmental stage of an organism. This emphasizes the important fact that biological function is tied to the transcript/protein, not to the gene, which may well encode various functions in various transcripts. There is also an important consequence for the analysis of regulatory networks behind signaling or metabolic pathways. It is not sufficient to identify which genes are involved in that pathway, but of utmost importance to identify the promoters associated with that particular transcript/pathway. This is also the reason that the very same pathway containing the same genes can still be differently regulated in different tissues, if different transcripts/promoters are involved in the different tissues. The upside of this complicated situation is that regulatory analysis based on the correct promoters is as close to the real biological situation as we currently can get with *in silico* methods. As it does not make any sense to simplify biology to fit our generic models it is well worth the effort to identify the conditionally important transcripts and promoters as this assures biological importance of the results.

6.2 Consequences for Microarray Analysis

Another field to which the bioinformatics of regulatory DNA regions can be expected to contribute significantly is the analysis of results from high-throughput experiments in expression analysis (e.g. all forms of expression arrays). Due to the discontinuous nature of regulatory regions there is no way of deducing common regulatory features from the expression data directly which are usually based on coding regions. However, the general availability of the corresponding genomic regulatory regions for many (and very soon all) of the genes analyzed in an expression array experiment enables attempts to elucidate the genomic structures underlying common expression patterns of genes. Expression arrays (described in detail in Chapters 24–28) directly deliver information, *which* genes are expressed *where* under the conditions tested. However, they cannot provide any clue to *why* this happens or how the same genes would behave under yet untested conditions. Identification of functional features by comparative sequence analysis (e.g. promoter modules) can reveal different functional subgroups of promoters despite common regulation under specific conditions. Consequently, the detection of known functional modules can suggest expression patterns under yet untested conditions [95]. Moreover, the organizational structures of promoters can also be used to identify additional potential target genes either within the same organism in other genomes or via comparative genomics. Given the exponential number of possibilities for combinations of conditions, bioinformatics of regulatory sequences will also become instrumental for the rational design of expression arrays as well as for selection of experimental conditions.

While this basic conduct of analysis of microarray data remains unchanged, our growing knowledge of alternative transcripts and alternative promoters has far-reaching consequences on strategies employed to analyze transcript levels on a large scale – the microarrays of DNA chips. The most obvious consequences of course are for the analysis of microarray data based on current chip designs that can be purchased from several vendors. As this is the most clear-cut consequence, let us focus on this point first. If there is a single transcript from a single promoter for a given gene, there is no problem, as none of the above complications applies. However, according to current knowledge probably more than 80% of all genes have alternative transcripts and maybe more than half also alternative promoters [99]. Both numbers are rough estimates from what we already know and can be expected to rise even further. This illustrates nicely that the carefree situation of single transcripts and promoters is most likely the exception, not the rule, for genes represented on micorarrays. It has already been recognized that this may cause problems with the traditional way of probe selection, rendering part of the probes on a microarray uninformative [39]. The problem with alternative splicing has been recognized already and studies in that direction have been carried out [49]. There are also efforts under way by microarray manufacturers to take alternative splicing into account. Fortunately, it became possible to check which probes can be reliably used and which probes might cause problems thanks to the high-quality genomic sequences available and our increasing knowledge about alternative transcripts. It should be noted that the set of useful probes depends to some extent on the experimental conditions, not the array used. Some probes might be very informative, whereas the alternative transcripts also recognized by the same probes are not expressed. Use of such probes might cause problems under conditions in which such alternative transcripts are coexpressed.

However, the case of alternative promoters is much less well recognized, but is of equal importance as in many cases transcripts appear to be the same, but originate from different promoters. For example, the CYP19A (also known as aromatase) gene that has at least seven promoters (probably even 10), all of which appear to encode the same transcript. The reason for that paradox is that all promoters are linked to alternative noncoding first exons of almost identical length all of which splice invariably to the identical coding region comprised of nine additional exons. Thus, basically all probes recognize any of the transcripts indifferently. However, events important in breast cancer include a switch of promoter usage not detectable that way [19]. Only transcript-specific probes will help here and they can only be designed based on knowledge about the alternative promoters.

As already mentioned, it is possible to reduce the amount of potentially ambiguous probes by utilizing the existing knowledge of alternative transcript structures [49]. Based on the huge promoter collection in ElDorado, Genomatix is currently evaluating genome-wide probe sets that are specific for alternative promoter usage in order to afford the design of microarrays that will directly indicate promoter selection. This will be of great use for subsequent promoter analyzes as it will take the guesswork out of the selection of promoters. This will also be the only way to tackle the problems of closely related transcripts such as in the case of the CYP19A gene discussed above. It is safe to assume that transcript- and promoter-specific microarrays will become the standard in the near future, bringing the results obtained with such arrays a lot closer to the underlying molecular mechanisms that present-day arrays allow.

7 Conclusions

The experimental dissection of functional mechanisms of transcription control has gained an enormous momentum over recent years. The ever-increasing number of publications on this topic bears witness to this development, which found one early hallmark manifestation in the introduction of a new section in the *Journal of Molecular and Cellular Biology* entirely devoted to analysis of transcription control, which just spearheaded widespread publication of similar articles in most other leading journals. The complex interleaved networks of transcription control certainly represent one of the cornerstones on which to build our understanding of how life functions, in terms of embryonic development, tissue differentiation, and maintenance of the shape and fitness of adult organisms throughout life (see also Chapter 21). This is also the reason why both the experimental analysis and the bioinformatics of transcription control will move more and more into the focus of medical/pharmaceutical research. A considerable number of diseases are directly or indirectly connected to alterations in cellular transcription programs (e.g. most forms of cancer). We recently demonstrated how promoter analysis can be used to elucidate some underlying molecular networks in insulin signaling with relevance to the maturity onset of diabetes of the young (MODY [25]). Furthermore, many drugs influence transcription control via signaling pathways (triggering TFs) [47], which could also be connected to certain side-effects of drugs [73]. The various genome-sequencing projects will provide us with a complete catalog of the components of a number of mammalian species probably within a few years. This will complement the blueprint of the material basis of a human already derived from the human genome sequence. However, only the analysis of the regulatory part of the genome and the corresponding expression patterns and the complex metabolic networks will provide deeper insight into how the complex machinery called life actually works. Definition and detection of regulatory regions by bioinformatics will contribute to this part of the task, and will become instrumental in guiding experimental approaches as well.

As a final note it should be emphasized that transcriptional regulation necessarily involves thousands of proteins, which is why proteomics analyses will also make important contributions to our understanding of regulatory events (see Chapter 28). However, despite its much longer history, protein research has not yet reached the level where it can be readily merged with the DNA-based analysis of transcription control. Nevertheless, we are quite confident that in the very near future protein research will be as integrated into the analysis of genome regulation as are nucleotide sequence- based methods today. Biology simply cannot be divided into DNA, RNA and protein "fields" as all of this is required to define and support the wonderful concerted action called life.

7 Finding Repeats in Genome Sequences

Brian J. Haas and Steven L. Salzberg

1 Introduction

An essential component of genome sequence analysis is the identification of repetitive sequences (repeats). A repeat is a substring that occurs multiple times within a sequence or collection of sequences. Repeats are commonly found in the genomes of both prokaryotes and eukaryotes, although generally to a lesser extent in the compact genomes of prokaryotes. In some cases, the number of repeats and their contribution to overall genome size and content is staggering, e.g. ;ore than half of the human genome is composed of repetitive sequences [34]. In addition, the large genomes of higher plants including maize and wheat are composed mostly of repetitive sequences [3, 7, 19]. In some bacteria, repetitive plasmid sequences are so similar to one another that it is extremely difficult even to determine how many plasmids are present, as in the case of the Lyme disease spirochete [20].

Although repeated sequences represent a diverse group of features, they tend to fall into one of two broad categories: tandem repeats or dispersed repeats. Tandem repeats are those that are found directly adjacent to one another, contiguously arrayed. These are often termed "satellite" DNA. Simple sequence repeats (SSRs or microsatellites) are tandem repeats where the repeat unit is very short, typically 1–6 nucleotides. SSRs tend to have a uniform distribution within genomes, and are sometimes found within protein coding and untranslated regions of genes. Trinucleotide repeats within genes are of special interest since they have been linked to several human genetic disorders, including Fragile-X mental retardation, Huntington's disease and myotonic dystrophy [37, 50, 51]. The term "satellite repeat" typically refers to repeat units greater than 100 bp, which are found as contiguous stretches that can span up to tens of thousands or even millions of base pairs of chromosomal DNA. Such satellite repeats include the 170- to 180-bp repeat units found at centromeres of higher eukaryotes [12, 23] and the long contiguous rDNA cassettes that comprise nucleolus organizer regions [47]. The term

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

minisatellites is used to refer to tandem repeats with unit lengths intermediate to SSRs and satellites.

Dispersed repeats predominantly consist of transposable elements – mobile sequences that can cut and paste or copy themselves to other locations in a genome (for details, see Refs. [11, 13]). Complete autonomous transposons encode one or more proteins that are required for their mobility, and can exceed 10 kb in length. Nonautonomous transposable elements also parasitize genomes; these numerous elements lack the machinery for their own transposition and rely on the proteins encoded by other complete elements to mediate their transposition. Transposons tend to be most abundant in regions of heterochromatin, typically in pericentromeric regions mostly devoid of expressed genes. These elements are sometimes found within introns of genes or interrupting an exon, in which case the gene is likely rendered nonfunctional. Dispersed repeats account for a majority of the repeat content in large eukaryotic genomes. Little is known about the purpose of transposons; they are often regarded as "selfish" elements that provide no benefit to the host organism.

Molecular events resulting in gene duplication, including unequal crossing over during meiotic recombination, recombinational repair or, at the extreme, whole genome duplications, also generate repeated sequences. On the smallest level, slippage of the DNA replication machinery can result in short repeats gaining additional copies. Depending on the event responsible for the genomic rearrangement and the resulting configuration of the genetic material, the duplicated segments may appear in tandem or at remote locations typical of dispersed repeat families. Repeat regions are involved in multiple human diseases, the most well-known being Down's syndrome, which involves an extra copy of chromosome 21. Both Huntington's disease and Fragile X syndrome result from an expansion of trinucleotide repeats. At another level, repeats are used for the new science of microbial forensics; as these regions are among the most highly variable in many species, they provide unique DNA-based signatures that distinguish bacteria from one another, including very closely related strains of organisms such as the anthrax bacterium, *Bacillus anthracis* [49].

Rigorous studies of genome sequence repeats involve identifying similar sequence pairs, grouping the related elements to examine their number and distribution within the genome, differentiating repeats of known function from those of unknown function (and genes from nongenes), and unraveling the details of the length, number of copies and orientation of repeat elements. Each step of the analysis is complicated by the nature of the underlying repetitive sequences, including the degree of divergence between related elements, the background of genomic architectural rearrangements which disrupt or conceal the original repeats and the resulting mosaic nature of repeat elements such that related repeats may share only a subsequence in common. In particular, the boundaries of repeats are notoriously difficult to resolve, complicated by issues described above coupled with the difficulty in obtaining pairwise alignments which terminate precisely at repeat boundaries. An often-cited statement made by Bao and Eddy [4] nicely summarizes the state of automated repeat finding: “the problem of automated repeat sequence family classification is inherently messy and ill-defined and does not appear to be amenable to clean algorithmic attack”. This remains true today, although new algorithms, tools and ideas regarding repeat analysis continue to shed light on the problem.

Repetitive sequences impose formidable challenges to sequence analysis in the postgenomic era. They create havoc for genome assembly; regions rich in repeats are difficult if not impossible to assemble correctly using currently available tools and algorithms, and often lead to misassembly of regions flanked by repeats or excessive fragmentation of what would otherwise be a more cohesive genome sequence (see also Chapter 2). Subsequent to sequence assembly, genome annotation is also confounded by repeats. In particular, the transposon sequences found between genes and within introns can be easily mistaken for exons of protein-coding genes by gene-finding programs. This “junk” DNA requires prior recognition and exclusion to facilitate more accurate identification of the coveted host genes localized to the remaining sequence (see also Chapter 5).

This chapter focuses on the algorithms and tools commonly used for identifying repeats in genome sequences. The impact of repeats on genome assembly and methods used by assemblers to circumvent associated problems are described. Additional topics include methods for clustering elements to organize repeat families, resolving repeat boundaries, efforts to untangle the mosaic nature of related repeats and the annotation of repeat sequences.

2 Algorithms and Tools for Mining Repeats

Sequence alignment is at the very core of repeat identification. In contrast to aligning sequences from different genomes to identify regions of homology, sequence alignment is applied to a single genome, as a single sequence or collection of sequences, to identify significant intra- and inter-sequence similarities. The more general application of repeat analysis is summarized as first finding all pairwise alignments, then clustering related elements. Finding all pairwise alignments is relegated to standard sequence alignment tools and algorithms, a topic described in Chapter 3 and so minimally covered here. Clustering of repeat elements into repeat families is a major challenge, and recent efforts to deconvolute pairwise alignments into more meaningful repeat sets are described. Finding tandem repeats is a related, but distinct challenge; a vast amount of literature exists on this topic, describing algorithms and tools which are specially designed for this aspect of repeat structure. Because of this, tandem repeats are the focus of a separate section in this chapter.

2.1 Finding Intra- and Inter-sequence Repeats as Pairwise Alignments

Pairwise sequence alignment algorithms are well suited to the problem of repeat identification; due to the enormous complexity of the problem in large genomes, heuristics are required to improve efficiency. The Smith–Waterman alignment algorithm [54] finds the single best-scoring local alignment between two sequences. If the sequences being compared are two distinct entries from the collection of sequences corresponding to the single genome under study, this best local alignment would suffice as a repeat. This approach cannot be used, however, when the genome is a single contiguous sequence, as is often the case for complete bacterial, archaeal and viral genomes. Comparing a sequence to itself to find the best local alignment would yield only the obvious perfect alignment along the diagonal corresponding to the alignment of the sequence matching itself from beginning to end. A modification to the Smith–Waterman algorithm, as described by Waterman and Eggert [58], affords the identification of all nonintersecting high scoring alignments, rather than just the single best local alignment between two sequences (see also Chapter 3). This modification unravels the internal repetitive structure of a sequence when aligned to itself. Huang and Miller [24] describe the sim algorithm, which yields all high scoring nonintersecting alignments using linear space, and the lalign utility of Bill Pearson's fasta2 toolsuite (http://ftp.virginia.edu/pub/fasta/) is a popular tool that implements this algorithm. The accompanying plalign utility generates an illustration of the repetitive structure as a postscript file.

Although these algorithms are well suited to repeat finding, they are simply not fast enough to tackle large genomes and so we turn to heuristics. The "seed and extend" heuristic is perhaps the most common strategy to quickly ascertain significant pairwise alignments between sequences. Early uses of this strategy include the FASTA algorithm [43], followed by the hugely popular BLAST algorithm [1, 2], among other database search and alignment tools including MUMmer [14, 15, 32], PatternHunter [35, 36] and BLAT [29], and a less well known but similarly useful tool for studying repeats called ICAass [41], the repeat mining utility of the Miropeats software [42]. Here, matches to exact words of predefined length provide the seeds for alignments, which are extended in both directions to extract the maximal scoring alignment containing the seed (see also Chapter 3). A major limitation of these methods is the requirement of a predefined seed length. A seed length that is too short requires numerous extensions, few of which lead to significant alignments. A seed length that is too long involves fewer extensions, but many significant alignments may lack such a seed and are missed. The programs MUMmer and Reputer [31, 33] take a more sophisticated approach, employing a suffix tree data structure to find exact word matches. The suffix tree is not limited to finding seeds of a constant length; all exact matches are found regardless of length and this is done very fast, in linear time and space.

The focus of repeat-finding software can vary; the focus may be to find all matching substrings within a sequence or among a collection of sequences, or the focus may be the postprocessing of pairwise alignments to cluster related elements into families, resolve repeat boundaries or to illustrate the mosaic nature of repeated sequences. Progress in repeat analysis, as in other areas, builds upon previous contributions to the field. As such, we present an overview of each contribution in roughly chronological order.

2.2 Miropeats (alias Printrepeats)

Miropeats [42] is perhaps one of the earliest and most popular repeat-finding analysis tools to find widespread use in genome sequence analysis (see, e.g. Refs [52]). The repeat-finding engine of Miropeats is the program ICAass of the ICAtools suite [41]. ICAass finds maximal gap-less aligned segment pairs (MSPs) within a single sequence and/or among a collection of sequences using a "seed and extend" strategy similar to that used in BLASTN [1b]. All overlapping 8-mers are loaded into a hash table, using two-bits per base encoding and so allowing 4 bases per byte. All sequences to be examined are indexed and the 8-mers are then used to seed potentially longer alignments. Those ungapped alignments meeting the minimum score threshold are reported. While the ICAass program includes additional components, only the MSP identification steps are utilized by Miropeats. Miropeats is a Unix C-shell script that calls ICAass to identify MSPs as repeats, and then writes a postscript file which illustrates the positions and associations among the repeats. Arcs are drawn between the matching end-points of each repeat pair and arcs are drawn in such a way to help ascertain their relative orientation and overlap. Although ICAass is used, in theory, any program capable of generating meaningful pairwise alignments could be employed, including BLAST (i.e. WU-BLAST with the -span option selected), BLAT or PatternHunter, although Miropeats would require some minor customization to accept this. The strength of Miropeats as a repeat analysis tool lies in its illustration capabilities, particularly with respect to those repeats found in close proximity along the nucleotide sequence, e.g. the structures of transposable elements typically include some form of terminal repeat, either direct or inverted, at the elements' boundaries. The illustration of repeats within transposon-rich regions helps to elucidate their terminal repeat structures as well as their relative abundance along the genomic contig; an example is provided in Figure 1, where the long terminal repeats (LTRs) of a gypsy-family retrotransposon are nicely illustrated by the Miropeats software). (A "contig" is a contiguous stretch of DNA without gaps. Whole-genome shotgun (WGS) sequencing projects generally produce nearly complete genomes that consist of a set of contigs separated by gaps.) As with other repeat-finding applications, the use of Miropeats extends beyond repeat analysis and includes additional areas of sequence comparison, such as to position a small set of bacterial artificial chromosomes (BACs) in a section of a genome BAC tiling path by defining the overlaps among their ends (see also Chapter 2). Due to the relatively slow ICAass repeat-finding step and because of the static illustration of the repeat structures provided by Miropeats, the software is limited in practice to analyzing sequences whose length is no more than a few hundred thousand base pairs, although application to longer sequences is not restricted.

2.3 REPuter

Of the methods available for finding repeated strings in genomic sequences, those based on suffix trees are most efficient and practical for large-scale genome analyses. A suffix tree is a data structure specifically designed to capture a text string and all of its substrings, which makes it well suited for capturing DNA and protein sequences. The tree itself is set of nodes and edges, where each edge is labeled with a string. A suffix of a string *S* (which might be an entire genome, for example) is simply a substring that starts within *S* and extends to the end of *S*. A suffix tree represents all suffixes of *S* implicitly; each suffix is a path from the root node to a leaf node of *S*. Internal nodes of *S* represent other (nonsuffix) substrings; in fact, a suffix tree contains all substrings of *S*. Suffix trees represented a major advance over previous sequence analysis techniques because of two key properties: (i) the size of the tree is a linear function of the size of the sequence, and (ii) the tree can be constructed and searched in linear time. This contrasts with alternative sequence alignment methods, which are quadratic in time, space or both. Details regarding construction and search algorithms for suffix trees are described in Ref. [22].

Stefan Kurtz's REPuter software [31,33], the first production quality repeat-finding software to employ suffix trees, can mine complete eukaryotic genomes (megabase pairs) for all maximal repeats in a matter of seconds on a personal computer. REPuter has existed in two versions. The earlier version, first described in 1999, was limited to finding identical maximal repeats. An enhanced tool suite was released under the package name REPuter in 2001 with the search engine named REPfind, capable of extending the problem of

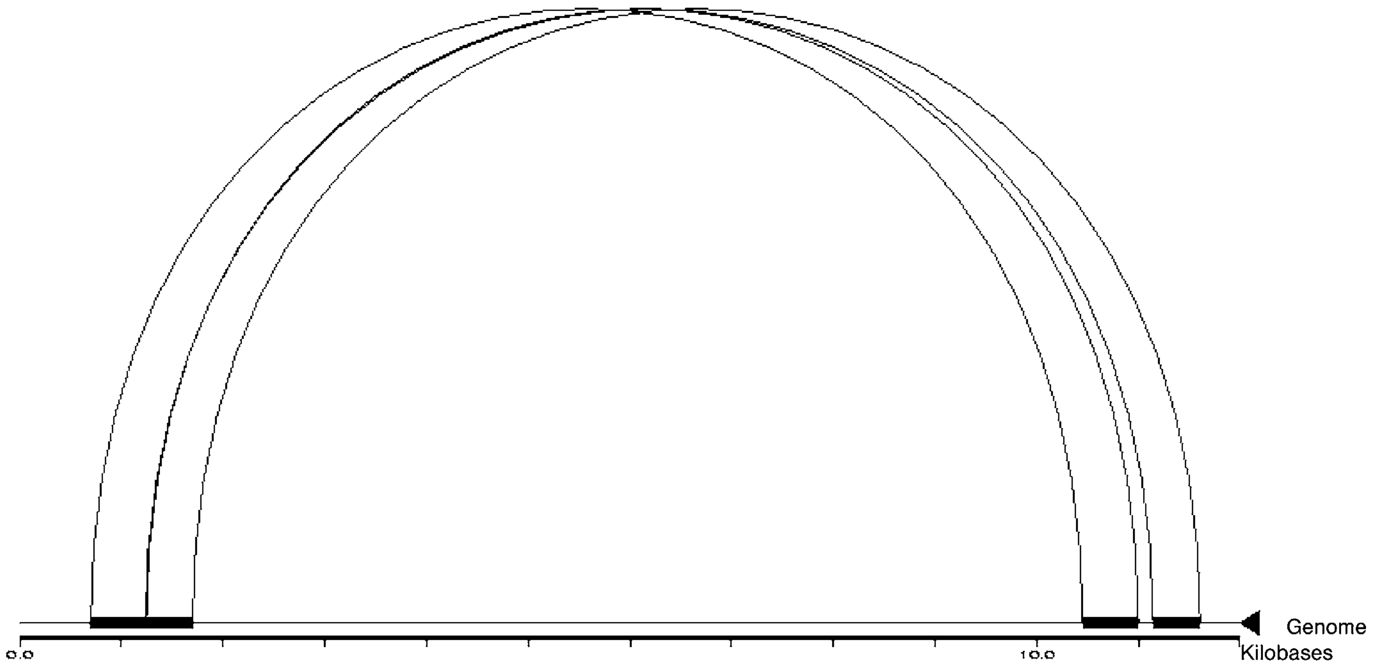

Figure 1 LTRs of gypsy-like retrotransposon family (Athila) element of *Arabidopsis* (locus At1g40077) found and illustrated using Miropeats. Arcs are drawn connecting pairwise matches found in an approximately 12-kb stretch of genome sequence, corresponding here to the LTRs of an *Arabidopsis* gypsy-family retrotransposon.

repeat finding from identical repeats only, to approximate repeats, allowing for mismatches and indels. Each version introduced key concepts and contributions to repeat analysis, so each is described here in order of their availability. To distinguish between the two versions, the earlier version is referred to as REPuter and the later version as REPfind.

As stated earlier, REPuter is limited to finding exactly identical maximal repeats; the repeats are maximal in that extending the alignment between two paired sequence regions would introduce a mismatch and violate the requirement of identical sequence pairs. REPuter can find the following four classifications of repeats, each exemplified using the 4-mer "gcta" and the forward sequence orientation (top strand only):

Forward:	5′-gcta-3′ with 5′-gcta-3′
Palindromic (reverse complemented or inverted):	5′-gcta-3′ with 5′-tagc-3′
Complemented:	5′-gcta-3′ with 5′-cgat-3′
Reversed:	5′-gcta-3′ with 5′-atcg-3′

Although cataloguing all identical sequence substrings is a useful component of repeat analysis, few repeats, unless very recently duplicated, will be free of mismatches or indels. As a result, these repeated identical substrings are often parts of larger repeat units that are nonidentical, although detectibly similar in sequence. REPfind takes this into account and is able to find degenerate repeats, allowing for mismatches and insertions/deletions (indels) as part of the larger repeats.

REPfind exhaustively finds all degenerate repeats in a genome sequence given a user specified minimum length and maximum number of errors. Errors are measured by one of two methods: hamming distance or edit distance. Hamming distance corresponds to the number of mismatches in a gap-free sequence alignment. Edit distance includes the number of differences in an alignment possibly containing indels. The identification of approximate repeats relies on the basis that every degenerate repeat contains a substring of identical sequence.

To find approximate repeats, REPfind locates all exact word matches followed by an extension process to determine if the word match is part of a longer degenerate repeat. Approximate repeats of two types are found: maximal mismatch repeats using the MMR algorithm and maximal difference repeats using the MDR algorithm, as described below. Both types of repeats rely on the existence of an exact word match; the exact word matches are found as described earlier by the original REPuter software.

The MMR algorithm finds a gap-less maximal mismatch repeat by looking for the longest alignment that contains the seed and has no more than k mismatches (the degenerate repeat in this context called a maximal k-mismatch repeat; here k is a specified parameter. This is done by identifying the first $k + 1$

mismatched nucleotides to the left of the seed [ordered from left to right (l_1, $l_2, \ldots, l_{(k+1)}$)], followed by identifying the first $k + 1$ mismatches to the right of the seed (ordered r_1, r_2, …, $r_{(k+1)}$), with the mismatches l_1 and $r_{(k+1)}$ bounding a sequence region of k mismatches from the left or right of the seed boundary, respectively. For all values of i, from 1 to $k + 1$, the substring with coordinates $l_i + 1$ to $r_i - 1$ contains exactly k mismatches. The k-mismatch substring with the greatest length is reported.

The MDR algorithm extends seeds taking into account insertions and deletions. The idea is similar to the MMR algorithm in that k-differences are explored to each side of the seed, and the combination of coordinates within this range which maximize repeat length and satisfy the k-mismatch criteria are chosen. The primary difference is that, instead of searching for nucleotide differences along a single dimension as with MMR, a search is performed in two dimensions allowing for insertions and deletions. A dynamic programming matrix banded at $\pm \pm (k + 1)$, extending from both ends of the seed, is used to find all alignment termini yielding each of 1 to k maximum number of mismatches. Each pair of alignment termini are examined and the pair of left and right termini providing the longest repeat length and a maximum of k-differences is reported.

It is often the case that a single maximal k-difference repeat will contain multiple seeds. To avoid outputting distinct maximal k-difference repeats which contain seeds of neighboring k-difference repeats, the alignment extensions to the left of a target seed are restricted to the right of any previously occurring seed. This guarantees that each maximal k-difference repeat will derive from the extension of its left-most containing seed.

By default, REPfind reports only exact matches, as done by the earlier REPuter program. Options are available to pursue either k-mismatch repeats using the MMR algorithm or k-difference repeats using the MDR algorithm. Unless there is a keen interest in obtaining gap-less repeats only, it is sensible to mine maximum difference repeats exclusively using the MDR algorithm, given that it will report maximum matches with or without gaps, whichever provides the maximal k-difference repeat. Rather than setting the k-value directly, the user can specify the parameter values of minimum repeat length and a maximum error rate, from which the value of k is computed internally.

An improvement over the earlier REPuter software is the inclusion of statistical significance for each of the repeats found in the form of an E-value (see Chapter 3 for an explanation of the concept of an E-value). In the case that multiple solutions exist for the maximal k-mismatch or k-difference repeat, the single repeat yielding the sequence with the smallest E-value is reported. By selecting the option "-allmax", each solution is reported in the case of ties among candidates meeting the maximum length k-difference criteria.

REPuter is available to researchers in several forms: a set of command-line driven utilities for local installations, a comfortable web interface for more interactive and targeted analyses and most recently as a web service enabling distributed computing environments with repeat analysis capabilities.

We should note that the REPuter package, although still widely used and available to researchers, has more recently been subsumed by the Vmatch large-scale sequence analysis software (Kurtz, unpublished; http://www.vmatch.de). Improvements include the use of suffix arrays in place of suffix trees, which reduces memory requirements and processing time. Also, the alphabet of sequences to be aligned is no longer restricted to nucleotide characters, allowing one to examine protein sequences as well.

2.4 RepeatFinder

Given fast and efficient methods to detect pairwise similarities within or among sequences, some repeat analysis software is devoted to the postprocessing of pairwise alignment data to collect and organize the repetitive sequences identified. An early example of this is the Repeat Pattern Toolkit (Agarwal and States [1a]) applied to the clustering of WU-BLAST ungapped alignments derived from 3.6 Mbp of the *Caenorhabditis elegans* genome, placing the alignments into a graph, and finding the minimum spanning tree for connected components to represent the relationships between repeats. A more modern approach involves the postprocessing of repeats found using suffix trees.

Natalia Volfovsky's RepeatFinder [56] uses a catalog of exactly repeated strings to further refine the definitions of individual repeated elements followed by the construction of repeat classes. In contrast to our canonical definition of a repeat as a pair of sequences which share similarity from beginning to end, RepeatFinder describes merged repeats where a merged repeat is found elsewhere in the genome at least once, and may be found in partial copies. The exactly repeated strings are found using the original REPuter software; a newer version of RepeatFinder uses REPfind. These exact matches compose the initial repeat set and these are redefined as repeat elements using a merging procedure. Since repeated sequences are expected to contain mismatches and indels, few complete repeats will be reported as exact matches. The merging procedure serves to consolidate regions defined as repeats that are found in close proximity or overlapping along each genomic sequence. By doing so, indels and mismatches fragmenting single repeats into disparate word matches are merged into larger degenerate repeats, and the dispersive and the fragmented nature of repeat regions is accounted for (i.e. portions of a larger repeat may be found as separate fragments elsewhere in the genome). The merging procedure to redefine repeat regions is restricted to either merging overlapping repeats, or merging neighboring repeats, with minimum overlap or gap size as user-specified parameters, respectively.

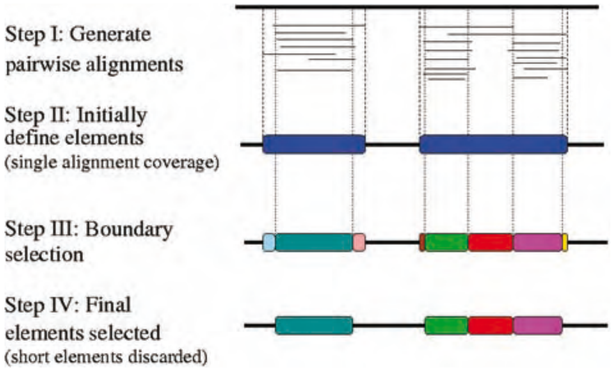
Each merged repeat retains a list of all the originally identified repeats (considered subrepeats) contained by it. Clustering of related merged repeats is done by grouping those merged repeats containing subrepeats in common into the same class. In order to further collapse clusters of similar elements, an "all-vs-all" BLASTN search is performed and separate clusters containing elements with sequence similarity (below a specified *E*-value threshold) are grouped into a single cluster.

Although the software is useful for rapidly extracting repetitive sequences from the genome and grouping related elements, the boundaries of the repeats remain ill-defined and all members of each cluster are not guaranteed to be similar to each other given the transitive relationships established via the clustering algorithm employed. More sophisticated clustering methods employed by RECON [4] address these issues more satisfactorily.

2.5 RECON

Bao and Eddy's development of RECON [4] for repeat analysis was viewed as a pioneering effort, as it represented the first tool to attempt to delineate boundaries of repeat elements in a biologically meaningful way. The algorithm of RECON is broken down into the following major tasks: obtaining pairwise alignments among the input sequences, defining elements based on the pairwise alignments and, finally, grouping elements into families. In contrast to RepeatFinder which obtains the pairwise alignment data using REPuter, RECON uses BLASTN of the WU-BLAST package [21]. The process of defining repeat elements based on pairwise alignment data is illustrated in Figure 2.

Repeat elements are initially defined by collapsing the overlapping pairwise alignments along the genomic sequence (Step II in Figure 2). Multiple alignment information is used to infer the boundaries of the element, and also to recognize and partition those elements found to be composed of multiple distinct repeat units. Given the set of overlapping alignments that initially define a repeat element in the genomic sequence, a preponderance of alignment ends found clustered to a short region of genomic sequence signifies a boundary of an element. Some candidate boundaries may be misleading because they derive from related but distinct repeat elements, those which share subrepeats in common, but are otherwise different. Misleading alignments between pairs of elements are identified by their proportionally large amount of unaligned sequence when compared to the entire element lengths (not shown). These are then discarded from subsequent element boundary refinement methods.



Step I: Generate pairwise alignments
Step II: Initially define elements (single alignment coverage)
Step III: Boundary selection
Step IV: Final elements selected (short elements discarded)

Figure 2 RECON's algorithm for defining repeat elements. In the first stage, WU-BLAST is used to generate pairwise alignments. These pairwise alignments are collapsed along the genomic sequence to define regions of alignment coverage. Clusters of alignment boundaries within short windows are used to redefine element boundaries and initial elements are repartitioned at these boundaries into separate elements. Short elements likely resulting from falsely extended alignments (from the first step) are removed to yield the refined final element set.

After eliminating the misleading alignments, the remainders are examined for the purpose of boundary refinement. Aggregations of alignment endpoints are identified by sliding a short window of predefined length (default 30 nucleotides) along the repeat element, clustering all neighboring alignment ends found separated by no more than the window size. The ratio of alignments with clustered ends to the total number of alignments spanning the corresponding region is used as an indicator of the significance of an aggregation point. A ratio above a specified threshold (default of 2.0) infers a boundary condition and the boundary is defined as the mean coordinate value for the clustered ends. Upon finding a significant aggregation point, the original element is considered composite. The composite element and its underlying supporting alignments are split at the boundary, and the split alignments are reassigned to their corresponding split element (Step III of Figure 2). Elements without significant aggregation points remain as originally defined. Split elements or the split supporting alignments found shorter than a minimum length cutoff are presumed artifacts due to the short random extensions that occur in pairwise alignments and these are discarded (Step IV of Figure 2). The remaining elements provide the set of repeats with defined boundaries.

Following the identification of the individual repeat elements as described above, the elements are classified into families. Special effort is taken to group related but distinct families separately. First, candidates for family membership are chosen by examining alignments between element pairs. For the purpose of clustering the elements, a graph is constructed in which elements are represented by nodes and relationships between nodes represented by edges. Edges are classified into two types: primary edges are used to link elements of the same family, those elements found to align to more than a specified threshold of length coverage of either element (default 90%); secondary edges link elements of different but related families that contain significant alignments but below the threshold of alignment coverage required for family membership. Before clustering family members based on the primary edges, all edges require reevaluation because some edges may have been falsely classified as primary edges. Partial elements are easily misclassified with primary edges during edge assignment since they pass the alignment coverage test with complete elements to which they are compared. It is by virtue of the secondary edges that false primary edges are identified and remedied. False primary edges are found via triangles of inequality: for example, elements A and B are deemed from the same family (primary edges), and elements A and C are deemed from the same family (primary edges), but elements B and C are deemed from separate families (secondary edge). In this case, element A is presumed partial given that it aligns with high coverage separately to the two elements B and C, which themselves lack significant coverage of alignments between them. To prevent element A from grouping the two related but distinct families together, all but the single primary edge extending from A, corresponding to its most similar element, are removed. Following the conversion of false primary edges to secondary edges, all the secondary edges are removed and families are generated by transitive closure of the remaining primary edges.

The algorithm of RECON addresses the problem of delineating the boundaries of individual repeat elements as they are found in the genomic sequence, but it does not describe the mosaic nature of the related repeat elements nor the consensus boundaries and length of a prototypical element among a family of elements. A rough consensus sequence for large RECON-defined repeat families can be derived from alignments of the longest repeat elements within each large family. This is a useful approximation and works well for some repeat families, but is not rigorous enough to yield a consensus for each repeat family in a biologically meaningful way.

2.6 PILER

As discussed in the Introduction, repeats are diverse features, with wide variety in size, location and biological function. Major classes of repeats, including dispersed or tandem repeats, yield specific patterns in the context of whole-genome self-alignments. Bob Edgar's PILER [16] includes a suite of tools each of which focuses on specific patterns evident in sets of alignments to reliably identify elements of the corresponding repeat class. Examples of patterns

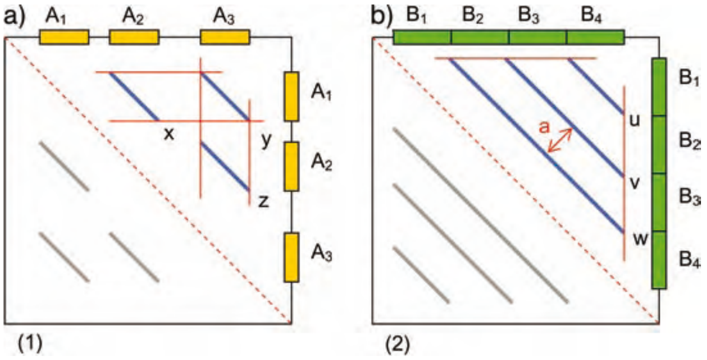


Figure 3 Patterns of sequence alignments targeted by PILER. Dot plots are shown for a comparison of a genome sequence against itself, with the dotted line as an indicator of the main diagonal of the plot. (a) Patterns of alignments generated by alignments of members of a family of dispersed repeats A_1, A_2 and A_3. (b) The "pyramid" pattern generated by alignments from a stretch of tandem repeats B_1 through B_4, indicating a repeat length of a. Figures were derived from Ref. [16], and reproduced here with permission from author Bob Edgar and Oxford University Press.

sought by PILER are illustrated in Figure 3. The individual tools of PILER and corresponding repeat classes are: PILER-DF for detecting individual intact elements of a dispersed repeat family, PILER-PS to find pseudo-satellites, PILER-TA to find tandem arrays, and PILER-TR to find repeat elements that have terminal repeats (a common characteristic of intact transposable elements).

Similarly to RepeatFinder, RECON, and other repeat finding and clustering tools, a set of intra-genome alignments is required. Rather than rely on REPUTER or BLAST to generate alignments, PILER includes an efficient alignment program called PALS (Pairwise Alignment of Long Sequences), which is specially designed with optimizations for detecting repetitive sequences; optimizations targeted towards searching a sequence against itself, limiting searches to banded regions and unrestricted reporting of numerous colocalized alignments, among others. After generating all alignments, overlapping hits along the genome sequence are linked together into a "pile" of contiguously overlapping alignments. These piles of hits are further subjected to specific analyses provided by the PILER-* utilites.

PILER-DF is designed to detect "Dispersed Families" of repeats with characteristics of transposable elements. The specific signature of a dispersed family as revealed by pairwise alignments is illustrated in Figure 3(a). The isolated elements are found as globally alignable regions, all with alignments of similar lengths. The goal of PILER-DF is to find aligned pairs that have similar characteristics. This is done by analyzing aligned sequence pairs such that each aligned region is found in a different pile (dispersed). Given a pairwise alignment between X and Y, such that X and Y are in different piles, an edge is drawn between X and Y if each aligned region spans most of its corresponding pile [(length of X)/(length of pile containing X), (length of Y)/(length of pile containing Y)]. After examining all pairwise alignments in this matter, all connected components are found in the resulting graph. The connected components are interpreted as dispersed families of complete repetitive elements.

PILER-PS searches for "Pseudo-Satellites; – repeats with features of satellite sequences in that they are found clustered locally in the genome. The algorithm here is identical to PILER-DF with the exception that the pairwise alignments result from a banded search, requiring that the alignments be in close proximity to one another.

PILER-TA finds "Tandem Arrays". The repeat-finding tools described so far are mostly limited or specially tuned to find dispersed repeats. PILER-TA is an exception in that it purposely mines these features from the genome. Please note that the general topic of finding tandem repeats is the major focus of the next section of this chapter and so it will be mentioned only briefly here as it relates to PILER. Sequences arrayed in tandem leave a specific signature in the pairwise alignments termed "pyramids" (see Figure 3b). The first observation is that pairwise alignments in a given pyramid are restricted to the same pile since all of them overlap. A banded search is used to find pairs of alignments within a pile that have the following characteristics: the shorter alignment pair is at least half the length of the longer alignment pair, and the distances between the alignments' respective start and end coordinates are each within a predefined percentage of the shorter alignment length. All pairs of alignments meeting such criteria are connected by an edge and, at completion, all connected components are gathered. Each connected component is interpreted as a tandem array. Simple heuristics are employed to define boundaries between the individual repeat elements. Diagonal distances that are in good agreement define the element length and sequences of this length from hit end-points provide representative elements of the array.

PILER-TR finds families of elements with "Terminal Repeats". This search is geared towards finding transposable elements with terminal repeats, such as the long LTR retrotransposons. The signature of these features is a set of repeats, about 50–2000 bp, separated by anywhere from 50 to 15 000 bp (all default parameters). A banded search is used to find candidate terminal repeats. To avoid reporting tandem repeats and pseudo-satellites that would also be found via a banded search, these are found and masked as a prerequisite to this search. After finding candidate terminal repeats, a second search is carried out to find different elements with matching terminal repeats, in which case a nonbanded regular search is performed. All candidates with matching terminal repeats are clustered and reported as families of terminal repeat elements.

2.7 RepeatScout

Alkes Price and Pavel Pevzner's RepeatScout [46] takes a distinct approach to repeat family identification, which circumvents some of the difficulties associated with the more traditional approach involving the postprocessing of pairwise alignments. Generating pairwise alignments as the first step of repeat sequence identification can take a long time, utilize many CPU cycles and generate copious output that can consume an enormous amount of disk space. With large genomes, this can be intractable and further effort is required to partition data sets into more manageable inputs, all of which can adversely affect the results obtained. In contrast, RepeatScout employs a repeat family search stage heuristic similar to that used in database-searching algorithms like BLASTN [1b]. Where BLASTN requires that two potentially homologous sequences share at least one exact word match in common, RepeatScout requires that all initially targeted members of a repeat family share at least one exact word in common. In basic terms, RepeatScout uses an exact word match (seed) to identify potential members of a repeat family, and then maximally extends alignments of all targeted regions to the left and right of the seed to compute a consensus sequence representation of the repeat family with repeat boundaries optimized. The specifics of this approach are described below.

The first phase of the RepeatScout algorithm involves scanning the genome for frequently occurring words. A collection of genomic sequences are scanned and the positions of all words of user specified length (i.e. 13-mers) are catalogued. Closely spaced repeat word occurrences are ignored to avoid tandem repeats [tandem repeat finding is relegated to Tandem Repeat Finder (TRF) [9] and is not an objective of RepeatScout]. After the scanning is complete, frequently occurring word matches are fed to the final phase of RepeatScout – the repeat family identification and consensus sequence construction stage.

Starting with the most frequently occurring word, RepeatScout attempts to extend all such word occurrences to the left and to the right, terminating the extension at what are considered to be the most appropriate boundaries of the repeated element, and simultaneously generating a consensus sequence for this repeat family. The extension phase is perhaps the most distinctive and critical feature of the RepeatScout algorithm, and it is the extension algorithm that rigorously defines the repeat boundaries. The consensus sequence generated by the word extension phase is optimally aligned to all members of that repeat family and cannot be further extended without reducing the total alignment score. This is accomplished by the following objective function, which computes the score of the consensus sequence as the sum of the scores of each individual repeat element aligned to the consensus:

$$A(Q;S_1,\ldots,S_n) = \left\lfloor \sum_k \max\{a(Q,S_k),0\} \right\rfloor - c * \text{length}(Q)$$

where $a(Q,S_k)$ corresponds to the score of an alignment between the consensus sequence Q and a genome sequence substring (S_k) of equal length that extends from both ends of the seed. The constant c imposes a minimum threshold on the number of individual repeat elements (S_n) that must align with the consensus sequence to provide a suitable representation of a repeat family.

The choice of alignment function $a(Q,S_k)$ determines how the consensus sequence boundaries are positioned. With a Smith–Waterman local alignment function [54], short partial repeats would not be penalized and spurious alignment extensions to the more complete elements could drive the consensus boundary position beyond more appropriate repeat boundaries. Towards the other extreme, a fit-alignment algorithm, which fits one sequence into another [57] could be used to force all underlying complete and partial elements to match the consensus, but this can have the affect of yielding consensus boundaries that underrepresent the true boundaries. As a more suitable compromise between these two scenarios, the authors introduce a *fit-preferred* alignment function that yields a consensus sequence shared by some but not all of the underlying complete and partial copies. The fit-preferred alignment function is described below:

$$\begin{aligned}
f(i,0) &= \max(-\gamma i, -p)\ , \\
f(0,j) &= 0\ , \\
f(i,j) &= \max \begin{cases} f(i-1,j-1) + \mu_{ij} \\ f(i,j-1) - \gamma \\ f(i-1,j) - \gamma \\ -p \end{cases} , \\
a(Q,S) &= \max_{i,j} \begin{cases} f(i,j) & \text{if} \quad i = |Q| \\ f(i,j) - p & \text{if} \quad i < |Q| \end{cases}
\end{aligned}$$

where the match/mismatch score is provided by μ_{ij}, the gap penalty score by $\gamma\gamma$ and the fixed incomplete-fit penalty provided by p. Here, $f(i,j)$ is the score of a best alignment between the $1, \ldots, i$ characters in the consensus sequence Q and $1, \ldots, j$ characters in the repeat element S. The fit-preferred alignment score $a(Q,S)$ is simply $f(i,j)$ if the best alignment includes the entire consensus sequence. If not, the incomplete-fit penalty is subtracted from the best alignment score, penalizing the alignment for not including the entire consensus sequence.

The fit-preferred alignment algorithm is used by RepeatScout to generate alignments separately to the left and to the right of the word match. The fixed incomplete-fit penalty (p) is subtracted from the score of any optimal alignment to the consensus sequence that fails to extend all the way to the left boundary of the consensus sequence; an analagous penalty applies to the right boundary. If the alignment is incomplete on both boundaries, the penalty is subtracted twice. The result is that partial copies of the element are penalized in the presence of longer, more complete elements, and the consensus sequences that are generated are more suitable representations of the underlying repeat copies targeted by the exact word match. False-positive candidate elements targeted by the initial word matching strategy do not pose problems for RepeatScout; these will acquire negative alignment scores and are eliminated from contributing to the consensus by virtue of the main objective function.

The most rigorous approach to generating the consensus sequence would involve n-dimensional dynamic programming (where n is the number of sequences), but this would not be practical or even possible for more than a few sequences given that this task would be NP-hard. Instead, a heuristic approach is taken to generate the consensus whereby the word match is extended to the left and right one nucleotide at a time. A single nucleotide extension is attempted using each of the four nucleotides (G, A, T and C) and the single nucleotide extension providing the optimal alignment score is chosen. The consensus sequence is constructed greedily in this way until a maximal score is obtained and a predetermined number of subsequent iterations fails to improve upon this maximal score. The consensus sequence providing the maximal score is chosen to represent the underlying set of repeats and the termini of the consensus sequence delimit the repeat boundaries.

The RepeatScout algorithm, as described, is applied to each frequently occurring word match, beginning with those most frequent. As a single repeat family is likely to contain many exact word matches, effort must be taken to prevent re-identifying the same repeat family based on other yet-to-be processed frequently occurring words. In an attempt to prevent this effect, the counts of words found within approximate occurrences of the consensus sequence are readjusted within the set of frequently occurring words, decreasing the chance but not absolutely preventing the possibility of finding the same (or a portion of a) repeat family identified previously. A future release of RepeatScout may improve upon this functionality for identifying approximate occurrences of the consensus sequence, in order to more completely preclude repeat family rediscovery based on subsequent word matches.

The task of finding occurrences of repeat family members in the genome is relegated to searching the genome with the database of consensus sequences using RepeatMasker, BLAST or another sequence search and alignment utility. These homology searches may find repeat elements that have diverged considerably from those used by RepeatScout to generate the consensus (i.e. they lacked an exact word match required to be included in the consensus sequence construction stage of RepeatScout). This procedure provides a powerful mechanism to rigorously identify and annotate the individual elements of a larger repeat family.

3 Tandem Repeats

Tandem repeats form a special class of repetitive sequences, composed of a contiguous stretch of two or more copies of a repeat pattern. The length of the repeat pattern is called the period. This class of repeats, termed satellites, is of great biological relevance, found to correspond to specialized structures within eukaryotic genomes such as the short pentamer to heptamer repeats that form telomeres, and the longer repeats that form centromeres (e.g. 180-bp period repeats in *Arabidopsis*). Microsatellites (SSRs), found both within and between genes, are of great interest to those studying biodiversity and population genetics, and for DNA fingerprinting studies. Expansions in trinucleotide repeats have been correlated with various disease states, including Huntington's disease and Friedreich's ataxia, among others.

The problem of finding tandem repeats has received much attention from computer scientists and biologists alike, due to both the tractability of the problem from an algorithmic perspective and because of the importance of tandem repeats in their diverse biological roles. The challenge of finding tandem repeats involves identification of the repeated pattern and the number of times the pattern is repeated. Over the past decade, many algorithms have been proposed for the identification of tandem repeats, some of which seem to be academic exercises in algorithm development and few are found implemented in publicly available software for the general application of tandem repeat finding in the postgenomic era. One exception is Gary Benson's TRF [9], which has seen widespread use in genome sequence analysis and remains the most popular tandem repeat analysis software today. Alternative tools for finding tandem repeats have recently become available and extend the repertoire of essential software available to genome researchers. Here, we survey a few of these tools and describe the algorithms employed for finding tandem repeats.

3.1 TRF

Gary Benson's TRF is a powerful software tool capable of finding exact and approximate (containing mismatches or indels) tandem repeats in genomic sequences [9]. The algorithm employed in TRF is broken into two stages; first, the detection component which identifies candidate tandem repeats using a set of statistical criteria, followed by the analysis component calculates the consensus repeat pattern and period size using sequence alignment methods.

TRF initially detects tandem repeats based on the premise that similar sequences found contiguously arrayed are likely to share exact substrings, and the distance between paired substrings will be approximately the same and correspond to the period of the tandem repeat. In a search for these exact substrings that may target a tandem repeat, the genomic sequence is scanned from left to right for exact word matches, with some fixed word length w.

All further analyses of the candidate tandem repeat during this detection phase rely on statistical analyses whereby the alignment between candidate tandem repeats are modeled as a sequence of independent and identically distributed (iid) Bernoulli trials, equivalent to a sequence of coin tosses such that heads correspond to matching pairs of nucleotides, and tails correspond to mismatches or indels. The probability pM of a match and the probability pI of an indel are user-defined parameters that provide an upper limit to the allowed divergence between candidate tandem repeats.

The probabilistic model of the iid Bernoulli sequence is used with several statistical criteria to evaluate candidate tandem repeats: the *sum of heads distribution* to dictate the number of matches required among candidate repeats; the *random walk distribution* to model the indels between tandem repeats that might cause variability in the apparent period length; the *apparent size distribution* to distinguish between tandem repeats and dispersed repeats by analyzing the distribution of matches along the proposed period length; and the *waiting time distribution* to choose match search criteria that are most suitable for different period lengths. Each of the above distributions depend on the period length, word length used for scanning matches, and the user-defined cutoffs of pM and pI.

During the scan of the genomic sequence from left to right, word matches are accumulated. The position of each word is kept in a history list and the distance between word matches is kept in a distance list. Once a word match is found, the distance separating the words is presumed a candidate period length for a tandem repeat. The candidate tandem repeat would require additional matches along the remainder of its period length. These additional matches are found by querying the distance list, searching for word matches separated by the same period length, with the leading word match positioned between the triggering word matches. The statistical test using the sum of heads distribution determines the minimum number of matches required for a candidate tandem repeat. Here, the normal distribution is used to determine the minimum number x of matches, such that 95% of the time, at least x nucleotides (heads) are counted as part of exact word matches (head runs of length w) along the period length. To account for indels between word pairs of approximate tandem repeats, the period length is not fixed at a constant during this phase, but allowed to vary slightly, consistent with the random walk distribution. The allowed variation is restricted to that expected within 95% of random occurrences based on the indel probability *pI*, under the hypothesis of a random walk along one dimension with maximal displacement equal to *d***pI*.

Candidate tandem repeats which pass the sum of heads test are further analyzed to differentiate tandem repeats from local repeats that are not arrayed in tandem. Tandem repeats are distinguished from nontandem direct repeats, i.e. repeats found in close proximity but not directly adjacent, by the distribution of matches along the period length of the candidate tandem repeat. Nontandem direct repeats will tend to have matches concentrated on the right side of the period length (because the algorithm processes them from left to right), whereas the tandem repeats should have leading word matches distributed throughout. The apparent repeat length is calculated as the maximal distance between the first and last run of matches found using the exact word match scan. This apparent repeat length is likely to be smaller than the actual repeat length, but provides a useful approximation for this analysis. A minimum apparent repeat length threshold for a tandem repeat is determined by simulation. An apparent size distribution is generated from random Bernoulli sequences using the *pM* value to model an alignment between two genuine tandem repeats with period length *d*, and the distances between the first and last runs of exact word matches are collected. A minimum apparent repeat length is chosen such that 95% of the time, the apparent repeat length determined for random Bernoulli sequences with *pM* exceeds this cutoff length. Candidate tandem repeats passing the minimum apparent repeat length threshold are further subjected to the analysis component.

The waiting time distribution is used to pick word lengths used during the initial genome scan. Random Bernoulli sequences are used to determine the minimum number of aligned residues (coin tosses) to find an exact word match (run of heads) of length w, 95% of the time, given a probability of a match (*pM* or probability of heads). As with other sequence alignment software, such as BLAST, the choice of word length is very important and affects the sensitivity and running time of the analysis. Short word lengths accumulate large history lists and many false-positive matches, unlikely to be indicative of tandem repeats. Alternatively, large word lengths accumulate few false positives, but are unlikely to detect short approximate tandem repeats. Therefore, the word length needs to be chosen in accordance with the repeat length under consideration. The waiting time distribution is used to pick a set of word lengths to apply to different ranges of pattern sizes, given *pM*. Word lengths of 3–7 bp are chosen to detect tandem repeats with periods of up to 500 bp and at least 75–80% identity.

Those candidate tandem repeats passing the above statistical criteria are further examined under the analysis component of TRF. The analysis component involves aligning the interval of the candidate tandem repeat to the surrounding genomic sequence using the technique of wrap-around dynamic programming (WDP) [18], nicely described in Ref. [10] and Appendix A of Ref. [8]. The technique of WDP provides a method whereby a single copy of the tandem repeat can be aligned with all copies in a larger stretch of genomic sequence, such that the alignment is allowed to wrap around the tandem repeat from end to beginning again, to continue alignments to the subsequent copies of the repeat. The candidate tandem repeat used in WDP may not be the optimal sequence, as the consensus among the repeat copies may contain nucleotide differences or indels when compared to the initial candidate used to generate the alignments. A consensus pattern is generated from the alignment, and this consensus is realigned to calculate the period length and number of copies of the tandem repeat. TRF is limited to finding tandem repeats with unit lengths up to 500 bp.

3.2 STRING (Search for Tandem Repeats IN Genomes)

The algorithm underlying STRING relies almost exclusively on sequence alignment methods to identify tandem repeats [40]. As with TRF, the algorithm consists of two stages; first, the identification of candidate tandem repeats, followed by a more detailed analysis stage to resolve the tandem repeat structures. The identification of candidate tandem repeats involves what are referred to as autoalignments, which involves aligning a sequence to itself. A variation of the Waterman–Eggert algorithm [58] is implemented to identify all nonintersecting local alignments, with a modification to avoid reporting the trivial alignment of the complete sequence to itself along its entirety. Features of some autoalignments are found characteristic of tandem repeats: aligned sequence pairs with overlapping or neighboring coordinates indicate a tandem repeat with a period equal to the distance between coordinates of aligned residues. Such autoalignments do not rigorously define the tandem repeat, but rather highlight the regions of genomic sequences which are strong candidates for containing tandem repeats, to be analyzed in a subsequent tandem repeat finding search stage. Candidate regions are selected by grouping all autoalignments with overlapping coordinates and including those nonoverlapping autoalignments that are found in close proximity that could be extensions of tandem repeats not captured during the autoalignment stage.

Each candidate region is further subjected to the tandem repeat search stage, as follows. A set of words are chosen such that each distinct word is a potential isolated element of larger tandem repeat. A variation of WDP is used to align each word against the larger candidate region. This involves performing the Waterman–Eggert-style alignment using a cyclically addressed word, capturing all high scoring non-intersecting local alignments. Each word and alignment, as a unit, is referred to as a Single-Expansion Interpretative Pattern (SIP). All SIPs found within a candidate region are compared to each other in a pairwise fashion in order to eliminate redundancy and resolve conflicts between overlapping SIPs (some SIPs may be found as insignificant versions of larger SIPs). Remaining SIPs are reported as tandem repeat tracts with the triggering word as the consensus for the tandemly repeated element. STRING is limited to finding tandem repeats of unit length smaller than 100 bp.

3.3 MREPS

A distinguishing feature of the newer MREPS program is its ability to find tandem repeats of any length, from microsatellites to large tandem segmental genome duplications [30]. At the heart of MREPS is a very efficient combinatorial algorithm based on advanced string processing techniques, which finds approximate tandem repeats, also called k-mismatch repeats, running in linear time $O(nk\log(k) + S)$ for a sequence of length n containing S repeats with at most k mismatches per tandem repeat copy. MREPS finds all k-mismatch repeats for values of k up to a user-specified maximal resolution parameter, enabling the program it to find highly divergent repeats. Additional processing time is spent refining the results of this search to report biologically meaningful repeats, coping with artifacts resulting from the algorithmic definition of k-mismatch repeats and consolidating redundant repeats found at different k-mismatch runs, as described below.

The mathematical definition of the k-mismatch repeat requires that the repeat be maximal. For this purpose, mismatches are sometimes added to the repeat boundaries, extending the repeat length to enforce the maximal k-mismatch repeat definition. MREPS attempts to identify these unwanted extensions and trim them from the repeat termini, retaining the more meaningful and longer core of the repeat.

Another postprocessing step consolidates redundancy among repeats and computes their optimal period value. The same region of genomic sequence can be reported as having tandem repeat sequences with different periods. For example, a tandem repeat with period of 2 may also be reported with periods that are multiples of 2. Each period may be associated with a different degree of degeneracy, based on the k-mismatch limit for reporting the repeat. The optimal period for the repeat is chosen as that which minimizes the number of mismatches between tandem copies with period p.

This is done for every period from 1 to p and the period with minimum error rate is reported. After computing the optimal period, repeats with the same period and overlapping by at least two periods are merged together to form a single repeat. By doing this, repeats originally found as k-mismatch repeats are redefined in a more satisfying way.

The tandem repeats found as a result of this process are filtered to retain only those that are considered to be statistically significant. In this case, the statistically significant repeats are those that are unlikely to be found within random sequences. Empirical thresholds for minimum length and maximum error rates were determined for various resolution parameters using shuffled genomic sequences, and these thresholds are applied to the collection of repeats to remove insignificant entries.

4 Repeats and Genome Assembly Algorithms

Genome assembly is perhaps the computationally most demanding task in genomics, requiring days or weeks of computation time for the largest genomes, even on the latest vintage computers. The assembly problem itself is simple enough to state: given a collection of input sequences, compute how these sequences overlap one another and use these overlaps to reconstruct the original chromosomes. A large mammalian genome assembly generated from a WGS sequencing project might include over 20 million input sequences of approximately 800 bp in length. Most of the sequences are generated in pairs, by sequencing both ends of a larger DNA fragment; these fragments are grouped into “libraries” with a characteristic fragment size. The assembly algorithm must keep track of those sizes in order to place the sequence pairs (or “mates”) approximately the right distance apart in the final assembly. A thorough account of the computational assembly of genomes is given in Chapter 2.

Repetitive sequences make genome sequence assembly hard; without repeats, almost any algorithm can correctly assembly a genome. This follows from the fact that without repeats, any overlapping sequence shared by two or more individual sequence “reads” clearly implies that the reads came from the same chromosomal location and can be assembled together. As repeats are so central to the assembly problem, much effort has been dedicated within large-scale assembly systems to the repeat identification problem.

Assembly systems are only looking for repeats that will confuse them, which are a subclass of all repeats. First of all, assembly algorithms must compare large numbers of reads (as many as 30 million) looking for overlaps. The fundamental goal of assembly from a WGS sequencing project is to unify overlapping reads if they originated from the same place on the same chromosome. Consequently, the reads should be identical up to the limits of sequencing error. Thus, assemblers look for shared sequences that are nearly identical – a typical threshold is to require that two reads must overlap by at least 40 bp and the overlapping region must be at least 98% identical. This leads naturally to the observation that any pair of repetitive sequences that is less than 98% identical will not cause any serious problems for assembly. Such divergent repeats can be sorted out and placed into the correct locations in the genome. Of course, this is a somewhat simplistic view; e.g. it is often the case that short regions in the middle of long repeats are identical – and therefore confusing – even if the entire repeat is not.

Second, any repeat that is contained entirely within a sequencing read does not cause a problem, because the unique sequence flanking the repeat will allow the read to be placed correctly in the genome assembly. Current sequencing technology generates reads of 800 bp or longer; therefore a repeat region that spans less than 800 bp rarely presents a problem. Note that the phrase "repeat region" here refers both to single-copy repeats and to tandem repeats. If a repeat occurs in 20-bp units, but those units occur in tandem arrays spanning 100 copies, then the repeat region spans 2000 bp and is definitely a problem for assembly, even though the repeat unit itself is quite short.

Thus, it should be clear that assembly algorithms must identify sequence reads that are comprised entirely of repetitive sequence, and they must handle these repeat reads differently. For the sake of discussion, we will describe how they are handled in the Celera Assembler [38], although many of these strategies are similar to those employed by Arachne [5,25] and other current assemblers. (Note that the Celera Assembler is now open source and includes many enhancements not described in the original paper; the code is available at http://sourceforge.net/projects/wgs-assembler.)

4.1 Repeat Management in the Celera Assembler and other Assemblers

There are two main tasks in repeat processing for assembly: (i) one must identify repeats and (ii) one must attempt to place them in the assembled genome. We will discuss these two issues in order.

4.2 Repeat Identification by k-mer Counts

The first major computation in most assembly algorithms is the overlap step, in which all reads must be compared to all other reads. In order to compute this essentially quadratic operation efficiently, most assemblers employ a hashing strategy: they create a hash table and record in it all *k*-mers of a certain length. Each *k*-mer entry stores the read identifier and the position within that read where the *k*-mer occurred. Typical values of *k* are 22 (used in the TIGR Assembler [55] and Celera Assembler) and 24 (used in the Arachne assembler); this is long enough that in a random DNA sequence, the vast majority of *k*-mers will not occur at all.

The *k*-mer hash array provides a simple and natural vehicle for identifying repeats. Recall that we want to identify sequence reads that are entirely repetitive; i.e. satisfying the condition that no unique sequence can be found within the read. After scanning all reads for all *k*-mers, it is a trivial matter to note the average depth of coverage by computing the mean number of entries for each *k*-mer in the table. Based on this value, one can determine a threshold above which a *k*-mer can safely be assumed to be repetitive, e.g. 3 times the mean. The Celera Assembler then scans the reads a second time and for each read looks at the counts of each *k*-mer in the read. If all *k*-mers in a read have a count above the threshold for repeats, then the read itself is labeled as a repeat. Arachne takes a slightly different approach, eliminating all *k*-mers that are overrepresented so that they will not be used in the overlap calculation.

4.3 Repeat Identification by Depth of Coverage (Arrival Rates)

A second method for identifying repeats occurs later during the assembly process, after at least one round of contig creation. Once the assembler has a set of contigs built, it can ask whether entire contigs are repetitive. The simplest method here is based on coverage: for a genome covered at, for example, 8 times coverage, any contig with significantly deeper coverage is highly likely to be repetitive. As the average coverage is easy to compute, it is also easy to detect any contigs whose coverage is 2 or 3 times normal. However, such a simple approach fails to account for the fact that, statistically, a longer contig is likely to have coverage closer to the mean than a short contig. For example, in an 8 times assembly, a long contig with 15 times coverage is far more likely to represent a repeat than is a short contig with the same coverage.

The Celera Assembler models the expected coverage of a contig using an "arrival rate" statistic. The idea is the following: assuming that the WGS reads are generated by a uniform random process that samples every location in the genome equally, then the reads should "arrive" at a contig (i.e. they should align to it) at a rate that can be modeled as a Poisson process. This arrival rate statistic is computed as follows [38]. Suppose that the genome size is G, the sequencing project generated F reads and we are examining a contig containing k of those reads. Consider the positions where all k reads begin in the contig; these are the arrival locations. If the contig occurs just once in the genome, then we should have sampled it at the same rate as any other interval on the genome; in this case, if we look at the region of length r between the first and last arrival locations, then the probability of seeing $k - 1$ arrivals in that interval is $[(rF/G)^k/k!]e^{(-rF/G)}$. If the contig occurs twice in the genome (and therefore we expect twice the arrival rate) then the probability of seeing $k - 1$ arrivals is $[(2rF/G)^k/k!]e^{(-2rF/G)}$. The "$A$ statistic" in the Celera Assembler is computed as the log ratio of these two probabilities; i.e. $A = (\log e)rF/G - (\log 2)k$. In simple terms, this statistic computes whether a contig is more likely to occur once than twice in the genome. By adjusting this single parameter, the assembler can be more or less cautious about what it considers a repeat.

4.4 Repeat Identification by Conflicting Links

A third way of identifying repeats is to notice that a contig has two or more adjacent contigs according to mate-pair information. If a repeat occurs at multiple distinct locations (i.e. not in tandem), then the paired sequences that align to the repeat will have mates (links) that point to different loci. This can be recognized relatively easily during the scaffolding stage of assembly.

4.5 Repeat Placement: Rocks and Stones

Once a repeat has been identified, the assembler must decide what to do with it. A number of assemblers, including Celera Assembler, first assemble the obviously nonrepetitive sequences and then try to place the repeats. One strategy for doing this in Celera Assembler is called the "rocks and stones" approach. The idea is to first build scaffolds from the unique sequences, linking contigs together only if at least two mate-pairs (i.e. the pair of sequences that comes from opposite ends of a single DNA fragment) agree on the linkage. Rocks and stones are repetitive contigs (based on the A statistic) that are "thrown" into these gaps if mate-pair links indicate they belong there; rocks must have at least two links and stones only need one. The assembler then attempts to join the flanking contigs together by finding a tiling of reads across the contigs and the newly placed stones. Note that one weakness of this approach is that it is sometimes difficult to determine whether one or multiple copies of a stone belong in a gap and it is possible that the wrong number of copies of a tandem repeat will end up in the assembly.

4.6 Repeat Placement: Surrogates

One final issue surrounding repeats in an assembly is the precise mapping of the reads to the final consensus sequence. Even if the consensus sequence, i.e. the genome sequence that ends up being deposited in public archives, is correct, it may be impossible to determine exactly which sequences belong to particular regions of the genome. For regions that are 100% identical and that are longer than a single read, multiple reads can be mapped to multiple distinct genomic locations and it may simply be impossible to tell where each read goes, since all the repetitive reads can go in each copy of the repeat. The Celera Assembler algorithm handles this problem through the use of "surrogate" contigs: the reads are assembled into a contig which is labeled as a surrogate, meaning that it apparently occurs more than once in the genome. This surrogate can then be placed in multiple locations in the genome based on mate pairs and on reads that span the repeat boundary. However, internal reads cannot be mapped to the genome, so the final consensus assembly points only to the surrogate, but not to the multi-alignment of all the reads. An alternative strategy, used in Arachne, is to place the reads multiply, allowing them to occur at two or more locations in the genome. Neither solution is entirely satisfactory, but in both cases the genome assembly can be constructed correctly.

4.7 Repeat Resolution in Euler

A different approach to repeat identification is taken by the Euler assembler [45]. In this unusual assembly algorithm, the normal overlap computation is handled quite differently from the hash table approach of Celera Assembler and Arachne. Instead, an overlap graph is created in which nodes represent overlap and edges represent *k*-mers. Contigs can be created by finding an Eulerian path through such a graph, called a de Bruijn graph, a problem that can be solved in linear time. (A Eulerian path through a graph is a path that uses each edge in the graph exactly once, here meaning that each overlap is realized exactly once – from left to right – as it should be in assembling genomes.) To reconstruct the sequence of the contig, the algorithm follows the Euler path and "reads off" the *k*-mers found on each edge in the path.

A fuller description of the Euler assembler is beyond the scope of this review, but it is worth mentioning how it handles repeats. In the de Bruijn graph created for the purpose of assembly, repeats appear as edges that share the same label. These edges can be superposed, yielding a new data structure (the A-Bruijn graph, see below) in which some nodes have many edges entering or exiting them. Then repetitive sequences correspond to edges whose boundaries are at such nodes. A critical aspect of the Euler algorithm is its error correction: in any large genome project, the small number of sequencing errors in individual reads can easily be confused with slight variations between repeat copies. By reducing the error rate, the algorithm can more easily tell if two near-identical sequences represent two different repeat copies. Euler takes advantage of the fact that errors tend to be random and, therefore, that short *k*-mers with a very low count probably represent such errors. This enables the algorithm to identify and correct a large majority of sequencing errors, and this in turn enables it to separate repeats that are very close to identical.

Despite all the efforts in Celera Assembler, Arachne, Euler and other assemblers, some classes of repeats continue to confound large-scale genome assembly algorithms. Although this is not widely known or discussed, the genomes available today in public archives likely contain numerous assembly errors. The most common errors are collapses of tandem repeats into too few copies; in addition, gross rearrangements around repeats have also been discovered (and in some cases corrected). The continuing problems highlight the fact that more work needs to be done to continue to improve the quality of "finished" genomes.

5 Untangling the Mosaic Nature of Repeats (The A-Bruijn Graph)

Pavel Pevzner and coworkers introduce a graph data structure, the A-Bruijn graph, to describe repeated sequences ascertained from pairwise alignments and to reveal the complex mosaic structure commonly encountered among related sequences [44]. This A-Bruijn graph has found use in several applications, including genome fragment assembly, multiple sequence alignment and *de novo* repeat finding [44, 48]. The graph glues similar sequence regions together into edges of the graph. When applied to a single genome, the glued-together edges correspond to repeated sequences, and when applied to related sequence sets from different genomes, homologous sequence regions are found glued together. The graph itself provides a compact view of the related regions among a collection of sequences, in addition to the sequence regions found to be unique to a single sequence or subset of sequences. Software packages implementing the A-Bruijn graph include the ABA multiple sequence aligner [48], and the *de novo* repeat-finding program RepeatGluer [44], which is the focus here.

The A-Bruijn graph is constructed from a set of pairwise alignments. All genome alignments generated by an alignment program (those tested include BLAST, PatternHunter and BLAT, among others) are decomposed into the A-Bruijn graph by "gluing" paired genome regions together as edges in a graph bounded by nodes, with similar sequences forming a single edge and forking at a node into separate edges where sequences diverge. After constructing the graph, edges with a multiplicity greater than one correspond to repeated regions of sequences. By removing all nonrepetitive sequences from the graph by discarding all edges with multiplicity of one, the A-Bruijn graph is broken into sets of connected components termed tangles. The tangles represent

the repeat elements, specifically the structure of subrepeats that form larger mosaic repeats. Each complete repeat element found in the genome can be reconstructed by traversing edges of valid paths in the corresponding tangle, and the relationships among different mosaic repeats are elucidated by virtue of their subrepeats found in common.

The identity and structure of each representative repeat element, termed by Pevzner and coworkers as the "elementary repeat", is provided by the A-Bruijn graph as a maximal simple path with multiplicity greater than one. RepeatGluer generates the repeat graph in a text file format compatible with graph viewing software (i.e. dotty program of the Graphviz package [17]). Additionally, the genomic sequences corresponding to each subrepeat are extracted and a consensus for each is provided in FASTA format. An example of a repeat graph is shown in Figure 4, highlighting the largest repeat tangle found in the repeat-rich genome of *Deinococcus radiodurans*.

6 Repeat Annotation in Genomes

Given the great diversity and functional significance of repetitive sequences, their annotation in completed genomes is an important task. Annotating repeats is similar to annotating other features in the genome in that a set of coordinates is required to delimit the feature location, along with a description of the biological significance of that feature, if known. The location of repetitive sequences can be obtained in two different ways or in their combination. Repeats are mined directly from the genome sequence based on algorithms that locate repeated sequences based exclusively on the genome sequence composition; these tools and algorithms were the focus of previous

Figure 4 Largest tangle in the repeat graph for *Deinococcus radiodurans* as constructed by RepeatGluer. Repeat consensus sequences yielded for edges in this tangle mostly correspond to parts of transposons (often called "insertion sequences" in bacterial genomics). The coding sequence for the transposase of one transposon (annotated gene identifier DRB0020, gi10957398) is shown threaded through the graph with wide edges. This graph was illustrated using graphviz. Unique identifiers are assigned to each node and edge. Edges correspond to subrepeats and nodes bound the subrepeats that are found in common between larger repeats. The length of the subrepeat and its multiplicity are specified to the right of the edge identifier. Only edges with multiplicity above 1 are shown. As repeats on the forward strand can be merged into single edges with repeats on the reverse strand, the graph is constructed using both strands as if they were independent sequences, which yields symmetry in the resulting graph; the transposase coding sequence described above is highlighted on only one side of the symmetric graph.

discussions. Alternatively, repeats can be identified based on homology to entries in a preexisting library of known repeat sequences.

The advantage of the former method is that no prior knowledge is required. Any newly sequence genome can be applied to the earlier described *de novo* repeat finding methods to rapidly identify the repeats. These are considered *de novo* methods simply because repeats are found based on an analysis of the genome sequence alone, without prior knowledge of the location or sequence composition of the repeats. The disadvantage is that other than knowing that a sequence is a repeat, we do not know what the repeat sequence represents biologically (i.e. gene, transposon, satellite, segmental duplication).

The latter method, based on repeat libraries, is currently the most widely used and most trusted method for annotating repeat sequences. Entries of repeat libraries are typically well annotated with some indication of function when functional information is known, and homology found to a known repeat reveals both its location and identity. Both software and repeat libraries are available as resources for genome annotation. Repbase began as a collection of human representative repeat sequences and fragments, and grew into a large collection of repeats from a variety of (mostly) model organisms, now known as Repbase Update [27]. Repbase Update includes separate repeat libraries for primates, rodents, zebrafish, *C. elegans*, *Drosophila* and *Arabidopsis*, with prototype sequences that correspond to consensus of large families and subfamilies of repeats. A "Simple" library, which can be applied to any genome, provides entries that help identify low complexity microsatellite sequences.

The program originally used to search genome sequences against Repbase libraries is CENSOR [28]. Due to the growing data volume in the libraries and the need for faster searching programs, CENSOR was eventually replaced by the more efficient alignment program RepeatMasker [53]. RepeatMasker identifies regions of homology to Repbase entries using Phil Green's cross_match algorithm (http://www.genome.washington.edu/UWGC/analysistools/Swat.cfm) and then replaces these homologous regions in the genomic sequence with "N" characters, effectively masking them in the genome sequence. A further 30-fold speed increase is obtained by using WU-BLAST in place of cross_match, as implemented by MaskerAid [6] as an enhancement to RepeatMasker. By masking the sequence, these repeat regions are precluded from subsequent sequence analyses in a larger annotation pipeline; hidden from gene finding programs, and transcript and protein homology searches, focusing subsequent analyses on the remaining unique sequence. For perspective, almost half of the human genome is masked due to the repeat content and this step is incredibly important when trying to find components of genes that remain hidden in the unmasked nonrepetitive regions.

The disadvantage with the repeat library-based scanning method is that comprehensive repeat libraries are available only for those organisms that have been well studied, and have attained the status of model organisms. Repbase is a tremendous resource for repeat annotation when corresponding repeat libraries are available, but it is of limited utility for many organisms whose genomes are currently being sequenced because of the limits of homology detection at the level of the nucleotide sequence coupled with the rate of divergence within repeats across evolutionary boundaries. Independent efforts are sometimes necessary to generate comprehensive repeat libraries to supplement that offered by Repbase [39].

A use of *de novo* repeat-finding programs is to automate the generation of repeat libraries that can be used with RepeatMasker. RepeatScout, in particular, yields consensus sequences for repeat families that are to be subsequently searched against the genome using RepeatMasker to identify locations of individual members of the family. Care must be taken with this approach if the repeats are to be masked from the genomic sequence and hidden from subsequent analyses. The Repbase libraries include many transposable elements and other repeat features which are excluded from the host gene set, and so masking homologous features from the genome should not interfere with subsequent efforts to find genes. The output from *de novo* repeat finding tools contains transposable elements but may also include repetitive features such as members of large gene families, and by blindly masking these "repeat" features from the genome, important features will be inadvertently disguised. None of the *de novo* repeat-finding programs directly address the problem of deducing the biological significance of the repeats that are found computationally. This is a difficult problem, currently left to the biologists and bioinformaticians, and examined on a case-by-case basis.

Searching for occurrences of repeats using representative repeat sequences or consensus sequences is limited by the information provided by that single sequence. By searching with profile representations of repeat families, the sensitivity of a search can be improved; a study by Juretic and coworkers demonstrates improved sensitivity in the detection of transposable elements in Rice by using hidden Markov model (HMM) profiles created for known transposable element families [26]. Although this methodology or similar profile methods are popular for finding members of protein families or occurrences of protein domains, HMM profiles for repeats are not currently widely employed, but do show great promise for repeat detection and analysis, and should be considered along with the existing alternatives.

Acknowledgments

We would like to thank the following individuals for reviewing an earlier version of the manuscript: Stefan Kurtz, Pavel Pevzner, Bob Edgar, Zhirong Bao, and Alkes Price. Your comments were invaluable. S.L.S. was supported in part by the US National Institutes of Health under grants R01-LM06845 and R01-LM007938.

8 Analyzing Genome Rearrangements

Guillaume Bourque

1 Introduction

The study of comparative maps and the rearrangements they evidence was pioneered in the late 1910s at the Morgan *Drosophila* lab [45, 74]. In the context of phylogenetics, the analysis of genome rearrangements was first introduced by Dobzhansky and Sturtevant in a study of inversions in *Drosophila pseudoobscura* [22]. What followed was a succession of developments in the fields of comparative mapping and comparative genomics. In particular, breakthroughs in mapping and sequencing afforded genome-wide analyses of gene order in various sets of genomes [3, 12, 20, 27, 51, 53, 54, 63]. Recently, the considerable investments in large sequencing projects have made accessible detailed sequences and maps for many eukaryotic genomes [26, 32, 37, 79, 84]. One of the stated purpose of these endeavors is to further our understanding of these species through comparative analyses [50]. The availability of these large genomes leads to great opportunities, but also challenges, in the study of genome rearrangements.

The exploration of large-scale events shaping whole-genome architecture provides a complementary perspective on the evolution of these organisms as compared to more traditional molecular studies focused on the analysis of individual genes. In fact, rearrangement studies allow detailed reconstructions of evolutionary scenarios, including ancestral reconstructions of entire eukaryotic genomes [13, 14]. Furthermore, such analyses can lead to the identification of regions of genomic instability (high rates of rearrangements, breakpoint reuse, etc.) that challenge and help refine our understanding of the dynamics of chromosome evolution [46, 57]. A related problem, also associated with genomic instability, is the study of cancer. Rearrangements in a tumor genome can be analyzed very much as if the tumor was a new organism that had recently diverged from the normal human genome. The interest is that although cancer progression is frequently associated with genome rearrangements, the forces behind these alterations are still poorly understood.

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

This chapter is organized as follows. Section 2 presents some of the basic concepts required for the analysis of genome rearrangements such as how the genomes are modeled and what types of rearrangements are considered. Section 3 presents three criteria that can be used to compute the distance between a pair of genomes: the breakpoint distance, the rearrangement distance and the conservation distance. Section 4 shows how the same criteria can be use to infer phylogenies when multiple genomes are considered using three different approaches: distance-based, maximum parsimony and maximum likelihood. Section 5 presents a few recent applications of analysis of genome rearrangements in large genomes and also recent work studying genome rearrangements in cancer. Finally, Section 6 concludes with some remarks on important challenges and promising new developments for the comparative analyses of gene order.

2 Basic Concepts

2.1 Genome Representation

Initially, the focus of genome rearrangement studies was on the comparative analyses of small genomes such as mitochondria [12, 53, 54, 63], chloroplasts [20, 51, 54], viruses [27] and small region of larger genomes [3]. In this context, the relative order of homologous genes in different organisms was used to infer phylogenetic relationships and even rearrangement scenarios. An example showing differences between the order of homologous genes in two mitochondria is given in Figure 1.

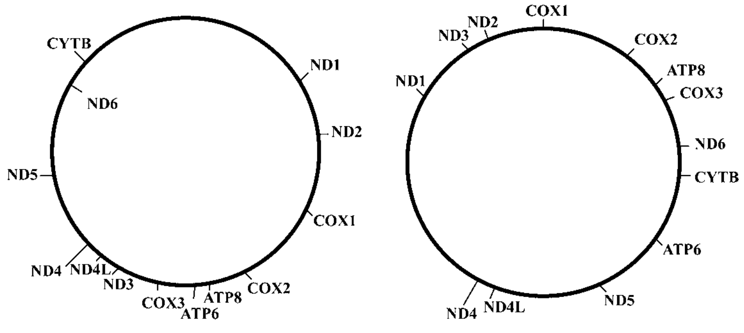

Figure 1 Coding genes on the human and on the earthworm mitochondrial DNA (mtDNA). The list of genes is the same, but their order differs. For instance, ND1 and ND2 are adjacent in Human but they are seperated by ND3 in the earthworm. tRNA genes have been left out of this figure to simplify the example. GenBank accession numbers: NC_001807 and NC_001673.

For this purpose, the relative gene order of different genomes can be encapsulated into a set of *signed permutations*. One of the genomes is identified as the reference genome and is associated to the identity permutation where each integer corresponds to one of its genes. The permutation associated to each other genome can directly be obtained from the order of appearance of the homologous genes. Furthermore, a sign corresponding to the relative orientation (strand) of the gene, as compared to the reference genome, is given to each integer of the new permutation. To continue with the example shown in Figure 1, if the mtDNA is selected as the reference genome, and we label the genes starting with COX1 in Human as "1" and going clockwise until ND2 is assigned "13", we obtain the permutations shown in Table 1. Of all the genes in the two mtDNAs, only ND6 in Human was on the reverse DNA strand, which is why it is represented by "-10" in Earthworm as its relative orientation is reversed.

Table 1 Signed permutations associated with the two mitochondria genomes shown in Figure 1

Human	1	2	3	4	5	6	7	8	9	10	11	12	13
Earthworm	1	2	3	5	-10	11	4	9	7	8	12	6	13

This genome representation can be adapted and generalized for data sets with other distinctive features such as multiple chromosomes, unsigned gene orders, unequal gene content and different source of homology markers. We briefly present these variants.

2.1.1 Circular, Linear and Multichromosomal Genomes

A genome can consist of a single chromosome or a collection of chromosomes and is called *unichromosomal* or *multichromosomal* accordingly. There are two types of chromosomes: circular and linear. The mitochondria shown in Figure 1 are circular genomes. Linear chromosomes have two separated endpoints. Unless otherwise stated, multichromosomal genomes will be assumed to have linear chromosomes. The different types of genomes can also be represented by permutations, but additional markers are required for multichromosomal genomes to mark the boundaries of the chromosomes.

It is important to specify the type of chromosomes we are considering because they will lead to different equivalent representations. For instance, consider the three genomes:

$$\begin{array}{rcrrr} G_1 & = & 1 & 2 & 3 \\ G_2 & = & 2 & 3 & 1 \\ G_3 & = & -3 & -2 & -1 \end{array}$$

As circular chromosomes, all three representation are equivalent; however, as linear chromosomes, only G_1 and G_3 correspond to the same representation (there is usually no distinction between the two end-points of a linear chromosome and so a complete flip leads to an equivalent representation).

2.1.2 Unsigned Genomes

If the orientation of genes in a set of genomes is unknown, the relative gene order can still be encapsulated into a set of unsigned permutations. Unfortunately, many genome-rearrangement problems, such as calculating the reversal distance, are significantly harder for unsigned permutations [17] compared to signed permutations (see Section 3.2). For this reason, but also because the relative orientation is usually obtainable, we will assume that we are dealing with signed genomes in the rest of this chapter.

2.1.3 Unequal Gene Content

In representing genomes with permutations, we have assumed that a set of n genes was found with a unique homologous counterpart in all genomes. In fact, in many cases this assumption will be violated: a genome may have gained additional genes through rearrangements events such as insertions or duplications and it may have lost genes following deletions. To encapsulate the relative gene orders of genomes with unequal gene content we need to generalize the representation to account for this variable alphabet. Although models that are not restricted to equal gene content are more complete and realistic (see Ref. [24] for a review), they are also more challenging algorithmically and have been limited to few applications [23, 66, 69]. We will focus on genomes with equal gene content in the rest of this chapter except for the presentation of some rearrangement events affecting gene content in Section 2.2.

2.1.4 Homology Markers

So far, it was implicit that the signed permutations representing the genomes were constructed based on the relative position of homologous genes. Actually, however, any type of marker with an homologous counterpart in all genomes can be used to construct similar permutations. This is important because, especially in large eukaryotic genomes (e.g. human, mouse) where genes only cover a small fraction of the genome, the ability to use markers extracted from raw DNA sequence allows to study rearrangement events that occur anywhere in the genome. This will be covered in more detail in Section 5.1.

2.2 Types of Genome Rearrangements

During evolution, an assortment of events can modify the genome. These events are known as mutations and they can occur especially during DNA replication. Mutations are divided into two major categories: point mutations and chromosomal mutations. Point mutations are at the single-base level. Although point mutations can have a significant impact on the genome (e.g. a base change could be responsible to the insertion of an early stop codon that completely annihilates a gene), they will not be considered further here as they mostly affect individual genes. In contrast, chromosomal mutations affect directly the architecture of genomes by modifying the gene order or the gene content. There are various types of chromosomal mutations, but the most common are reversals (or inversions), translocations, fusions, fissions, transpositions, inverted transpositions, insertions, deletions and duplications. See Figure 2 for a cartoon example of how reversals and deletions could occur during DNA replication. Only translocations, fusions and fissions are specific to multichromosomal genomes. The first six types of chromosomal mutations rearrange the genes, but they do not modify the set of genes present in a given genome. Insertions, deletions and duplications, on the other hand, modify the gene content of a genome by adding, or removing, some genes or by generating multiple copies of the same gene. The effect of these different chromosomal mutations are exemplified in Table 2.

Table 2 Examples of chromosomal mutations that impact either gene order or gene content

Mutation type	Before		After	Impact
Reversal	$1\ 2\ \boxed{3\ 4\ 5}\ 6$	⇒	$1\ 2\ -5\ -4\ -3\ 6$	gene order
Translocation	$1\ 2\ \boxed{3\ 4\ 5}$ $6\ 7\ \boxed{8}$	⇒	1 2 8 6 7 3 4 5	gene order
Fusion	$\boxed{1\ 2\ 3\ 4}$ $\boxed{5\ 6}$	⇒	1 2 3 4 5 6	gene order
Fission	$\boxed{1\ 2\ 3\ 4}\ \boxed{5\ 6}$	⇒	1 2 3 4 5 6	gene order
Transposition	$1\ \boxed{2\ 3}\ 4\ 5\ \boxed{}\ 6$	⇒	1 4 5 2 3 6	gene order
Inverted transposition	$1\ \boxed{2\ 3}\ 4\ 5\ \boxed{}\ 6$	⇒	$1\ 4\ 5\ -3\ -2\ 6$	gene order
Insertion	$1\ 2\ 3\ 4\ \boxed{}\ 5\ 6$	⇒	1 2 3 4 7 5 6	gene content
Deletion	$1\ \boxed{2\ 3}\ 4\ 5\ 6$	⇒	1 4 5 6	gene content
Duplication	$1\ 2\ \boxed{3\ 4}\ 5\ 6$	⇒	$1\ 2\ 3\ 4\ 3'\ 4'\ 5\ 6$	gene content

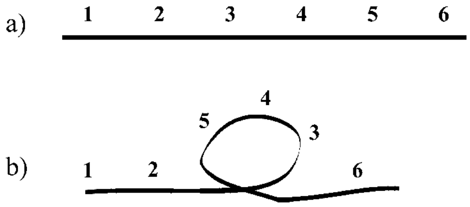

Figure 2 (a) DNA fragment with each integer corresponding to a gene. (b) The same DNA fragment but twisted. During replication, if the twisted loop is copied, it leads to a *reversal* and the fragment becomes 1 2 −5 −4 −3 6. Note that the sign or the strand of the genes is modified at the same time as the order. If the twisted loop is ignored, it results in a *deletion* and the fragment is transformed into 1 2 6.

3 Distance between Two Genomes

In this section, we review different criteria that can be use to measure the distance between two genomes based on comparative gene order. The first criterion, the *breakpoint distance*, counts the number of disruptions of the relative gene order between a pair of genomes. The second criterion, the *rearrangement distance*, relies on the *a priori* definition of a set of permissible operations (e.g. only reversals) and then minimizes the number of such operations required to convert one gene order into the next. The final criterion described is the *conservation distance*, which, similar to the breakpoint distance, circumvents the requirement of a rearrangement model. Under this criterion, the disruption of the relative gene order is measured by the number of conserved or common intervals.

3.1 Breakpoint Distance

The breakpoint distance [48,85] compares two permutations by directly counting the number of gene order disruptions between two genomes. Formally, given two signed permutations of size n, π and γ, the first step to compute the breakpoint distance is to extend both permutations so that they start with 0 and end with $n+1$: $\pi = 0, \pi_1, \pi_2 \ldots \pi_n, n+1$ and $\gamma = 0, \gamma_1, \gamma_2 \ldots \gamma_n, n+1$. Then, the *breakpoint distance*, $d_{\text{break}}(\pi, \gamma)$, is defined as the number of pairs (γ_i, γ_{i+1}), $0 \leq i \leq n$, such that neither the pair (γ_i, γ_{i+1}) nor $(-\gamma_{i+1}, -\gamma_i)$ appears in π. For instance, using the example from Table 1 and setting $\pi =$ human and $\gamma =$ earthworm, we get $d_{\text{break}}(\pi, \gamma) = 9$. The nine breakpoints are displayed in γ using arrows:

$$\begin{array}{ccccccccccccccccccccccccccccc} 0&&1&&2&&3&&5&&-10&&11&&4&&9&&7&&8&&12&&6&&13&&14\\ &&&&&&&\uparrow&&\uparrow&&\uparrow&&\uparrow&&\uparrow&&\uparrow&&&&\uparrow&&\uparrow&&\uparrow&&& \end{array}$$

Two important strengths of this criterion measuring the degree of similarity are that (i) it is easily computable in linear time and (ii) it does not require any assumptions about the underlying rearrangement mechanisms.

3.2 Rearrangement Distance

Given two permutations π and γ and a set of permissible rearrangements, the rearrangement distance, $d_{\text{rear}}(\pi, \gamma)$, is defined as the minimum number of operations required to convert one permutation into the other. For example, given that reversals are the only allowed operations, what is the minimum number of events required to convert the permutation associated with the earthworm mtDNA into the one associated with the human mtDNA shown in Table 1? The problem is quite challenging. In this particular case, the answer is seven and Table 3 shows one such scenario. We will use d_{rev} for the special case of d_{rear} when reversals are the only permissible operations.

The interest in looking for the minimum number of steps is that, under the assumption that such events are rare (and that our rearrangement model is correct), we hope to recover the sequence of rearrangements that really occurred. The caveat is that it is well known that the most parsimonious scenario underestimates the actual number of operations when this number is above a threshold of θn, where n is the size of the permutation and θ is in the range from $1/3$ to $2/3$ [15,35,83].

Table 3 Example of a most parsimonious rearrangement scenario with seven reversals between earthworm and human mtDNA

Earthworm	1	2	3	5	−10	11	4	9	7	8	12	6	13
$\rho(6,11)$	1	2	3	5	−10	11	4	9	7	8	12	6	13
$\rho(9,12)$	1	2	3	5	−10	−12	−8	−7	−9	−4	−11	6	13
$\rho(7,10)$	1	2	3	5	−10	−12	−8	−7	−6	11	4	9	13
$\rho(6,12)$	1	2	3	5	−10	−12	−11	6	7	8	4	9	13
$\rho(4,6)$	1	2	3	5	−10	−9	−4	−8	−7	−6	11	12	13
$\rho(4,7)$	1	2	3	9	10	−5	−4	−8	−7	−6	11	12	13
$\rho(6,10)$	1	2	3	4	5	−10	−9	−8	−7	−6	11	12	13
Human	1	2	3	4	5	6	7	8	9	10	11	12	13

Based on different sets of permissible rearrangements, various methods have been proposed to efficiently compute the rearrangement distance and sort a pair of genomes. Of all the choices of permissible operations, the reversal-only model is probably the most extensively studied. The work was pioneered by Sankoff and Kececioglu [68], but was followed by the development of increasingly efficient polynomial-time algorithms [1,8,9,28,34]. Other studied sets of permissible operations include transpositions [2,81], inversions, translocations, fusions and fissions [29, 52, 75], and more recently block interchange (a more general type of transposition) [19, 41, 86].

In the remainder of this section, we review a methodology that was developed to compute the distance between a pair of genomes using reversals only (for unichromosomal genomes) or reversals, translocations, fusions and fissions (for multichromosomal genomes). We will refer to it as the Hannenhalli–Pevzner (HP) theory. This methodology was developed in Bafna and Pevzner [4] and in Hannenhalli and Pevzner [30], it was summarized in Pevzner [58], it was improved in Tesler [75], and, finally, it was implemented in a program called GRIMM [76].

3.2.1 **HP Theory**

We first describe the methodology for unichromosomal genomes where reversals are the only permissible operations. Assume we have a permutation γ that we wish to sort with respect to the identity permutation π. The first step is to convert γ, a signed permutation, into γ', an unsigned permutation, by mimicking every directed element i by two undirected elements i^{t} and i^{h} representing the tail and the head of i. Since γ is a permutation of size n, γ' will be a permutation of size $2n$. We now extend the permutation γ' by adding $\gamma'_0 = 0$ and $\gamma'_{2n+1} = n + 1$. The next step is to construct the breakpoint graph associated with γ. The *breakpoint graph* of γ, $G(\gamma)$, is an edge-colored graph with $2n + 2$ vertices. Black edges are added between vertices γ'_{2i} and γ'_{2i+1} for $0 \leq i \leq n$. Grey edges are added between i^{h} and $(i+1)^{\mathrm{t}}$ for $0 < i < n$, between 0 and 1^t, and between n^h and $n + 1$. Black edges correspond to the actual state of the permutation while grey edges correspond to the sorted permutation we seek. See Figure 3 for an example.

Bafna and Pevzner [4], and later Hannenhalli and Pevzner [30], showed that $G(\gamma)$ contains all the necessary information for efficiently sorting the permutation γ. The first step is to look at the maximal cycle decomposition of the breakpoint graph. Finding the maximal cycle decomposition of a graph in general can be a very difficult problem; however, fortunately, because of

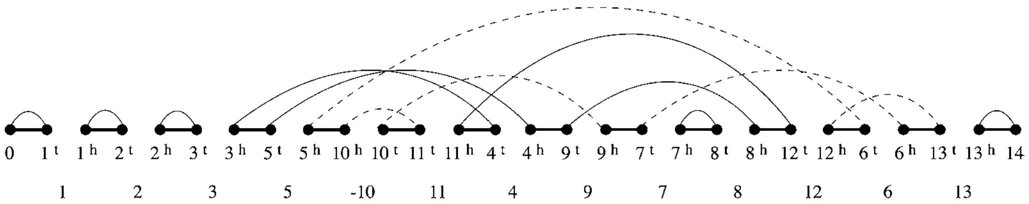

Figure 3 Breakpoint graph associated with the two permutations from Table 1. Black edges are shown using think lines. All other lines (both solid and dashed) correspond to grey edges. Dashed lines are used to show the only nontrivial oriented cycle.

the way the breakpoint graph was constructed for a signed permutation, each vertex has degree two and so the problem is trivial. Suppose $c(\gamma)$ is the maximum number of edge-disjoint alternating cycles in $G(\gamma)$. The cycles are alternating because, in the breakpoint graph of a signed permutation, each pair of consecutive edges always has different colors.The important lower bound:

$$d_{\text{rev}}(\pi,\gamma) = d(\gamma) \geq n + 1 - c(\gamma).$$

was first presented by Kececioglu and Sankoff [35].

A few additional concepts on the breakpoint graph are required to present the result of Hannenhalli and Pevzner [28]. A grey edge in $G(\gamma)$ is said to be *oriented* if it spans an odd number of vertices (when the vertices of $G(\gamma)$ are arranged in the canonical order $\gamma'_0, \ldots, \gamma'_{2n+1}$). A cycle is said to be *oriented* if it contains at least one oriented grey edge. Cycles which are not oriented are said to be *unoriented* unless they are of size 2, in which case they are said to be *trivial*. The term "oriented" comes from the fact that if we traverse an oriented cycle we will traverse at least one black edge from left to right and one black edge from right to left. In the breakpoint graph shown in Figure 3, there are only two nontrivial cycles: one where the grey edges are displayed using solid lines and one where the grey edges are displayed using dashed lines. The cycle with solid lines is unoriented since it does not contain an oriented edge but the cycle with dashed lines is oriented because it contains an oriented edge [e.g. $(10^{\text{h}}, 11^{\text{t}})$].

For each grey edge in $G(\gamma)$ we will now create a vertex v_e in the *overlap graph*, $O(G(\gamma))$. Whenever two grey edges e and e$'$ overlap or cross in the canonical representation of $G(\gamma)$, we will connect the corresponding vertices v_{e} and $v_{\text{e}'}$. A *component* will mean a connected component in $O(G(\gamma))$. A component will be oriented if it contains a vertex v_e for which the corresponding grey edge e is oriented. As for cycles, a component which consists of a single vertex (grey edge) will be said to be trivial. In Figure 3, there are five trivial components and one larger oriented component since at least one of its grey edge is oriented. The difficulty in sorting permutations comes from unoriented components.

Unoriented components can be classified into two categories: hurdles and protected nonhurdles. A *protected nonhurdle* is an unoriented component that separates other unoriented components in $G(\gamma)$ when vertices in $G(\gamma)$ are placed in canonical order. A *hurdle* is any unoriented component that is not a protected nonhurdle. A hurdle is a *superhurdle* if deleting it would transform a protected nonhurdle into a hurdle, otherwise it is said to be a *simple hurdle*. Finally, γ is said to be a *fortress* if there exists an odd number of hurdles and all are superhurdles in $O(G(\gamma))$ [71].

The main result fromHannenhalli and Pevzner [28] is that:

$$d_{\mathrm{rev}}(\pi,\gamma) = d(\gamma) = n + 1 - c(\gamma) + h(\gamma) + f(\gamma),$$

where $h(\gamma)$ is the number of hurdles in γ, and $f(\gamma)$ is 1 if γ is a fortress and 0 otherwise. However, the machinery to recover an optimal sequence of sorting reversals was also presented. The fact that the distance between the human and earthworm is 7 can directly be extracted from this formula and from the breakpoint graph shown in Figure 3 since there are 13 genes, seven cycles and no hurdles or fortress.

Finally, Hannenhalli and Pevzner [29] derived a related equation to compute the rearrangement distance between two multichromosomal genomes when permissible operations are: reversals, translocations, fusions and fissions. We refer the reader to Pevzner [58] and Tesler [75] for the details of the calculation, but we will briefly present how the formula can be obtained.

The main idea to compute the rearrangement distance between two multichromosomal genomes Π and Γ is to concatenate their chromosomes into two permutations π and γ. The purpose of these concatenated genomes is that every rearrangement in a multichromosomal genome Γ can be mimicked by a reversal in a permutation γ. In an *optimal* concatenate, sorting γ with respect to π actually corresponds to sorting Γ with respect to Π. Tesler [75] also showed that when such an optimal concatenate does not exist, a *near-optimal* concatenate exists such that sorting this concatenate mimics sorting the multichromosomal genomes and uses a single extra reversal which corresponds to a reordering of the chromosomes.

3.3 Conservation Distance

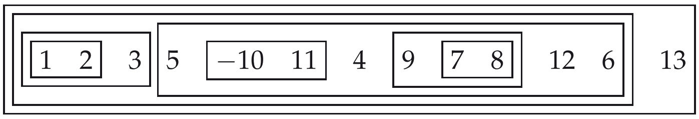
Recently, two criteria were proposed to measure the level of similarity between sets of genomes: common intervals [31,78] and conserved intervals [7]. In a way, both of these criteria represent a generalization of the breakpoint distance but consider intervals instead of only adjacencies. There are two important properties that common/conserved distances share with the breakpoint distance:

(i) It can be directly defined on a set of more than two genomes and allows the identification of shared features in a family of organisms.

(ii) It does not rely on an a priori model of rearrangements.

3.3.1 Common Intervals

Given two signed permutations, π and γ, a *common interval* is a set of two or more integers that is an interval in both permutations [31,78]. Using the example from Table 1, we get that there are 14 common intervals, eight of which are shown in the earthworm using boxes:



The additional common intervals not displayed are: $[2,3]$, $[2,3,5,\ldots 6]$, $[2,3,5,\ldots 13]$, $[3,5,\ldots 6]$, $[3,5,\ldots 13]$ and $[5,10,\ldots 13]$.

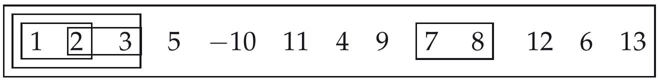
Suppose $C(\pi,\gamma)$ and $C_i(\pi,\gamma)$ are the number of common intervals and the number of common intervals of size i in π and γ, respectively. We note that the maximum number of common intervals for two permutations of size n is achieved for identical permutations and is simply:

$$\sum_{i=2}^{n} C_i(\pi,\pi) = \quad (n-1)+(n-2)+\ldots+1 = \frac{n(n-1)}{2}.$$

Of course, the more common intervals between two permutations, the higher the conservation. In the example above, there is only 14 common intervals while the maximum achievable is 78.

3.3.2 Conserved Intervals

Given two permutations, π and γ, a *conserved interval* is an interval $[a,b]$ such that a precedes b or $-b$ precedes $-a$, in both π and γ, and the set of elements, without signs, between a and b is the same in both π and γ [7]. Continuing with the example from Table 1, there are only five conserved intervals between the human and earthworm mtDNA:



Although, initially the definition of conserved intervals may seem unnatural, it is tightly connected to the HP theory (it corresponds to *subpermutations* in Ref. [29]) and it was shown that it can be used to efficiently sort permutations by reversals [5].

4 Genome Rearrangement Phylogenies

An important challenge in the comparative analysis of gene order is the construction of phylogenies based on genome rearrangements that describe the genetic relationships between the organisms. Phylogenies are represented by unrooted binary trees such that the leaf nodes of the trees correspond to contemporary genomes and the internal nodes correspond to their extinct ancestors (see Figure 5 for an example). Phylogenetic tree reconstruction is difficult largely because the number of unrooted trees grows at a rate that is more than exponential with the number of leaf nodes.

We review three main classes of approaches that can be used for phylogenetic tree reconstruction based on relative gene order: distance-based methods, maximum parsimony methods and maximum likelihood methods. These main classes of approaches are very similar in spirit to the ones developed for phylogenetic tree reconstruction based on sequence evolution with point mutations instead of chromosomal mutations (see Chapter 4). Links for some of the programs available to analyze genome rearrangements described in this section are provided in Table 4.

4.1 Distance-based Methods

These approaches construct trees strictly based on the pairwise distances between the leaf nodes of the tree. The first step computes the pairwise distance matrix for the genomes of interest using one of the criterion described in Section 3 or from other criterion such as EDE, the “empirically derived estimator", that attempts to correct the bias in the parsimony assumption for large distances [83]. Distance-based methods differ in the second step in how they make use of the distance matrix to reconstruct the trees. Currently, the most common family of distance-based methods is probably “neighbor-joining” which was first proposed by Saitou and Nei [62].

Methods in this class are typically very efficient; in many cases phylogenies can be inferred in polynomial time. When applied to gene order data, one of the limitations of distance-based approaches is that they do not label the internal nodes and they do not associate a rearrangement scenario to the phylogeny. For challenging data sets, this may lead to infeasible or less accurate solutions [82]. This limitation is addressed both by maximum parsimony and by maximum-likelihood methods.

4.2 Maximum Parsimony Methods

Methods seeking the most parsimonious scenario attempt to recover the tree, and its internal nodes, that minimizes the number of events on its branches. It corresponds to the Steiner Tree Problem [33] on various metrics. The first methods of this type were developed for sequence data [25] but they were later adapted for gene order data [27,64]. Formally, given a set of m genomes, the problem is to find an unrooted tree T, where the m genomes are leaf nodes, and assign internal ancestral nodes such that $D(T)$ is minimized:

$$D(T) = \sum_{(\pi,\gamma)\in T} d(\pi,\gamma),$$

where $d(\pi,\gamma)$ can be any of the distances described in Section 3. The special case of three genomes ($m = 3$) is called the median problem. Although the tree topology for this problem is trivial, the assignment of the optimal internal node can still be challenging.

If a rearrangement distance is used, a detailed rearrangement scenario could also be associated to the tree that will describe every intermediate step of the evolution of these genomes. Again, under the assumption that rearrangements events are rare [15,61], its reasonable to seek the most parsimonious scenario to recover the actual tree.

Although many of the pairwise distances can be computed in polynomial time (e.g. the breakpoint distance d_{break} and the reversal distance d_{rev}, see Section 3.2), it was shown that both the median problem for d_{break} and the median problem for d_{rev} are NP-hard [16,18,55]. Nevertheless, there are a few efficient heuristics to tackle both the median problem [67,72] and the full phylogeny problem [10,15,44] under different sets of assumptions. We briefly present some of these methods.

Sankoff and Blanchette [67] studied the median problem for the breakpoint distance; they described a clever reduction of this problem to the Traveling Salesman Problem for which reasonably efficient algorithms are available. Using this result, Blanchette and coworkers [10] developed BPAnalysis, a method to recover the most parsimonious scenario for m genomes also under the breakpoint distance. That method first looked for the optimal assignment of internal nodes for a given topology by solving a series of median problem (this is also known as the small parsimony problem). The next step was to scan the space of all possible tree topologies to find the best tree (large parsimony problem). One of the drawbacks of this approach is that, as we have seen, the tree space quickly becomes prohibitive. This limitation was partially addressed by Moret and coworkers [44] who develop GRAPPA which improves on BPAnalysis by computing tight bounds and efficiently pruning the tree space. Another program to reconstruct phylogenies based on the breakpoint distance is GOTREE (see Table 4). A special feature of this last tool is that it is not restricted to genomes with equal gene content.

Siepel and Moret [72] studied a different problem: the median problem for the reversal distance. They derived a branch-and-bound algorithm to prune the search space using simple geometric properties of the problem and the linear-time machinery to compute the reversal distance [1]. Concurrently, Bourque and Pevzner [15] developed a method called MGR for both the median and the full phylogeny problem that made use of properties of additive or nearly additive trees. This algorithm, combined with GRIMM [76], is applicable to unichromosomal genomes for the reversal distance and to multichromosomal genomes for a rearrangement distance that allows reversals, translocations, fusions and fissions. The main idea of the algorithm is to look for rearrangements in the starting genomes that reduce the total distance to the other genomes and iteratively “reverse history". The key is to use good criterion to chose the order in which the rearrangements are selected.

The first method that used the conservation distance as the criterion to be minimized in the phylogenetic reconstruction problem was presented by Bergeron and coworkers [6]. Even though the problem was restricted to finding an assignment of internal nodes on a fixed phylogeny (small parsimony problem), this is a promising and active area of research.

4.3 Maximum Likelihood Methods

If we make assumptions about the mechanisms of evolution and the rates at which these changes occur, we can seek the tree which is the most likely to have generated the data observed. Such methods are called maximum likelihood methods. They tend to be computationally intensive but they have the advantage of providing a global picture of the solution space in contrast to maximum parsimony which provides a unique solution for instance.

In the context of the comparative analysis of gene order, a maximum likelihood approach turns out to be quite challenging because of our incomplete understanding of the frequency of rearrangement events but mostly because of the significantly large number of potential states at internal nodes and of phylogenetic trees [70]. Nevertheless, Dicks [21] developed one such method for gene order data, but the method presented was restricted to small instances of the problem. Other promising approaches involve the construction of a Bayesian framework and the use of Markov chain Monte Carlo to sample parameter space for two unichromosomal genomes [42, 87] or m unichromosomal genomes [38, 39]. Specifically, Larget and coworkers [39] developed the program BADGER and used it to quantify the uncertainty among the relationships of metazoan phyla on the basis of mitochondrial gene orders. So far, although these frameworks are propitious, their range of applications has been limited. It will be interesting to see if these approaches can be further applied and adapted to larger and also multichromosomal genomes.

5 Recent Applications

We have already seen some applications in which genome rearrangements acted as complementary phylogenetic characters to study evolutionary relationships in a group of organisms such as mitochondria, chloroplasts, viruses or small regions of larger genomes [3, 12, 20, 27, 51, 53, 54, 63]. We will now show how the same concepts and methodologies can be applied to compare entire eukaryotic genomes. Apart from the topology of the phylogeny, interesting questions arise from studying rates of rearrangements, types of rearrangements and predictions at ancestral nodes. We will also present some preliminary work studying genome rearrangements in cancer.

5.1 Rearrangements in Large Genomes

Genome rearrangements studies have traditionally been based on the relative order of homologous genes; however, as hinted at in Section 2.1, they can also be based on the relative order of a common set of homology synteny blocks (HSBs). These blocks can be defined either directly from sequence similarity [36, 56] or from the clustering of homologous genes [88]. In this context, rearrangement studies for large genomes will be reconfigured into a two-step process:

(i) Identification of HSBs shared by the set of genomes under study.

(ii) Genome rearrangement analysis of the HSBs.

In Step (i), both for sequence-based and gene-based HSBs, thresholds need to be set to allow the HSBs to extend over minor local inconsistencies that could stem from different sources: sequencing and assembly errors, small rearrangement events not enclosed in the rearrangement model of Step (ii) (e.g. transposons), inaccurate prediction of orthologous genes (e.g. in the presence of many paralogous copies), etc. For the identification of HSBs, there are advantages to using both sequence and gene data.

The most important benefit of using raw sequence data is probably to circumvent the limitation of analyzing strictly coding regions (these regions only cover a small portion of the eukaryotic genomes). Other benefits include that it avoids annotation problems, it is less sensitive to gene families and, finally, it preserves additional information on *micro-rearrangements* (rearrangements within HSBs) that can then be used as additional independent phylogenetic characters [13]. Advantages of using gene-based HSBs are that it focuses

the investigations on critical regions of the genome, the thresholds are length independent and it avoids some of the noise created by repeat regions.

After Step (i), the comparison of the respective arrangements of the HSBs in the different genomes can be performed using the models, algorithms and programs described in Sections 3 and 4. This two-step analysis was used to compare the human with the mouse genome [56] and suggested a larger number inversions than previously expected [48]. It also helped motivate a model for chromosome evolution in which some breakpoints are reused nonrandomly [40, 57].

When many genomes are compared, rearrangement analysis provides information not only on phylogenetic relationships, but also on rates of rearrangements and on putative genomic architecture of ancestral genomes [13, 14, 46, 47]. For instance, the availability of the rat genome [26] allowed a comparative study with the human and the mouse [14] that confirmed an observation made using lower-resolution studies that rodent genomes have had an accelerated rate of inter-chromosomal rearrangements (e.g. translocations, fusions and fissions). The same study also conjectured on the genomic architecture of the putative murid rodent ancestor. The addition of the chicken genome [32] acting as an outgroup allowed us to look further back in time and predict the potential architecture of the mammalian ancestor [13]. This analysis also suggested:

- Variable rates of inter-chromosomal rearrangements across lineages.
- High ratio of intra-chromosomal versus inter-chromosomal rearrangements in the chicken lineage.
- Low rate of rearrangements in chicken, in the early mammalian ancestor or in both.

More recently, a comprehensive analysis of eight mammalian genomes, three sequenced genomes (human–mouse–rat) and five with high-resolution

←

Figure 4 Inferred genomic architecture of the mammalian ancestor (adapted from Ref. [46]). Each human chromosome is assigned a unique color and is divided into HSBs. These HSBs correspond to stretches of DNA for which sufficient similarity has been retain to unambiguously allow the identification of the homologous regions in all other species. The size of each block is approximately proportional to the actual size of the block in human. In human, blocks are arranged on each chromosome from left (p-arm) to right (q-arm) and physical gaps between blocks are shown to give an indication of coverage. Numbers above the rec onstructed ancestral chromosomes indicate the human chromosome homolog. Diagonal lines within each block indicate their relative order and orientation. Black arrows under the ancestral chromosome indicate that the two adjacent HSBs separated by the arrow were not found in every one of the most parsimonious solutions explored; these are considered *weak adjacencies*.

radiation-hybrid maps (cat–dog–cow–pig–horse), afforded a detailed analysis of the dynamics of mammalian chromosome evolution [46]. This study also produced a refined model of the genomic architecture of the mammalian ancestor, see Figure 4.

Applications focusing on specific areas of the genomes allow for the identification of very detailed scenarios. For instance, in the results of the study by Murphy and coworkers [46], it is possible to focus exclusively on the HSBs found on human chromosome 17; there are 14 such blocks. Chromosome 17 is interesting because, similarly to the X chromosome, it has seldom exchanged genetic material with other chromosomes during mammalian evolution. Specifically, the 14 blocks are found in one contiguous segment on a single chromosome in mouse, rat, cat and pig. They are found in two contiguous pieces on two chromosomes in cow and in three contiguous pieces on three chromosomes in dog (horse is left out of this analysis because of insufficient data). See Figure 5 for a parsimonious rearrangement scenario describing the mammalian history of this chromosome. This example once again seems to point towards uneven rates of rearrangements with no rearrangement between the cetartiodactyl ancestor and pig, but five rearrangements in cow during the same period of evolution. According to this reconstruction, the pig chromosome 12 (the homolog of human chromosome 17) is ancestral in the sense that no large-scale rearrangement has occurred on it since the divergence of these species.

5.2 Genomes Rearrrangements and Cancer

The previous section described examples of the use of genome rearrangements to study the evolution of a group of organisms. Now, because a rapid increase of chromosomal mutations is frequently observed in cancer cells, it is possible to study the cancer genome very much like as it was a new organism that had recently diverged from the normal human genome. The interest is that although cancer progression is frequently associated with genome rearrangements, the mechanisms behind these rearrangements are still poorly understood. There are many challenges in studying rearrangements in cancer cells: the heterogeneity of the cells, the complexity of the rearrangements (which include translocations, but also frequent duplications), but mostly the fact that detailed sequence is only sparsely available. So far, the cost of sequencing has been a prohibitive factor preventing large cancer genome sequencing projects, but new emerging sequencing techniques such as End Sequence Profiling [80] and Ditags [49] might help alleviate this problem. Such techniques justify the development of algorithms and tools, related to the analysis of genome rearrangement, to extract detailed tumor architecture from such data sets [59, 60].

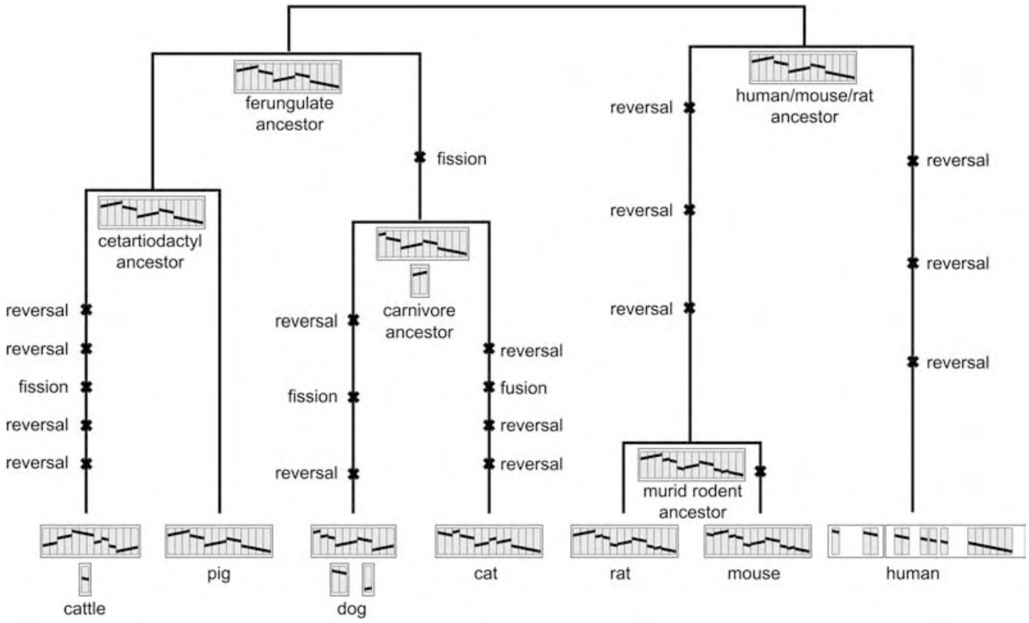

Figure 5 Mammalian history of human chromosome 17. The arrangements of 14 blocks (stretches of DNA) from human chromosome 17 with syntenic counterparts in seven other mammalian genomes (mouse, rat, cat, dog, pig and cattle) are shown at the bottom of the tree. Blocks are drawn proportionally to their size in human. A diagonal line traverses the blocks to show their order and relative orientation. In human, blocks are arranged from left (p-arm) to right (q-arm) and physical gaps between blocks are shown to give an indication of coverage. In other species, the same blocks are drawn also from left to right but in some cases these blocks are found on multiple chromosomes [cattle (2), dog (3) and carnivore ancestor (2)]. Crosses on the edges of the tree are labeled and indicate putative rearrangement events even though their exact timing is unknown. Data adapted from Ref. [46].

A complementary approach for the study of rearrangements in cancer involves looking at breakpoint regions. Many such regions have already been characterized in a large population of cancer patients [43]. Studying their distribution with respect to either chromosomal location [65] or evolutionary breakpoints [46] (identified from multispecies comparisons) is likely to provide invaluable information on the forces acting on these aberrant genomes.

6 Conclusion

6.1 Challenges

Comparative analyses of gene order would greatly benefit from established benchmarking data sets. These instances could be use to compare and refine current approaches for the study of genome rearrangements. Of course, the challenge is that for data sets generated from real genomes, the actual rearrangement history for these organisms is unknown. Thus, recovered scenarios can only be evaluated with respect to some limited aspects of their solution such as topology of the recovered tree [12, 20]. This is a suitable criterion to evaluate the merits of an approach because the topology can also be inferred from alternative, more traditional, approaches such as the comparison of individual genes. Even then, ambiguities will remain since for many interesting sets of species, some aspects of the topology are debatable (e.g. especially when deep branches are involved) and the information extracted from genome rearrangements might be different from that provided from sequence analysis but not necessarily erroneous.

Other criteria that can be used for the evaluation of solutions are some of the coarse features of the recovered ancestors such as the ancestral chromosomal associations. These are associations between modern chromosomes (e.g. human chromsomome) that are inferred to have been present in the ancestors [73]. Unfortunately, once again, definitive evaluation is difficult for two reasons: (i) the expected associations rely on low-density comparative maps and are likely to be incomplete, and (ii) multiple alternative ancestors are typically recovered in rearrangement studies making more than a single prediction [13, 14]. Now that high-quality sequences are increasingly becoming available for many genomes, one would actually expect to see the knowledge on such associations to be expanded and refined, especially after carrying out combinatorial analyses that take into account more than just co-occurrences.

A logical alternative to real benchmarking data sets with unknown rearrangement history is provided by simulated data sets. Unfortunately, there are drawbacks inherent to this approach as well. In particular, simulated data sets will always bias the evaluation towards approaches that have an underlying rearrangement model that is most compatible with the model that was used to generate the data. Such data sets can be a great asset in evaluating alternative methods that have the same assumptions, but they are of limited value in identifying whether a particular method will be successful on real data.

Another desired development would be a more systematic study and comparison of different distance criterion. Specifically, with the development of new measures [7,31,78], a detailed analysis of the strengths and weaknesses of the different approaches is needed to assess the context in which they are most applicable. For instance, model-free measures such as the breakpoint distance and the conservation distance are probably the most appropriate when the underlying rearrangements follow uncharacterized rules.

Finally, a key challenge associated with this type of analysis involves studying the causes and consequences of genome rearrangements. Although these events are well characterize in both evolution and cancer, the extent of the biological repercussions is still unclear. For instance, large rearrangement events can have a significant impact at the population level by creating subpopulations for which recombination in the affected region will be impossible but the question of whether such events also play a role in speciation for instance is still debated. On a different topic, is there a faster phenotypic evolution associated with a faster rearrangement rate? Given the amount of comparative data recently made available [26, 32, 37, 79, 84], the hope is that some answers might be within reach.

In order to start exploring these questions, looking at sets of highly diverse genomes spanning long evolutionary distances is not the most appropriate. Inherent to such data sets will always be ambiguities such as the accuracy of the rearrangement model, the quality of the solution obtained, the order of rearrangements found on edges of the phylogeny, the presence of alternative ancestors and the presence of alternative rearrangement scenarios. A more practical framework in which to ask questions about the impact of genome rearrangements would probably involve looking at more closely related species where the inferred rearrangement scenario is less disputable.

6.2 Promising New Approaches

The rearrangement model will always have a critical impact on the reconstructed scenario. In many of the applications presented [13, 14, 46], the rearrangement model includes reversals, translocations, fusions and fissions, but these events are considered equally likely (i.e. the weight of each of the events is the same when the distance is computed). In reality, short reversals are probably more common than fusions for instance. Consider the carnivore ancestor shown Figure 5; in the displayed solution, there is a fission between the ferungulate ancestor and the carnivore ancestor followed by a fusion in the cat lineage. An alternative solution exists with the same total number of rearrangements, but in which this fission plus fusion is replaced by a single fission on the dog lineage and a reversal in the cat lineage. Such a scenario is probably more realistic than the one displayed but it is masked by our assumption of equally likely events. Perhaps approaches with weighted events, such as in Blanchette and coworkers [11], or approaches that make use of a maximum likelihood framework, such as Larget and coworkers [39], could help alleviate some of these ambiguities.

Although strictly incorporating transpositions into the rearrangement model remains computationally challenging, there is renewed interest in allowing block interchanges, an operation which includes all types of transposition [19, 41, 86]. The inclusion of this process actually allows a dramatic simplification of the HP theory (see Section 3.2) [86] and is likely to enable new applications.

Nevertheless, because rearrangement models are always debatable, model-free approaches that make use of breakpoint or conservation distance, such as Bergeron and coworkers [6], are also attractive and interesting. Hopefully these approaches will be extended and applied to a larger variety of problems.

Finally, another promising area of research is the analysis of breakpoint regions. These regions typically contain an unusual mosaic of content [36,77] and they are also likely to harbor information on the mechanisms behind the rearrangements that created them. In the context of cancer, these are also the regions that have the potential to host the destructive fusion genes. Comparing cancer breakpoints with evolutionary breakpoints [46] might provide some information on the forces shaping the genomic architecture of modern organisms.

Part 4 Molecular Structure Prediction

9
Predicting Simplified Features of Protein Structure

Dariusz Przybylski and Burkhard Rost

1 Introduction

1.1 Protein Structures are Determined Much Slower than Sequences

At the end of 2005 there were about 30 000 experimentally determined protein three-dimensional (3-D) structures in public databases [17]. At the same time there were almost 40 million genes known [16] and approximately 1.5 million verified [11] protein sequences. This gap between structure and sequence continues to grow – despite successful efforts at large-scale structure determination ("structural genomics" [118, 150]), the rate of new structures (thousands per year) continues to increase much slower than the rate of new sequences (many millions per year). Moreover, experimental structure determination has been largely or entirely unsuccessful for important classes such as cell membrane proteins.

1.2 Reliable and Comprehensive Computations of 3-D Structures are not yet Possible

In principle, we could compute 3-D structures from sequences using basic physical principles [9]. However, the complexity of the problem exceeds by far today's computational resources. Speeding up molecular dynamics by a factor of 1000 appears an objective within reach to Schroedinger Inc. While this would undoubtedly yield important insights into the problem, it may still not bring reliable predictions of 3-D structures from sequence. Even given infinite CPU resources, another serious obstacle is raised by the

Bioinformatics – From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

minute energy differences between native and unfolded structures (around 1 kcal mol^{-1}). This minute difference along with the uncertainty in estimating constants needed for calculations based on first principles makes it very difficult to find an approximate approach that is both simple and sufficiently accurate. Although we cannot model from sequence, comparative modeling yields rather accurate predictions based on sequence homology to proteins of known structure [101]. Such modeling is based on the fact that proteins with similar sequences usually have similar structures. Assume we know the structure for K and that we want to predict the structure for U that is sequence-similar to K. Comparative modeling simply predicts U to have the same structure as K and models the structure of U based on the known backbone of K. However, for the majority of protein sequences no sufficiently detailed structural information is available or computable.

1.3 Predictions of Simplified Aspects of 3-D Structure are often very Successful

In the absence of experimental or predicted 3-D structures, many researchers concentrate on trying to simplify the problem and predict particular structural features. One of the first well-defined problems was the prediction of protein secondary structure. Progress in this field has been steady and current secondary structure predictions are useful for many biological applications. Techniques that were developed in the context of secondary structure predictions were successfully applied to the prediction of many other aspects of protein structure such as solvent accessibility, inter-residue contact maps, disordered regions, domain organization and specialized for distinctive cases such as transmembrane regions of proteins.

2 Secondary Structure Prediction

2.1 Assignment of Secondary from 3-D Structure

2.1.1 Regular Secondary Structure Formation is Mostly a Local Process

Three-dimensional structures exhibit extensive local conformational regularities known as regular secondary structure. These local structures (most importantly helices and sheets) can be described as ordered arrangements of a polypeptide chain without reference to amino acid type or actual 3-D conformations. They are stabilized primarily by hydrogen bonds formed between the atoms present in the polypeptide backbone, but interactions with solvent and other protein atoms also play an important role. It is believed that the formation of secondary structure is an important step toward folding. Identifying the rules for packing the elements of secondary structure against each other would afford the derivation of a very limited number of possible stable conformations. Unfortunately, the formation of secondary structure is not entirely a local process. Thus, a perfect prediction of secondary structure without knowledge of nonlocal information is unlikely. Note that secondary structure can be written in a string of assignments for each residue, i.e. it is essentially a 1-D feature of protein 3-D structure. (Unfortunately, some authors are lured into misusing the term 2-D structure, possibly in response to a misunderstanding of the word "secondary".)

2.1.2 Secondary Structures can be Somehow Flexible

Regular secondary structure is a striking, macroscopically visible aspect of 3-D structure. However, secondary structures are not rigid. Calculations and experiments indicate that structural shifting occurs, especially in surface regions. The adoption of a particular structure may depend on many environmental factors. This is illustrated by the fact that sometimes the secondary structure states differ among various crystals of the same protein as well as various nuclear magnetic resonance (NMR) models by as much as 5–15%. This variability constrains the upper limit of what we can expect from prediction methods – arguably levels of about 90% (percentage of residues predicted correctly in either of the three states helix, strand, other). While many residues can be confidently classified into one of the secondary structure types, there are also those for which classification is ambiguous. This problem is especially evident at terminal locations of secondary structure elements; it is just another aspect of the observation that protein structures are dynamic objects. Historically, assignments were carried out through visual inspection by experimentalists. That approach introduced a human-based inconsistency. In 1983, this inconsistency was first addressed by an objective, automatic assignment method [Dictionary of Secondary Structure of Proteins (DSSP), see below]. Many such methods followed; they all apply criteria consistent for all proteins but they often differ between each other.

2.1.3 Automatic Assignments of Secondary Structure

The first assignments of protein secondary structure were carried out by Pauling and others [126] even before experimental 3-D structures of proteins became available. They were based on intra-backbone hydrogen bonds. One of the first and most popular automatic methods, DSSP [76], used a similar approach. The DSSP method calculates the interaction energy between backbone atoms based on an electrostatic model [76]. It assigns a hydrogen bond if the interaction energy is below a chosen threshold (–0.5 kcal mol^{-1}). The structure assignments are defined such that visually appealing and unbroken structures are formed from groups of hydrogen bonds. Another popular automatic assignment method, the STRuctural IDEntification method (STRIDE [51]) uses ϕ–ψ torsion angles and empirically derived hydrogen bond energy. The parameters used by this method are optimized to reproduce visual assignments provided by experimentalists determining 3-D structures and so in effect the method averages out human bias. The method DEFINE [143] assigns secondary structure using C_α coordinates. The assignment is carried out through comparison of observed C_α distances with those derived from ideal secondary structures. If the distances are within set discrepancy limits, then the secondary structure is assigned. The method P-Curve [173] makes assignments based on geometrical analysis of protein curvature. It uses differential geometry-based representations of standard structural motifs and through a set of geometrical transformations tries to match these motifs with those found in known 3-D structures. P-Curve assignments differ significantly from those based on hydrogen bonds and/or ϕ–ψ torsion angles. DSSP, P-Curve and Define assignment methods agree for only about two-thirds of all residues [30]. There are various reasons for disagreements; the most important one may simply be that secondary structure is dynamic, i.e. that there simply is no such thing as a secondary structure "state". This problem is reflected in the DSSPcont method that introduces continuous secondary structure assignments [8]. The continuum results from calculations of weighted averages of DSSP assignments that are based on various hydrogen bond energy thresholds. As a result, each protein residue is assigned with likelihoods of all secondary structure states. Residues that have a higher probability for a single "state" appear to also be more rigid according to NMR measurements of motions on timescales important for protein function [8]. Other, more application-oriented approaches to defining local structures are possible. For example, one may try to define a new secondary structure alphabet with a goal of improving fold recognition algorithms [78]. The numerical values of prediction accuracy presented in this chapter are based on the most widely used DSSP assignment. Evaluations based on STRIDE tend to yield higher values and no state-of-the-art prediction method has been evaluated on P-Curve.

2.1.4 **Reduction to Three Secondary Structure States**

DSSP distinguishes eight different "states": three types of helical structures [α-helix ("H", four-residue period), π-helix ("I", five-residue period) and 3_{10}-helix ("G", 3-residue period)], extended β-sheet ("E"), β-bridge ("B"), turn ("T"), bend ("S") and other nonregular states (blank). Of those, α-helix and β-strand (Figure 1) comprise more than 50% of all protein residues. Some prediction methods attempt to predict all eight states. However, a widely used strategy is to map the eight "states" into three major "classes": helical, extended and other (often imprecisely referred to as "nonregular", "coil"

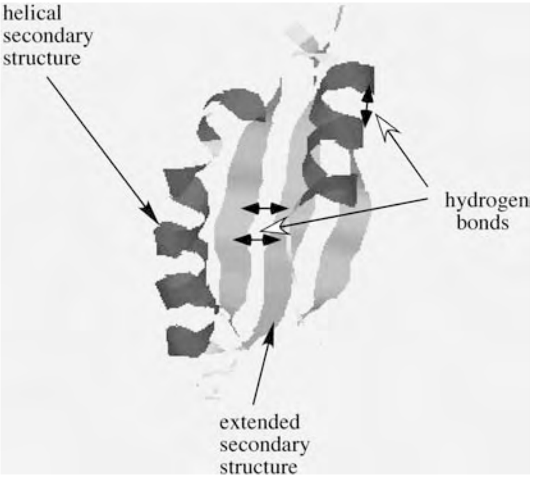

Figure 1 Ribbon diagram of protein secondary structure. Secondary structures are local arrangements of the protein backbone without reference to the amino acid type or the 3-D conformation. They are stabilized by hydrogen bonds between atoms of the main chain (backbone). Very roughly, secondary structures can be classified into three classes: helical (H), extended (E) (strand) and loopy (other) L. The figure contains a schematic representation of the E2 DNA-binding domain [21] (Protein Data Bank [17] code 1a7g).

or "turn"). Different maps are possible, but the most popular one (which incidentally is most difficult to predict [35]) is the following: [GHI] = helical ("h"), [EB] = extended ("e") and [TS] = nonregular (coil) ("I"). The alternative translation that results in seemingly higher prediction accuracies, i.e. [H] = helical, [E] = extended and [GITS] = nonregular, is sometimes used.

2.2 Measuring Performance

2.2.1 Performance has Many Aspects Relating to Many Different Measures

Depending on the application there are various views as to what constitutes a high-quality prediction. On the one hand, it is important to correctly predict the secondary structure "state" for each residue (per-residue accuracy); on the other hand, it may be more relevant to predict the coarse-grained presence of, for example, a helix than all residues in the helix (segment-based accuracy). Accordingly, many measures have been used to assess prediction quality: simple percentages of per-residue accuracy (Eq. 1), Matthew's correlation coefficients, percentage of confusion between strand and helix states [38] (Eq. 2); simple segment-based measures such as the number of correctly predicted segments, the average ratio of predicted to observed segment lengths, the difference between the distribution of predicted and observed segment lengths [156]; or the more elaborated and widely used segment overlap score *SOV* [160, 187] (Eq. 3). These are only some of the measures that have been applied. In this chapter, we focus on two measures for per-residue accuracy, i.e. percentages Q_K (Eq. 1) and the *BAD* score (Eq. 2), and one measure for per-segment accuracy, i.e. *SOV*.

2.2.2 **Per-residue Percentage Accuracy:** Q_K

Perhaps the most intuitive and simplest measure for performance is the average percentage of correctly predicted states. For a protein composed of L residues and for K possible secondary structure states the per-residue prediction accuracy Q_K is defined as:

$$Q_K = 100 \times \sum_{i=1}^{K} C_i / L \qquad (1)$$

where C_i is the number of residues correctly predicted in secondary structure state i. For a three-state alphabet this translates into a Q_3 measure. The average accuracy can be computed as an average per protein or an average per residue in which case the number of all residues is used for L.

2.2.3 **Per-residue Confusion between Regular Elements: *BAD***

Not all secondary structure prediction mistakes are equal. For instance, when using secondary structure predictions to model 3-D structure, confusing helix and extended (strand) is more detrimental than confusing regular with non-regular states. The percentage of such "bad" predictions constitutes the *BAD* score. If L is a total number of amino acid residues in a protein and *Bh* (*Be*) is the number of helical (strand) residues predicted in strand (helix) state, then the *BAD* score is expressed as:

$$BAD = 100 * \frac{Bh + Be}{L} \; . \qquad (2)$$

Two predictions with equal Q_3 and/or *SOV* scores can have very different *BAD* scores.

2.2.4 **Per-segment Prediction Accuracy: *SOV***

Regular secondary structure elements are built of continuous stretches of residues belonging to the same state, e.g. most helices are about 10 residues long. It can be argued that mis-predicting two residues at either end of a helix is not an important mistake (note: 2 + 2 out of 10 means 60% accuracy). In contrast, only predicting 60% of the helices in a protein is a severe problem. Such realities are reflected in segment-based measures. The most widely used is the segment overlap (*SOV*) measure [160,187]:

$$SOV = 100 \times \frac{1}{N} \sum_{i}^{K} \sum_{S(i)} \frac{minov(s_{\text{obs}}, s_{\text{pred}}) + \delta(s_{\text{obs}}, s_{\text{pred}})}{\text{maxov}(s_{\text{obs}} s_{\text{pred}})} \times len(s_{\text{obs}}) \qquad (3)$$

where K is the number of different secondary structure types; the second summation is over all overlapping secondary structure segments of observed s_{obs} and predicted s_{pred} secondary structure of the same type; *minov* is the number of positions at which segments overlap; *maxov* is the number of overlapping positions plus the number of remaining residues from each segment of the given pair; $len(s_{obs})$ is the length of a reference secondary structure segment (observed experimentally); N is the total number of overlapping segments pairs of the same type; and $\delta(s_{obs}, s_{pred})$ is the accepted variation between segments that assures ratio of 1.0 when the variations between s_{obs} and s_{pred} are minor. One can easily envision two different secondary structure predictions that have the same Q_3 and different *SOV* scores. For example, if instead of a observed long helix of length n one prediction consists of a shorter helix of length m and the second prediction comprises two short helices of combined length equal to m (other residues predicted as coil), then the Q_3 scores of both predictions are going to be the same while the *SOV* scores are going to be different.

2.3 Comparing Different Methods

2.3.1 Generic Problems

In this section we describe problems with the evaluation of prediction methods that are entirely generic, i.e. valid for all prediction methods. Although many ideas and concepts have been introduced to predict secondary structure and have then been used for other purposes, many of the mistakes in comparing methods have also been unraveled first and most clearly for the example of secondary structure predictions. Secondary structure prediction methods may be the only example of publications with claims to performance accuracy that survived more than a decade. (To put this into perspective: our section focuses on methods for which performance has, on average, been unusually well estimated; nevertheless, the only other field that we review for which *any* estimate survived 5 years was the prediction of solvent accessibility and the vast majority of publications in that field heavily overestimated performance!)

2.3.2 Numbers can often not be Compared between Two Different Publications

Prediction methods are often published with estimates of performance that are supported by cross-validation experiments. However, the terms "cross-validation" or the related term "jackknife" are by no means sufficiently well-defined to translate into "estimate ok". In fact, most publications make some serious mistakes as is demonstrated by the simple fact that very few estimates of performance have survived. One problem is the overlap between "training" and "testing" sets. It is trivial to reach very high performance by training on proteins that are very similar to those in the testing set. There are various strategies that deal with the similarity problem [67,188]. Another issue is that of using the performance of the test set to choose some parameters by, for example, reporting full cross-validation results for *N* different parameters and then concluding that the best of those *N* is the performance of the final method. Instead, performance estimates should always be based on a data set that was not used in ANY step of the development. However, even if we had two publications that both used cross-validation "correctly", we still cannot necessarily compare the numbers published by both directly. First, both have to have used the same standard of truth (here, the same assignment method, e.g. DSSP, and the same conversion of the eight DSSP states into three prediction classes). Second, they both have to have been based on identical test sets. Often, the test sets used by developers are not representative and differ from each other. Proteins vary in their structural complexity and such variation is correlated with prediction difficulty. We could argue that test sets should be frozen (and this has indeed been done in many cases). Such a set should be sufficiently large to allow proper evaluation of statistical differences among methods. Although a *sine qua non*, this freezing strategy does not suffice – data sets in biology change constantly, almost always more recent sets are more reliable and representative. Therefore, we also need evaluations based on sets that are as recent as possible. One way of merging these two demands is by carrying out two tests: one on a frozen set used by others and the other on a more recent set. As an aside, it is not necessary to use *n*-fold cross-validation experiments with the largest possible *n*. The exact value of *n* is not important as long as the test set is not misused for adjusting a method's parameters and it is representative of the entire structure space.

2.3.3 **Appropriate Comparisons of Methods Require Large, "Blind" Data Sets**

One of the solutions to the problem of comparing methods is to use a sufficiently large test set composed of proteins that were neither used nor are similar to any protein that was used for development of any method. This idea was first realized in the field of structure prediction through the Critical Assessment of Structure Prediction (CASP) experiments in which various prediction methods are tested over the course of a few months on sequences of proteins the 3-D structure of which is unknown at the time of the prediction ("blind" prediction). Those experiments evaluate fully automatic methods as well as human experts (see also Chapter 11 for a more detailed description of CASP and CAFASP). Due to a variety of reasons, CASP cannot be based on sufficiently large, representative data sets. Servers that automatically evaluate methods whenever new data is available address this shortcoming. Such servers base their comparisons on thousands instead of tens of test cases (as does CASP). Two such servers exist: EVA and LiveBench. EVA

[44] continuously evaluates automatic prediction methods (servers) providing results based on a large, statistically significant and, subsequently, more representative data sets. One of its principles is to facilitate comparisons on identical sets and to render comparisons on different sets very difficult. Another principle is to never distinguish in the rank between two methods if the difference in their performance is not statistically significant. Both principles are in stark contrast to what most CASP assessors did.

2.4 History

2.4.1 First Generation: Single-residue Statistics

First attempts to correlate amino acid residue frequency with secondary structure type can be traced to correlating the content of certain amino acids (e.g. proline) with the content of α-helix [176]. This was done even before the first crystallographic structures were available [81,127]. Attempts to correlate the content of all amino acids with the content of α-helix and β-strand opened the field of secondary structure prediction [19,20]. The early methods were usually based on single-residue statistics obtained from very limited data sets of known protein structures. As such they were not very accurate (Figure 2) and in addition their accuracy was overestimated at the time.

2.4.2 Second Generation: Segment Statistics

As the number of experimentally determined protein structures grew it became possible to estimate propensities for secondary structure based on consecutive segments of residues. Various numbers of adjacent residues (typically 11–21) were considered in assigning secondary structure to a central residue of a segment. Many different algorithms were applied, but they did not achieve per-residue prediction accuracies higher than slightly above 60% (Figure 2). Reports of higher accuracies were due to small data sets and did not hold for long. The main approaches used were (i) statistical information, (ii) physicochemical properties, (iii) sequence patterns, (iv) artificial neural networks, (v) graph theory, (vi) expert rules, (vii) nearest-neighbor algorithms and (viii) hybrid approaches of various algorithms.

2.4.3 Third Generation: Evolutionary Information

Proteins with similar sequences adopt similar structures [27,166]. In fact, proteins can change more than 70% of their residues without altering the basic fold [1,15,125,189]. However, the vast majority of possible sequences supposedly do not adopt globular structures at all. Rather, the exact substitution pattern of which residues can be changed and how is indicative of particular structural details. Consequently, the evolutionary information

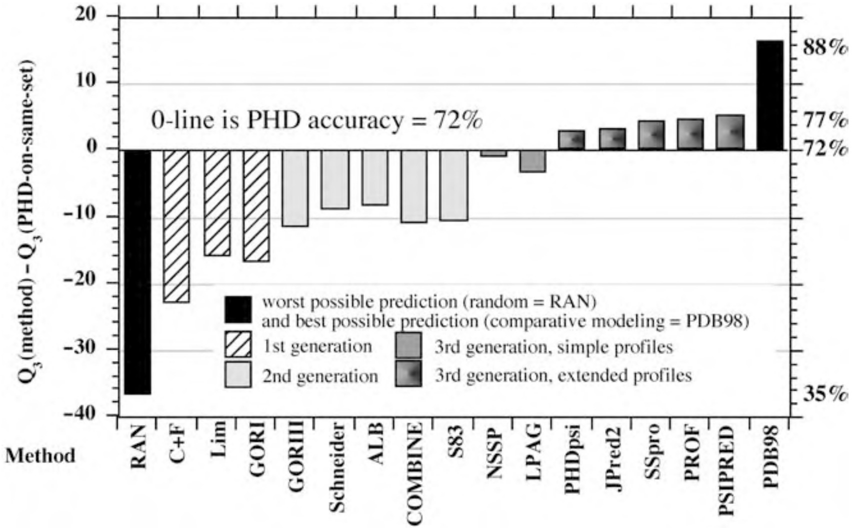

Figure 2 Three-state per-residue accuracy of various prediction methods. Included are only those methods for which we could run independent tests. Unfortunately, for most old methods this was not possible. However, for each method we had independent results from PHD (third generation, 1993) [151,154,159] available. We normalized the differences between data set by simply compiling levels of accuracy with respect to PHD. For comparison, we added the expected accuracy of a random prediction (RAN), and the best currently possible prediction accuracy achieved through comparative modeling of close homolog (PDB98). The methods were: C+F (Chou and Fasman; first generation, 1974) [28,29]; Lim (first, 1974) [93]; GORI (first, 1978) [53]; Schneider (second, 1989) [169]; ALB (second, 1983) [140]; GORIII (second, 1987) [57]; COMBINE (second, 1996) [52]; S83 (second, 1983) [77]; LPAG (third, 1993) [92]; NSSP (third, 1994) [175]; PHDpsi (third, 2001) [137]; JPred2 (third, 2000) [34]; SSpro (third, 1999) [12]; PROF (third, 2001) [149]; PSIPRED (third, 1999) [73].

contained in sequence alignments can aid structure prediction. In particular this approach improves prediction of β-strands. For the first and second generation of prediction methods β-strand prediction was particularly bad (often only slightly better than random). The pioneering method that used alignment information was proposed in the 1970s [41]. The first approaches were based on visual gathering of information from sequence alignments. In one of the first automatic algorithms making use of alignment information [107,189] the final secondary structure prediction was an average over all predictions compiled for each sequence in the alignment. The first method that succeeded in significantly improving performance by automatically using alignment information was PHD [151, 154, 157] (Figure 3). This method used a residue profile extracted from a multiple sequence alignment as an input to the artificial neural network. Many other methods used artificial neural networks [73, 123, 133], but various other algorithms were also applied successfully [38,

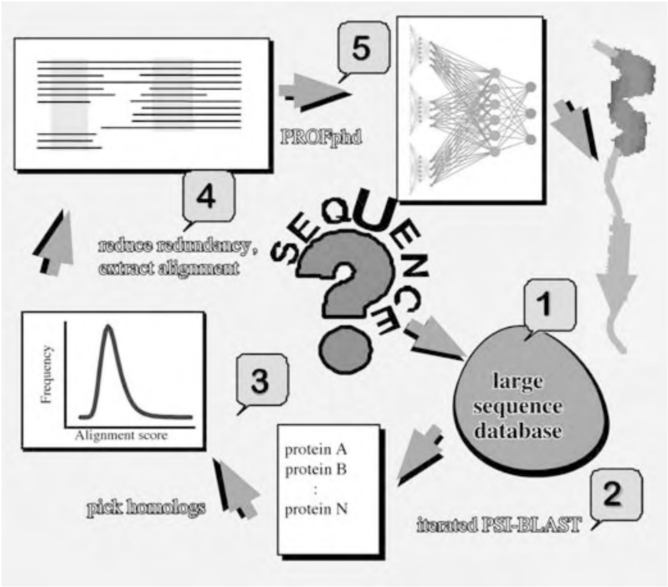

Figure 3 Using evolutionary information to predict secondary structure. Starting from a sequence of unknown structure (SEQUENCE) the following steps are required to feed evolutionary information into the PROFsec neural networks (upper right): (1 and 2) a database search for homologs through iterated PSI-BLAST [6,7] (protocol from Ref. [137]), (3) a decision for which proteins will be considered as homologs, (4) a reduction of redundancy (purge too many too similar proteins), and (5) a final refinement and extraction of the resulting multiple alignment. Numbers 1–5 illustrate where users of the PredictProtein server [151,161] can interact to improve prediction accuracy without changes made to the actual prediction method PROFsec.

39, 51, 91, 109, 146, 163] including support vector machines (SVMs) [68,181], hidden Markov models (HMMs) [79], nearest-neighbor algorithms [163].

2.4.4 **Recent Improvements of Third-generation Methods**

PHD tore down what once was a magical wall of 70% accuracy. The mark has been put much higher since. The first significant improvement was achieved by training neural networks on more diverse sequence alignments [73]. The alignments were generated by a new alignment method – PSI-BLAST [7]. It has been shown that a major improvement can be achieved by using previous types of neural networks with PSI-BLAST alignments [34]. Interestingly, it was also shown that a significant part of the improvement was simply due to the growth of sequence databases that resulted in more diverse profiles [137]. In general, the more divergent the alignment the better the prediction can be obtained. The input quality is also dependent on alignment quality. This is especially important for divergent homologous proteins where alignment methods tend to make many mistakes. Yet another simple source of improvement is related to the growth of the database of protein structures [17]. Apart from improvements in alignments, there is a lot of research pursuing development of more sophisticated and accurate algorithms. Those include new network architectures or learning techniques [3, 12, 78, 132, 133], SVMs [181] and many others.

2.4.5 **Meta-predictors Improve Somehow**

Different methods often make different mistakes. As long as those errors are not purely systematic, combining any number of methods can lead to improvements in prediction accuracy [62]. For example, the PHD method utilized this observation by combining differently trained neural networks. Various implementations of the similar concept were used in many other methods [24, 34, 128]. Alternatively, or in addition, different methods can be combined [5, 35, 36, 60, 83, 158, 170]. Overall, combinations of independent methods tend to top the single best method. However, it probably is not beneficial to use all of the available prediction methods in the meta-methods. For example, averaging over all methods evaluated by EVA evaluation server [44, 46] decreased accuracy over the best individual methods (Rost, unpublished). It is not fully straightforward how to decide whether to include a given method or not [5]. Concepts weighing the individual method based on its accuracy and "entropy" [128] appear to be successful only for large numbers of methods. More rigorous studies for the optimal combination may provide a better picture. An interesting approach resulted from attempts to improve meta-methods by developing new methods that are algorithmically different from the methods already used [85, 171]. Recently, an observation has been made indicating that optimizing meta-servers to achieve highest per-residue prediction accuracy is not always beneficial when using the final predictions in various applications [108]. Another issue that has first been introduced for secondary structure prediction is the measurement for the reliability of a prediction. To make an extreme point: a method that has 50% accuracy, but that always correctly identifies in which of the cases it is right and it which it errs (before knowing the answer), is more useful than a method with 75% accuracy and no notion about which 25% of the residues are wrong. State-of-the-art methods reliably estimate the reliability of a prediction. This is not the case for any of the existing meta-methods.

2.5 State-of-the-art Performance

2.5.1 **Average Predictions Have Good Quality**

Today's best methods reach average levels of almost 78% in Q_3 (Eq. 1) [44, 86]. They are able to accurately predict most segments (*SOV* scores around 76%).

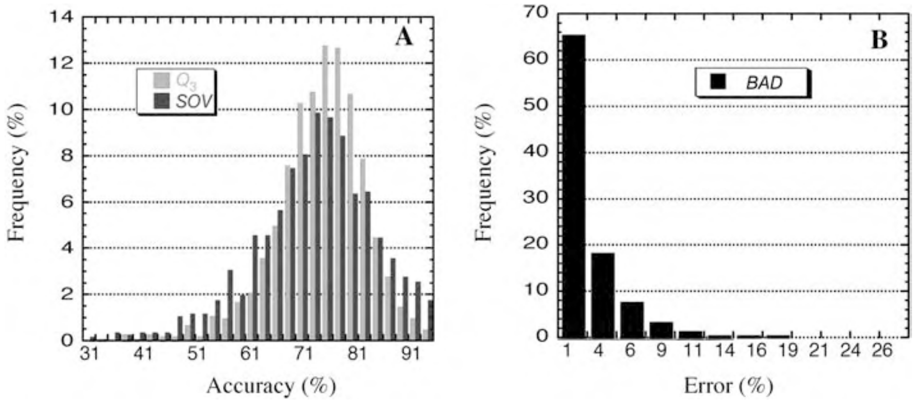

Figure 4 Expected variation of prediction accuracy for PROFsec. (A) Three-state per-residue (Q_3) and segment overlap (*SOV*) accuracies. (B) Percentage of *BAD* predictions, i.e. residues either predicted in helix and observed in strand or predicted in strand and observed in helix.

In addition the confusion between helices and strands is low (*BAD* score of less than 3%).

2.5.2 **Prediction Accuracy Varies among Proteins**

The standard deviation of three-state-per-residue accuracy computed on the per-protein basis is about 13% [44, 86] (Figure 4). Thus, some of the proteins are predicted very well (above 90%), while others are predicted very badly (even below 40% accuracy levels). The relatively large deviations are also found in prediction quality measured by other measures. The standard deviation of the *SOV* score is about 15% and that of the *BAD* score is about 5%. In particular, proteins having no sequence homologs (no alignment input) are poorly predicted. This is an important issue for the applicability of secondary structure predictions since badly predicted secondary structure is not very valuable.

2.5.3 **Reliability of Prediction Correlates with Accuracy**

For the user interested in a particular protein U, the fact that the prediction accuracy varies from protein to protein implies a rather unfortunate message: the accuracy for U could be lower than 40% or it could be higher than 90% (Figure 4). Is there any way to provide an estimate at which end of the distribution the accuracy for U is likely to be? Indeed, many methods provide numerical estimates of the expected quality of their predictions through so called reliability indices. Those indices correlate with accuracy. In other words, residues with higher reliability index are predicted with higher ac-

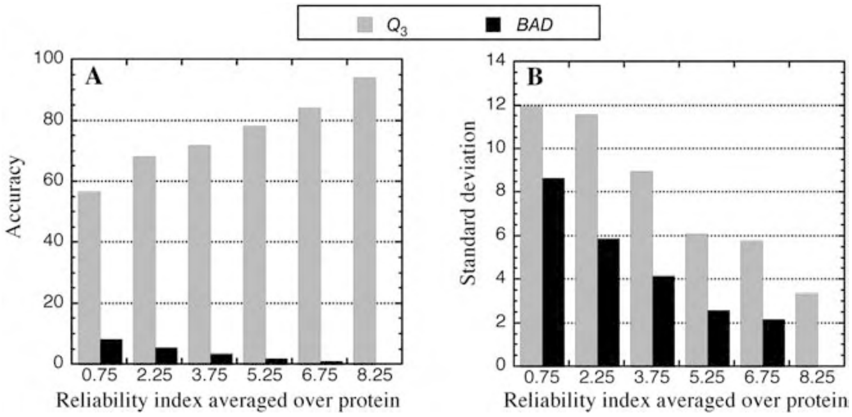

Figure 5 Prediction quality correlates with reliability indices. (A) Average three-state per-residue accuracy and *BAD* score at different reliability index thresholds (averaged over entire protein) as predicted by PROFsec [149]. (B) Corresponding values of standard deviation.

curacy [151,154,157]. Thus, the reliability index offers an excellent tool to focus on some key regions predicted at high levels of expected accuracy. Furthermore, the reliability index averaged over an entire protein correlates with the overall prediction accuracy for this protein (Figure 5).

2.5.4 **Understandable Why Certain Proteins Predicted Poorly?**

It is not easy to anticipate performance of a secondary structure prediction method based on overall structural features of proteins. However, prediction accuracy is correlated with alignment quality. Poor alignments (i.e. noninformative and/or falsely aligned residues) result in inaccurate predictions. Another interesting observation is that frequently the *BAD* predictions, i.e. the confusion between helix and strand are observed in regions that are stabilized by long-range interactions. Furthermore, helices and strands that are confused despite a high reliability index often have functional properties or are correlated to disease states (Rost, unpublished data). Regions predicted with equal propensity in two different states often correlate with “structural switches”.

2.6 Applications

2.6.1 **Better Database Searches**

Initially, three groups independently applied secondary structure predictions for fold recognition, i.e. the detection of structural similarities between proteins of unrelated sequences [50,152,162]. A few years later, almost every other fold recognition/threading method has adopted this concept [10, 37, 40, 63, 72, 74, 80, 87, 122, 124]. Two recent methods extended the concept by not only refining the database search, but by actually refining the quality of the alignment through an iterative procedure [65,71]. A related strategy has been employed to improve predictions and alignments for membrane proteins [117]. It has also been indicated that prediction mistakes tend to correlate among structurally related proteins [138], and that alignments based on purely predicted secondary structure have comparable quality with those based on matching predicted and observed states. Thus predicted secondary structure may prove useful in searching sequence databases.

2.6.2 One-dimensional Predictions Assist in the Prediction of Higher-dimensional Structure

Secondary structure predictions are now accurate enough to be used as input for methods that target the prediction of higher order aspects of protein structure automatically. A few successful applications include the following. Contact map predictions [13] have recently improved the level of accuracy significantly; an important contribution was the inclusion of secondary structure predictions [141]. They also help in the prediction of folding rates [69,142]. Secondary structure predictions have also become a popular first step toward predicting 3-D structure. Ortiz and coworkers [121] successfully use secondary structure predictions as one component of their 3-D structure prediction method. Eyrich and coworkers [47, 48] minimized the energy of arranging predicted rigid secondary structure segments. Lomize and coworkers [103] also started from secondary structure segments. Chen and coworkers [25] suggested using secondary structure predictions to reduce the complexity of molecular dynamics simulations. Levitt and coworkers [164, 165] combined secondary structure-based simplified presentations with a particular lattice simulation attempting to enumerate all possible folds.

2.6.3 Predicted Secondary Structure Helps Annotating Function

Secondary structure predictions are also useful to annotate/predict protein function. For example, secondary structure predictions have been used successfully in completely automatic predictions of subcellular localization [116]. A more typical use of secondary structure prediction is in aiding experts in finding similarities among proteins with insignificant sequence similarity. In this way functional annotation is sometimes transferred from one protein to another [184].

2.6.4 Secondary Structure-based Classifications in the Context of Genome Analysis

Proteins can be classified into families based on predicted and observed secondary structure [56, 139]. However, such procedures have been limited to a very coarse-grained grouping only sometimes useful for inferring function. Nevertheless, predictions of membrane helices and coiled-coil regions are crucial for genome analysis. More than one fifth of all eukaryotic proteins appear to have regions longer than 60 residues apparently lacking any regular secondary structure [102]. Most of these regions were not of low complexity, i.e. not composition biased. Surprisingly, these regions appeared evolutionarily as conserved as all other regions in the respective proteins. This application of secondary structure prediction may aid in classifying proteins, and in separating domains, possibly even in identifying particular functional motifs.

2.6.5 Regions Likely to Undergo Structural Change Predicted Successfully

Prions and prion-like proteins appear to aggregate through the transition of a regular secondary structure: what is "usually" a helical region switches to a strand that becomes the root of aggregation in the case of disease mutants. The reliability of the PHD secondary structure predictions combined with experimental evidence gave the first hint where this expected transition might occur [136]. Interestingly, it is still difficult to actually observe the strand in structures of even the mutant prion, while state-of-the-art prediction methods always predict the region with an observed helix to be in a strand. This example casts some light on the importance of transitions and the usefulness of predictions to capture such transitions. Young and coworkers [84] have pushed this observation further by unraveling an impressive correlation between local secondary structure predictions and global conditions. The authors monitor regions for which secondary structure prediction methods give equally strong preferences for two different states. Such regions are processed combining simple statistics and expert rules. The final method has been tested on 16 proteins known to undergo structural rearrangements and on a number of other proteins (one of those was a prion). The authors report no false positives and identify most known structural switches. Subsequently, the group applied the method to the myosin family identifying putative switching regions that were not known before, but appeared reasonable candidates [84]. This method is remarkable in two ways: (i) it is a very general method using predictions of protein structure to predict some aspects of function and (ii) it illustrates that predictions may be useful even when structures are known (as in the case of the myosin family). While the method is tailored to catch more subtle changes than occur in prions, there is some evidence that amyloid aggregation is also captured to some extent.

2.7 Things to Remember when using Predictions

2.7.1 Special Classes of Proteins

Prediction methods are usually derived from knowledge contained in proteins from subsets of current databases. Consequently, they should not be applied to classes of proteins not included in these subsets, e.g. methods for predicting helices in globular proteins are likely to fail when applied to predict transmembrane helices. In general, results should be taken with caution for proteins with unusual features, such as proline-rich regions, unusually many cysteine bonds or for domain interfaces.

2.7.2 Better Alignments Yield Better Predictions

Multiple alignment-based predictions are substantially more accurate than single sequence-based predictions [14, 39, 151]. How many sequences are needed in the alignment for an improvement; and how sensitive are prediction methods to errors in the alignment? The more sequences contained in the alignment diverge, the better (two distantly related sequences often improve secondary structure predictions by several percentage points). Regions with few aligned sequences yield less reliable predictions. The sensitivity to alignment errors depends on the methods, e.g. secondary structure prediction is less sensitive to alignment errors than solvent accessibility prediction.

2.8 Resources

2.8.1 Internet Services are Widely Available

Programs for the prediction of secondary structure available as Internet services have mushroomed since the first prediction service PredictProtein went on line in 1992 [159, 161]. The META-PredictProtein server [45] enables users to access a number of the best prediction methods through one single interface. Unfortunately, not all methods available have been sufficiently tested and some are not very accurate. This problem is addressed by the EVA server that evaluates prediction servers continuously and automatically [44, 86].

2.8.2 Interactive Services

The PHD/PROF prediction methods are automatically available via the Internet service PredictProtein [45]. Users have the choice between the fully automatic procedure taking the query sequence through the entire cycle or expert intervention into the generation of the alignment. Indeed, without spending much time users typically can improve prediction accuracy easily by choosing "good" alignments. A few of the state-of-the-art methods are also available to run locally. Note, however, that one crucial step is the generation of appropriate alignments; usually this is not "done for you" when you run the prediction method locally!

2.8.3 Servers

The following servers are publicly available (most links given by the EVA server): PROFsec [149], PHDsec [159], PHDpsi [137], PSIPRED [73], SSPRO [133], PORTER [132], SABLE [3], SAM-T02 [79], Jpred [34], APSSP, JUFO [110], PROF [123], YASPIN [94].

3 Transmembrane Regions

3.1 Transmembrane Proteins are an Extremely Important Class of Proteins

Approximately 15–30% of all proteins are estimated to contain transmembrane regions [97, 111]. Those proteins are responsible for the communication between the cell and its surroundings, and are of great importance to biomedicine. The cell membrane environment, composed of a lipid bilayer, is very different from one found in most cellular compartments. The transmembrane segments of proteins tend to be hydrophobic which enables them to remain within a membrane by avoiding the solvent present at both boundaries. The special features of transmembrane protein sequences serve as the basis for identifying them by computational methods. As in case of globular proteins, the transmembrane segments form regular secondary structures and can be assigned to two broad classes: those composed entirely of helices and those composed of strands (despite ardent searches and putative evidence, we still do not have any proof for the existence of a mixture of the two). By far the majority of all membrane proteins appear to be of the helical type [18]. An important characteristic of transmembrane proteins is the orientation of membrane segments with respect to the N-terminus of a protein, often referred to as the topology. Usually, the successful prediction of transmembrane segments requires proper identification of transmembrane regions in sequence, actual prediction of the secondary structure and deciphering the topology. It is very difficult to experimentally determine 3-D structures for transmembrane proteins. Despite considerable advances over the last decade, we still have experimental structures or theoretical models for supposedly less than 10% of, for example, all human membrane proteins (Punta, Liu and Rost, unpublished). Useful predictions of structural and functional aspects are therefore highly needed.

3.2 Prediction Methods

Although all known transmembrane regions constitute of regular secondary structures, most secondary structure prediction methods developed for nonmembrane proteins mostly fail to correctly predict membrane regions. Furthermore, very few methods have been developed for proteins with β-strands in the membrane. The first and most basic methods for helical membrane regions focused on identification of transmembrane segments based simply on residue hydrophobicity [90]. It was observed that positively charged residues are more abundant on the inside of the membrane (the "positive-in" rule). A simple Kyte–Doolittle hydrophobicity plot [90] can thus provide much information on the presence of such transmembrane segments. This led to the development of the method that predicted positions of helices and the topology of helical membrane proteins [179]. Next, neural networks were applied to better identify transmembrane helices, and differentiate between membrane and nonmembrane proteins [153]. Among other approaches were HMM methods attempting to match the sequence to the predefined "grammar" of transmembrane proteins [88] (see Chapter 3 for basics on HMMs) and many others [33,66]. Recently, groups have begun to venture into the development of methods that predict membrane regions with β-strands [18, 42, 59, 70].

3.3 Performance

Estimates for the accuracy in predicting membrane regions are extremely problematic because there are so few high-resolution structures available. Consequently, all methods in the past were evaluated by also using low-resolution information from biochemical experiments that provide some evidence for the location of transmembrane regions. Unfortunately, such experiments can be more inaccurate than prediction methods [26]. This was one of the reasons why the performance of prediction methods had been significantly overestimated by the end of the last millennium [26, 113]. It now appears that the best prediction methods correctly predict all membrane helices for about 50–70% of all proteins, very few methods avoid the confusion between very hydrophobic signal peptides and membrane proteins, and the best methods falsely identify membrane helices in about 10% of all nonmembrane proteins [26, 113]. However, results can be far worse, e.g. most hydrophobicity-based methods misclassify over 50% (!) of all globular proteins as "containing membrane helices" [26]. Overestimates in publications are also a very serious problem – even over the last few years, methods have been published in prominent journals with estimated levels of above 95% accuracy that failed to reach significantly above 50% and misclassified over 30% of the globular proteins [26]. Note also that there are a few top methods available at the moment; all of these have their own strengths and weaknesses, i.e. there is no single one “best method”. Predictions of β-barrel membrane regions currently appear to be more accurate than those for helical membrane regions; however, this may likely turn out to be an overestimate caused by the fact that we have too limited experimental information.

3.4 Servers

There are many more methods than the following available; however, the methods listed here have sustained many evaluations. Helical membrane proteins: PHDhtm [153], SOSUI [66], TopPred [179], TMHMM [88], DAS [33]; β-barrel membrane regions: ProfTMB [18].

4 Solvent Accessibility

4.1 Solvent Accessibility Somehow Distinguishes Structurally Important from Functionally Important

In 3-D structures of globular proteins some of residues are buried deep inside, whereas others are located on the surface and thus are more exposed to the surrounding solvent. Residues that are more exposed to solvent are also more accessible to other biological agents and, consequently, are much more likely to be involved in functional interactions which require spatial accessibility such as enzymatic activity, DNA binding, signal transduction, etc. However, buried residues are much more likely to play important roles in stabilizing structures of proteins. Thus, a good distinction between exposed and buried residues can be very useful to distinguish residues that are important for function (conserved and exposed) from those that are important for structure (conserved and buried).

4.2 Measuring Solvent Accessibility

Solvent accessibility is usually measured in terms of the surface area accessible to water molecules. The values can range from 0 Å for entirely buried residues to around 300 Å for the largest residues on the surfaces of proteins. A measure that is not dependent on the size of the amino acid residue is the relative solvent accessibility expressed as a percentage of the residue surface that is exposed to solvent. It appears that among homologous proteins the relative solvent accessibility is less conserved than secondary structures [155]. In addition, the solvent accessibility of protein residues is strongly influenced by nonlocal interactions, where residues located far away along a protein sequence can be in spatial proximity resulting in mutual screening from solvent. Thus, predicting solvent accessibility appears to be more difficult than prediction of secondary structure. It addition, it was shown that among the evolutionarily related proteins of similar structure buried residues (less than 10% accessible surface area) tend to be much more highly conserved than highly exposed residues (more than 60%) [155]. Thus, for methods that use evolutionary information derived from alignments of related proteins it should be easier to closely predict accessibility for buried residues than for the exposed ones. A simplified approach is to try to distinguish between residues below a certain solvent accessibility threshold ("buried") and those above it ("exposed"). There is no biophysical reason to choose one threshold over another, and different researchers often choose different thresholds (7, 9, 16 and 25% are used). On average, about half of all protein residues have more than 25% of their surfaces exposed.

4.3 Best Methods Combine Evolutionary Information with Machine Learning

Some of the methods that predict secondary structure also have the capability of predicting solvent accessibility, since essentially the same basic concepts apply to building a solvent accessibility predictor. For example, PHDacc [155] and PROFacc [149] methods, which are part of the PredictProtein [159, 161] server, use the same sequence profile input as do their respective secondary structure prediction counterparts (PHDsec and PROFsec). They use a neural network that assigns relative solvent accessibility into one of the 10 states corresponding to squares of relative solvent accessibility (state 10 corresponds to a range 81–100% of solvent accessibility). This 10-state scheme can be converted to a two-state scheme or to a prediction in terms of actual value of the exposed surface. Another well known method is Jpred [36]. It is also a server that predicts both secondary structure and solvent accessibility. The method uses alignments generated by HMMs and PSI-BLAST as input to a neural network. The output of predictions from two different networks is combined to give a final relative solvent accessibility. Many other variations and similar approaches have been attempted which include various types of neural networks [2, 4, 34, 131], SVMs [82], Bayesian networks [177], information-theoretic approaches [115] and simple baseline approaches [144]. Most recently the relation between secondary structure and accessibility was explored to develop methods that combine both predictions explicitly to improve each one [2, 149].

4.4 Performance

Unlike the prediction of secondary structure that is continuously assessed and monitored on identical data sets, methods for the prediction of solvent accessibility are not. Given that different groups use widely different data sets and different conventions to convert actual values of solvent accessibility into prediction states, it is impossible to compare and reasonably summarize levels of performance. However, two-state predictions (either buried or exposed) are predicted at levels above 75% accuracy. Whatever values you read, note that advanced methods are significantly more accurate than simple methods based on simple features such as hydrophobicity, polarity or simple statistics.

4.5 Servers

PROFacc [149], PHDacc [155], SABLE [2], Jpred [34], ACCpro [131].

5 Inter-residue Contacts

5.1 Two-dimensional Predictions may be a Step Toward 3-D Structures

Directly predicting 3-D structure still fails. Predictions of 1-D aspects of protein structure, such as secondary structure and solvent accessibility, provide very valuable information. However, 1-D predictions are far too simplified. There is a path seemingly in between these two extremes (1-D/3-D), i.e. the prediction of inter-residue distances. In fact, 3-D structures can be reconstructed more or less completely from 2-D distance maps. The catch is that distance maps are as hard to guess as 3-D coordinates. As a consequence, existing methods try to solve the simplified problem of predicting contact maps, where two residues are considered to be in contact if they are located within a certain spatial cut-off distance (this results in a binary classification of residue pairs, i.e. contact/noncontact pairs).

5.2 Measuring Performance

There is no widely accepted threshold for the maximal distance between two residues that are considered as "in contact". While the smallest physically possible distance could be agreed upon, the limit beyond which the interaction between two residues can be considered negligible is more difficult to define. However, the distance of 8 Å between C_β atoms is the most widely used threshold for the evaluation of the performance of these prediction methods. The output of contact prediction programs is generally a list of residue pairs, ranked according to some internal confidence score. Usually, only contacts between pairs that exceed a minimal sequence separation are evaluated. Although many different thresholds have been used, minimal separations of six and 24 sequence positions are most common for prediction of medium- and long-range contacts, respectively. These parameters are important as the task becomes more difficult with increasing separation (this tendency levels off for separations over 20).

5.3 Prediction Methods

One line of methods was based upon the observation that evolutionary pressure on maintaining protein structure would sometimes require correlation in the mutations of amino acid residues that are in spatial proximity to each other. In principle, such patterns of correlation could be discerned in the multiple alignments of protein sequences. Some of the early contact prediction methods have indeed used only correlated mutations computed from multiple sequence alignments [58, 119]. The currently best methods make also use of other protein features, such as evolutionary profiles of the nearest neighbors of the residue pair being predicted, sequence separation, secondary structure and solvent accessibility predictions. Further improvement of predictions was achieved through machine learning techniques such as: neural networks that use [49, 61, 120] or do not use [130, 141] correlated mutations, HMMs [22, 129, 172], SVMs [188] and genetic programming [104].

5.4 Performance and Applications

As the prediction of nonlocal contacts is difficult, progress in the field had been slow until recently when two promising new methods entered the CASP6 competition in 2004. When $L/2$ predictions are considered, the accuracy of state-of-the-art methods is around 30% for sequence separation of at least six and around 20% for sequence separation of at least 24. Although predicted contact maps are not very accurate, they are nevertheless better on average than the contact maps obtained from the best *de novo* predictions of 3-D structures [46]. As a result, the automatically predicted contact maps were successfully used in prediction of 3-D protein structures [119, 121, 174].

5.5 Servers

PROFcon [141], CORNET [120], CMAPpro [129], GPCPRED [104], Hamilton's server [61].

6 Flexible and Intrinsically Disordered Regions

6.1 Local Mobility, Rigidity and Disorder all are Features that Relate to Function

In crystal structures of proteins, the uncertainty of atomic positions can be represented by B-factors (Debye–Waller factors) [32]. B-factors represent the combined effects of thermal variation and static disorder. In general, the higher the B-factor of a residue, the higher is its flexibility. Further, it has been demonstrated that many proteins and protein regions lack a unique 3-D structure [180]. Those regions are often characterized as an ensemble of rapidly changing alternative structures with differing backbone torsion angles. Estimates indicate that a substantial fraction of all proteins (as much as 25%) may contain disordered regions or be entirely disordered [43, 102, 148, 182]. Many important functional interactions, such as cell-cycle regulation, signal transduction, gene expression and chaperon action, are associated with proteins containing very flexible and disordered regions. Determination of these regions also plays an important role in structural genomics, since such regions can be a source of problems in protein expression, purification and crystallization.

6.2 Measuring Flexibility and Disorder

Protein flexibility can be derived from normalized B-factors [23]. Characterization of disordered regions can be provided by many experimental techniques, but in particular by NMR spectroscopy. Regions of protein X-ray structures without atomic coordinates are often considered as intrinsically disordered regions. Successful predictions should be able to simply indicate intrinsically disordered regions, or in case of protein flexibility to assign accurate normalized B-factors to protein residues.

6.3 Prediction Methods

Methods predicting regions of low compositional complexity in protein sequences (SEG [185] and CAST [135]) can be considered as the first methods predicting disordered regions in proteins. However, the correlation between low-complexity regions and disorder is far from perfect. The low-complexity regions are highly repetitive in their amino acid composition but many of them have well defined 3-D structures [167]. There are methods that attempt to predict if entire proteins are in "natively unfolded" configurations based on hydrophobicity and charge information derived from sequences [178]. The disordered regions can be predicted based on disorder propensity assigned to each amino acid [95]. Other methods use machine learning algorithms such as neural networks [75, 95, 147] or SVMs [182]. The NORSp method [99] predicts extended nonregular secondary structure segments that often correlate with disorder. Predictions of B-factors were also carried out by methods using artificial neural networks [168] or support vector regression [186]. The prediction accuracy of those methods was not experimentally verified on the large scale yet.

7 Protein Domains

7.1 Independent Folding Units

The visual inspection of 3-D structures of large proteins often reveals compact structural subunits referred to as protein domains. Such domains are assumed to often constitute units that fold independently. Studies indicate that some of those proteins can be viewed as combinatorial arrangements of protein domains that are genetically mobile. Often, the structural domains are associated with particular biological functions. It is postulated that domains are independent folding units of large proteins. Knowledge of the domain organization of proteins of unknown 3-D structures can help experimental and computational attempts to elucidate their structure and function. Recent analyses of sequence-structure families suggest that over two-thirds of all proteins have more than one domain and that most domains span over about 100 residues [96].

7.2 Prediction Methods

The prediction of the domain organization is a challenging problem if we do not know the 3-D structure (and automatic assignment methods disagree much more than secondary structure assignment methods even if we know the structure). Many sequence-based methods predict domains that are significantly shorter than actual structural domains [98]. The first automatic prediction methods, such as ProDom [31], attempted to determine domains based on “boundaries” in multiple alignments of protein sequences. This approach often results in fragmentation of actual structural domains since sequence similarity conservation often does not extend over entire domains.

In a similar approach, domain constraints can also be obtained from sequence alignment databases such as BLOCKS [64]. Attempts to explicitly elongate sequence alignments were also made [54]. Other automatic prediction methods apply concepts from protein structure prediction [55] or try do derive domains from predicted contact maps [145]. There are methods that use statistics of domain size distributions [183] or a statistical approach toward combining various sources of information [89]. Some of the methods use artificial neural networks [112,114]. Others explore alternative ways of using sequence alignment information [105] or alignments of predicted secondary structure elements [106]. The most accurate methods (e.g. CHOP [96]) simply use sequence homology to proteins with known domain assignments. The downside of such methods is the low coverage, i.e. that they often do not find domains. None of these more recent methods has yet been experimentally verified on large scale.

7.3 Servers

CHOP (homology based) [96], CHOPnet [100], ProDom (homology based) [31], DOMAINATION [54], SnapDRAGON [55], DomSSEA [106].

Acknowledgments

We are grateful to Kaz Wrzeszczynski, Marco Punta and Avner Schlessinger (all from Columbia University) for valuable input. Thanks to Volker Eyrich (Schroedinger Inc.) and Ingrid Koh (Columbia) for their help in setting up the EVA server. The work of D. P. and B. R. was supported by the grant RO1-LM07329-01 from the National Library of Medicine. Last, not least, thanks to all those who deposit their experimental data in public databases and to those who maintain these databases.

Homology Modeling in Biology and Medicine

Roland L. Dunbrack, Jr.

1 Introduction

1.1 The Concept of Homology Modeling

To understand basic biological processes such as cell division, cellular communication, metabolism and development, knowledge of the three-dimensional (3-D) structure of the active components is crucial. Proteins form the key players in all of these processes, and the study of their diverse and elegant designs is a mainstay of modern biology. The Protein Databank (PDB) of experimentally determined protein structures [14] now contains nearly 40 000 entries, which can be grouped into about 1500 superfamilies [5]. The fact that proteins that share very little or no sequence similarity can have quite similar structures has led to the hypothesis that there are in fact only a few thousand different superfamilies [46, 84, 233] which have been adapted by a process of duplication, mutation and natural selection to perform all the biological functions that proteins accomplish.

Since it was first recognized that proteins can share similar structures [156], computational methods have been developed to build models of proteins of unknown structure based on related proteins of known structure [24]. Most such modeling efforts, referred to as homology modeling or comparative modeling, follow a basic protocol laid out by Greer [72, 73]: (i) identify a template structure related to the target sequence of unknown structure, and align the target sequence to the template sequence and structure; (ii) for core secondary structures and all well-conserved parts of the alignment, borrow the backbone coordinates of the template according to the sequence alignment of the target and template; (iii) for segments of the target sequence for which coordinates cannot be borrowed from the template because of insertions and deletions in the alignment (usually in loop regions of the protein) or because of missing coordinates in the template, build these segments using some construction method based on our knowledge of the determinants of protein structure; (iv) build side chains determined by the target sequence on to the

Bioinformatics – From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

backbone model built from the template structure and loop construction; (v) refinement of the model from the template backbone and toward the target structure.

The alignment step may involve a number of different strategies, including manual adjustment, even after the template structure or structures have been identified. Steps (iii) and (iv), backbone and side chain modeling, may be coupled, since certain backbone conformations may be unable to accommodate the required side-chains in any low-energy conformation. The refinement step involves moving beyond the aligned part of the backbone fixed in the template position and instead allowing it to adjust to the new sequence. For instance, two helices packed against each other may move apart to accommodate larger side-chains.

An alternative strategy has been developed by Blundell and colleagues, based on averaging a number of template structures, if these exist, rather than using a single structure [18,207,208]. More complex procedures based on reconstructing structures (rather than perturbing a starting structure) by satisfying spatial restraints using distance geometry [78] or molecular dynamics and energy minimization [118,173,174,180] have also been developed.

Many methods have been proposed to perform each of the steps in the homology modeling process. There are also a number of research groups that have developed complete packages that take as input a sequence alignment or even just a sequence and develop a complete model. In this chapter, we describe some of the basic ideas that drive loop and side-chain modeling individually as well as the complete modeling process. This chapter is a revised version of one that was published in 2001 [48]. In this revision, we emphasize those methods for which *usable* programs are currently publicly available. We also discuss more extensively the concept of modeling from the biological unit, including complexes of proteins with other proteins, DNA and ligands. The identification and alignment steps are covered in Chapters 3 and 11.

1.2 How do Homologous Protein Arise?

By definition, homologous proteins arise by evolution from a common ancestor. However, there are several different mechanisms for this and these are illustrated in Figure 1. The first is random mutation of individual nucleotides that change protein sequence, including missense mutations (changing the identity of a single amino acid) as well as insertions and deletions of a number of nucleotides that result in insertion and deletion of amino acids. As a single species diverges into two species, a gene in the parent species will continue to exist in the divergent species and over time will gather mutations that change the protein sequence. In this case, the genes in the different organisms will

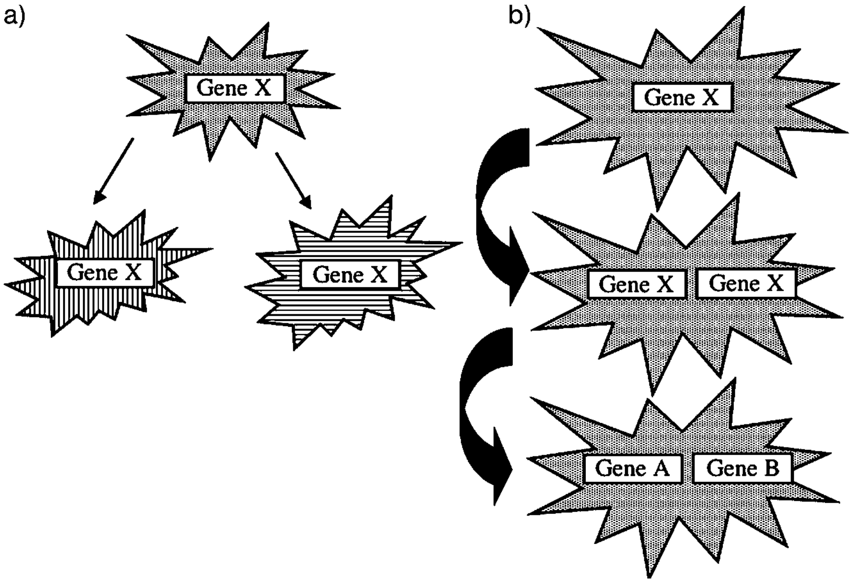

Figure 1 Orthologs versus paralogs. Schematic of the evolutionary process that gives rise to homologous proteins. (a) A single gene X in one species is retained as the species diverges into two separate species. The genes in these two species are *orthologous*. (b) A single gene X in one species is duplicated. As each gene gathers mutations, it may begin to perform new functions, or the two genes may specialize in carrying out two or more functions of the ancestral gene, thus improving the fitness of the organism. These genes in one species are paralogous. If the species diverges, each daughter species may maintain the duplicated genes, and therefore each species contains an ortholog and a paralog to each gene in the other species.

usually maintain the same function. These genes are referred to as orthologs of one another. A second mechanism is duplication of a gene or of a gene segment within a single organism or germ line cell. As time goes by, the two copies of the gene may begin to gather mutations. If the template gene performed more than one function, e.g. similar catalytic activity on two different substrates, one of the duplicated genes may gain specificity for one of the reactions, while the other gene gains specific activity for the other. If this divergence of specificity in the two proteins is advantageous, the duplication will become fixed in the population. These two genes are paralogs of one another. If the species with the pair of paralogs diverges into two species, each species will contain the two paralogs. Each gene in each species will now have an ortholog and a paralog in the other species.

1.3 The Purposes of Homology Modeling

Homology modeling of proteins has been of great value in interpreting the relationships of sequence, structure and function. In particular, orthologous proteins usually show a pattern of conserved residues that can be interpreted in terms of 3-D models of the proteins. Conserved residues often form a contiguous active site or interaction surface of the protein, even if they are distant from each other in the sequence. With a structural model, a multiple alignment of orthologous proteins can be interpreted in terms of the constraints of natural selection and the requirements for protein folding, stability, dynamics and function.

For paralogous proteins, 3-D models can be used to interpret the similarities and differences in the sequences in terms of the related structure, but different functions of the proteins concerned [121]. In many cases, there are significant insertions and deletions and amino acid changes in the active or binding site between paralogs. However, by grouping a set of related proteins into individual families, orthologous within each group, the evolutionary process that changed the function of the ancestral sequences can be observed. Indeed, homology models can serve to help us identify which protein belongs to which functional group by the conservation of important residues in the active or binding site [62]. A number of recent papers have been published that use comparative modeling to predict or establish protein function [95,106,142,222, 225]; see also Chapter 33.

Another important use of homology modeling is to interpret point mutations in protein sequences that arise either by natural processes or by experimental manipulation. The human genome project has produced significant amounts of data concerning polymorphisms and other mutations potentially related to differences in susceptibility, prognosis and treatment of human disease. There are now many such examples, including the Factor V/Leiden R506Q mutation [247] that causes increased occurrence of thrombosis, mutations in cystathionine β-synthase that cause increased levels of homocysteine in the blood, a risk factor for heart disease [101], and BRCA1 for which many sequence differences are known, some of which may lead to breast cancer [34]. At the same time, there are many polymorphisms in important genes that have no discernible effect on those who carry them. At least for some of these, there may be some effect that has yet to be measured in a large enough population of patients and therefore the risk of cancer, heart disease or other illness to these patients is unknown. This is yet another important application of homology modeling, since a good model may indicate readily which mutations pose a likely risk and which do not [92].

Homology models may also be used in computer-aided drug design, especially when a good template structure is available for the target sequence. For enzymes that maintain the same catalytic activity, the active site may be sufficiently conserved such that a model of the protein provides a reasonable target for computer programs which can suggest the most likely compounds that will bind to the active site (see also Chapter 16). This has been used successfully in the early development of HIV protease inhibitors [223, 224] and in the development of anti-malarial compounds that target the cysteine protease of *Plasmodium falciparum* [166].

1.4 The Effect of the Genome Projects

The many genome projects now completed or underway have greatly affected the practice of homology modeling of protein structures. First, the many new sequences have provided a large number of targets for modeling. Second, the large amount of sequence data makes it easier to establish remote sequence relationships between proteins of unknown structure and those of known structure on which a model can be built. The most commonly used methods for establishing sequence relationships such as PSI-BLAST [3] are dependent on aligning many related sequences to compile a pattern or profile of sequence variation and conservation for a sequence family. This profile can be used to search among the sequences in the PDB for a relative of the target sequence (see Chapter 11). The more numerous and more varied sequences there are in the family, the more remote are the homologous relationships that can be determined and the more likely it is that a homologous template for a target sequence can be found. Third, it is likely that the accuracy of sequence alignments between the sequence of unknown structure that we are interested in and the protein sequence of a template are also greatly improved with profiles established from many family members of the target sequence [184]. Fourth, the completion of a number of microbial genomes has prodded a similar effort among structural biologists to determine the structures of representatives of all common protein sequence families, or all proteins in a prototypical genome, such as *Mycobacterium tuberculosis* [15, 126, 163, 210, 241]. Protein structures determined by X-ray crystallography or NMR spectroscopy are being solved at a much faster pace than was possible even 10 years ago. The great increase in the number of solved protein structures has a great impact on the field of homology modeling, since it becomes ever more likely that there will be a template structure in the PDB for any target sequence of interest [221] (see also Chapter 13).

Given the current sequence and structure databases, it is of interest to determine what fraction of sequences might be modeled and the range of sequence identities between target sequences and sequences of known structure. In Figure 2, we show histograms of sequence identities of the sequences in several genomes and their nearest relatives of known structure in the PDB. These relationships were determined with PSI-BLAST as described in the legend. PSI-BLAST is fairly sensitive in determining distant homology relationships [85, 184, 232], although more sensitive techniques exist (see Chapter 11). The results indicate that on average 30–40% of genomic protein sequences are

easily identified as related to proteins of known structure, which presents a large number of potential targets for homology modeling. However, it should also be pointed out that the average sequence identity between target sequences and template structures in the PDB is less than 25%.

The low sequence identity between target and template sequences in Figure 2 presents a major challenge for homology modeling practitioners, since a major determinant in the accuracy of homology modeling is the sequence identity between the target sequence and the sequence of the template structure. At levels below 30% sequence identity, related protein structures diverge significantly and there may be many insertions and deletions in the sequence [31]. At 20% sequence identity, the average RMSD of core backbone atoms is 2.4 Å [31, 169]. However, as demonstrated in Figure 2, it is likely that we will most often face a situation where the target and template sequences are remotely related. Most widely used homology modeling methods have been predicated on much higher sequence identities between template and target, usually well above 30% [43,155,181]. What methods should be used at sequence identities in the 10–30% range is of crucial importance in this post-genomic era.

2 Input Data

To produce a protein model that will be useful and informative requires more than placing a new sequence onto an existing structure. A large amount of sequence data and other kinds of experimental data can often be gathered on the target sequence and on its homolog of known structure to be used for model building. This information can be used to build a better model *and* as the data to be interpreted in light of the model. The goal is to forge an

←

Figure 2 Distribution of sequence identities between protein in four genomes and their closest homologs in the PDB for those sequences in genomes with homologs in the PDB. PSI-BLAST was used to search the nonredundant protein sequence database with a representative set of PDB sequences as queries. The program was run for four iterations, with a maximum E-value of 0.0001 used to determine sequences which are included in the position-specific similarity matrix. After four iterations, each matrix was used to search each of the four genomes. Coiled-coil and low-sequence complexity sequences were removed from each genome and the nonredundant sequence database. All hits in the genomes with E-values less than 0.001 were saved and the histograms were built from the PSI-BLAST-derived sequence identities.

integrated model of the protein sequence, structure, and function, not merely to build a structure. In Table 1, we list the kinds of information that might be available for a target protein and how these data might be processed.

Table 1 Input information for homology model building

Target sequence
• Target orthologous relatives (from PSI-BLAST)
• Target paralogous relatives (from PSI-BLAST)
• Multiple sequence alignment of orthologs and paralogs (either BLAST multiple alignment or (preferably) other multiple alignment program)
• Sequence profile of ortho/paralogs
Template sequences and structures
• Homolog(s) of known structure [template(s)] determined by database search methods (BLAST, PSI-BLAST, intermediate sequence search methods, HMMs, fold recognition methods)
• Template orthologous sequences
• Template paralogous sequences
• Multiple sequence alignment of template orthologs and paralogs
• Biological units of available templates from RCSB and EBI/PQS
Alignment of target sequence to template sequence and structure
• Pairwise alignment
• Profile alignment
• Multiple sequence alignment of target and template sequence relatives
• Profile–profile alignment
• Fold recognition alignment
• Visual examination of proposed alignments and manual adjustment
• Assessment of confidence in alignment by residue (some regions will be more conserved than others)
Structure alignment of multiple templates, if available
• Align by structure (fssp, VAST, CE, etc.)
• Compare sequence alignments from structure to sequence alignments from multiple sequence alignments (see above)
Experimental information
• Mutation data (site directed, random, naturally occurring)
• Functional data, e.g. DNA binding, ligands, metals, catalysis, etc.
• Oligomer data, e.g. analytical ultracentrifugation, native gel electrophoresis

Since proteins act through their interactions with other molecules, it is important to gather information on known or putative ligands or binding partners of the target. Indeed, the target of the modeling may not be a single protein but a protein complex. As the number of structures of multiprotein complexes increases, there are more and more templates for this kind of modeling. Many proteins act as homo-multimers and so it is important to know whether the goal of modeling is a dimer or tetramer or other multimer of the target. While this may not be known for the modeling target itself, it may be known experimentally for homologs of the target through various experiments, including analytical ultracentrifugation, native gel electrophoresis and of course X-ray crystallography (see below in this section). Information on protein–protein interactions of the target, DNA binding, and other ligands such as ions and organic substrates or cofactors is also important and may be included in the modeling.

With the large amount of sequence information available, it is almost always possible to produce a multiple alignment of sequences related to the target protein. The first step in modeling therefore is to use a database search program such as PSI-BLAST [3] against a nonredundant protein sequence database such as NCBI's *nr* database [13] or the curated UniProt database [7]. With some care, a list of relatives to the target sequence can be gathered and aligned. PSI-BLAST provides reasonable multiple alignments, but it may be desirable to take the sequences identified by the database search and realign them with a multiple sequence alignment program such as ClustalW [211] and Muscle [55]. PSI-BLAST tends to create multiple sequence alignments with many gaps, because insertions relative to the query may be placed at slightly different positions (see also Chapter 3).

It may be that a database search consisting of several rounds of PSI-BLAST will provide one or more sequences of known 3-D structure. If this is not the case then more sensitive methods based on fold recognition or hidden Markov models (HMMs) [6, 8, 23, 53, 54, 93] of protein superfamilies may identify a suitable template structure (see Chapter 11). Once a template structure is identified, a sequence database search will provide a list of relatives of the template, analogous to searches for relatives of the target. At this stage it is useful to divide the sequences related to the target into orthologs of either the target or the template (or both). The sequence variation within the set of proteins that are orthologous to the target provides information as to what parts of the sequence are most conserved and therefore likely to be most important in the model. Similarly variation in the set of proteins that are orthologous to the template provide a view of the template protein family that can be used to identify features in common or distinct in the template and target families. These features can be used to evaluate and adjust a joint multiple alignment of both families.

If there are multiple structures in the PDB that are homologous to the target sequence, then it is necessary to evaluate them to determine which PDB entry will provide the best template structure and whether it will be useful to use more than one structure in the modeling process. In the case of a single sequence that occurs in multiple PDB entries, it is usually a matter of selecting the entry with the highest resolution or the most appropriate ligands (DNA, enzyme inhibitors, metal ions). In other cases, there may be more than one homolog related to the target sequence, and the task is to select the one more closely related to the target or to combine information from more than one template structure to build the model. To do this, a structure alignment of the potential templates can be performed with one of a number of available computer programs (Dali [82], CE [194], etc.). From alignments of the target to the available templates, the location of insertions and deletions can be observed, and often it will be clear that one template is better than others. This may not be uniform, however, such that some regions of the target may have no insertions or deletions with respect to one template, but other regions are more easily aligned with the other template. In this case, a hybrid structure may be constructed [207].

As noted above, it may be desirable to build a particular multimer of the target sequence. It is therefore important to gather information on the biological units for the available template structures. The biological unit is defined as the likely oligomeric state of a protein in its relevant biological context. By contrast, the asymmetric unit is the object for which there is independent experimental information in the crystallographic experiment. The asymmetric unit may be a monomer or dimer or higher multimer of the protein or proteins in the crystal. Quite often the biological unit is present within the crystal and may or may not coincide with the asymmetric unit. In some cases it may be made of parts or all of more than one asymmetric unit. In other cases, the asymmetric unit is composed of more than one biological unit.

The possibilities are illustrated in Figure 3, where the asymmetric units from three different crystal structures of hemoglobin are shown. Hemoglobin is a tetramer consisting of two α- and two β-chains. In the first structure, the asymmetric unit consists of an entire tetramer and therefore coincides with the biological unit. The second structure contains only an α–β dimer and therefore the biological unit is constructed with the space group symmetry operators to form a tetramer. In the third case, the biological unit consists of two tetramers and therefore contains two copies of the biological unit.

The probable biological units are obtainable from both the PDB and the European Bioinformatics Institute (EBI) from their Protein Quaternary Server (PQS) [80]. Often these two sources do not agree on the biological unit for a particular PDB entry and they should be interpreted as hypothetical

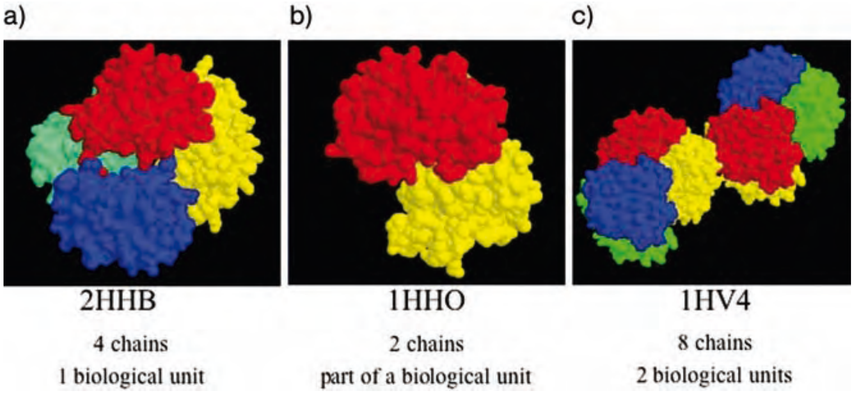

Figure 3 Asymmetric units for hemoglobin from three different structures. The biological unit consists of four chains (two α- and two β-chains). Three scenarios are shown: (a) the asymmetric unit consists of exactly one biological unit, (b) the asymmetric unit is smaller than a biological unit (in this case, it is one half of a biological unit) and (c) the asymmetric unit is larger than the biological unit (in this case, it is two biological units).

oligomers. By comparing the asymmetric units with those from the PDB and the EBI, we found that for over 50% of structures, the asymmetric unit does not correspond to the biological unit for PDB or PQS or both. The PDB and PQS agree 80% of the time on the biological unit (see Section 4.3). It is therefore important to choose a template that has the correct multimer status in its biological unit and to use this biological unit in the modeling process, rather than the asymmetric unit.

Finally, any other experimental data available on the target or template proteins may be very helpful in producing and interpreting a structural model. These can include inhibitor studies, DNA binding and sequence motifs, proteolysis sites, metal binding, mutagenesis data, etc. A number of databases are available on the web that summarize information on particular genes or that collect information on mutations and polymorphisms linked to disease, including: the Cancer Genome Anatomy Project [201], the Online Mendelian Inheritance in Man (OMIM) [76] and the Human Gene Mutation Database [102, 200].

3 Methods

3.1 Modeling at Different Levels of Complexity

Once an alignment is obtained between the target and a protein of known structure (as described in Section 2, and in Chapters 3 and 10), it is possible to build a series of models of increasing sophistication.

(i) *Simple model*: keep backbone and conserved side chains by renaming and renumbering coordinates in the template structure with the new sequence using the alignment of target and template; rebuild other side chains using a side chain modeling program (e.g. SCWRL [22, 30, 47]); do not model insertions or deletions (i.e. do not build new loops and do not close up gaps).

(ii) *Stepwise model*: borrow core backbone from template structure, minus coil regions with insertions or deletions in the sequence alignment; rebuild core side chains; rebuild coil regions with loop prediction method in conjunction with side-chain prediction method. Core backbone and side chains may or may not be held fixed during loop prediction. The entire model may be refined using energy minimization, Monte Carlo or molecular dynamics techniques.

(iii) *Jigsaw model*: borrow backbone from a common core of several structurally aligned templates, using loop regions from different templates according to the alignments, usually keeping those loops for which there is no gap in the alignment with the target sequence. Some loops may need to be modeled.

(iv) *Global model*: build entire protein from spatial restraints drawn from known structure(s) and sequence alignment (e.g. MODELLER [174,180]).

It is not always the case that more sophisticated models are better than simpler, less-complete ones. If elements of secondary structures are allowed to move away from their positions in the template and large changes are made to accommodate insertions and deletions, it may be the case that the model is further away from the target structure (if it were known) than the template structure was to begin with. This is the "added value" problem discussed by John Moult at the Critical Assessment of Protein Structure Prediction (CASP) meetings [138,140,141]. We would like methods that move the template structure closer to the target structure, such that they "add value" to a simple model or unrefined stepwise model based on an unaltered template structure, with side-chains replaced. Extensive energy minimization or molecular dynamics simulations often bring a model further away from the correct structure than toward it [59, 98].

The simple model is sometimes justified when there are no insertions and deletions between the template and target or when these sequence length changes are far from the active site or binding site of the protein to be modeled. This often occurs in orthologous enzymes that are under strong selective pressure to maintain the geometry of the active site. Even in nonorthologous enzymes, sometimes we are most interested in an accurate prediction of the active-site geometry and not in regions of the protein distant from the active site.

A stepwise model is probably the most common method used in homology modeling, since it is conceptually simpler than the more complex models and since each piece can be constructed and examined in turn. Some programs therefore proceed by taking the sequence–structure alignment, removing all regions where there are insertions and deletions, and reconstructing loops and side-chains against the fixed template of the remaining atoms. Some methods may also allow all parts of the template structure to adjust to the changes in sequence and insertions and deletions. This usually takes the form of a Monte Carlo or molecular dynamics simulation [118]. A global model, as described above, rebuilds a structure according to constraints derived from the known template structure or structures. This is in contrast to stepwise models that proceed essentially by replacing parts of the template structure and perhaps perturbing the structure.

Many computer programs for homology modeling are developed to solve a single problem, such as loop or side-chain building, and may not be set up to allow all atoms of the protein to adjust or to model many components simultaneously. In many cases these methods have been tested by using simplified modeling situations. Such examples include experiments with removing and rebuilding loops onto single protein structures, and stripping and rebuilding all side chains. In the next sections we review some of the work in these two areas.

3.2 Side-chain Modeling

3.2.1 Input Information

Side-chain modeling is a crucial step in predicting protein structure by homology, since side-chain identities and conformations determine the specificity differences in enzyme active sites and protein binding sites. The problem has been described as "solved" [117], although new methods [120, 133, 157, 193, 234] or improvements on older ones [30] continue to be published. Some side-chain prediction methods stand on their own and are meant to be used with a fixed backbone conformation and sequence to be modeled given as input. Other methods have been developed in the context of general homology modeling methods, including the prediction of insertion-deletion regions. Even when using general modeling procedures, such as MODELLER, it may be worthwhile subsequently to apply a side-chain modeling step with other programs optimized for this purpose [220]. This is especially the case when side-chain conformations may be of great importance to interpretation of the model. It is also often the case that insertion-deletion regions are far away from the site of interest and loop modeling may be dispensed with. Indeed, significant alterations of the backbone of the template, if they are not closer to the target to be modeled (if it were known) than the template, may in fact result in poorer side-chain modeling than if no loop modeling were performed. As described above, the choice of template may depend not only on sequence identity but also on the absence of insertions and deletions near the site of interest. If this is successful, side-chain modeling rises in importance in relation to loop prediction.

Side-chain prediction methods described in detail in the literature have a long history although only a small number of programs are currently publicly available (see Table 2). Nearly all assume a fixed backbone, which may be from a homologous protein of the structure to be modeled, or may be the actual X-ray backbone coordinates of the protein to be modeled. Many methods have in fact only been tested by replacing side-chains onto backbones taken from the actual 3-D coordinates of the proteins being modeled ("self-backbone predictions"). Nevertheless, these methods can be used for homology modeling by first substituting the target sequence onto the template backbone and then modeling the side chains. When a protein is modeled from a known structure, information on the conformation of some side chains may be taken from the template [22, 30, 204]. This is most frequently the case when the template and target residue are identical, in which case the template residue's Cartesian coordinates may be used. These may be kept fixed as the other side chains are placed and optimized or they may be used only as a starting conformation and optimized with all other side chains. Only a small number of methods use information about nonidentical side chains borrowed from the template. For instance, Phe ↔ Tyr substitutions only require the building or removal of a hydroxyl group while Asn ↔ Asp substitutions require changing one of δ-atoms from NH_2 to O or vice versa. Summers and Karplus [203, 204] used a more detailed substitution scheme, by which for instance the χ_1 angle of very different side-chain types (e.g. Lys ↔ Phe) might be used in building side chains. In the long run, this is probably not advantageous, since the conformational preferences of nonsimilar side-chain types may be quite different from each other [50].

3.2.2 Rotamers and Rotamer Libraries

Nearly all side-chain prediction methods depend on the concept of side-chain *rotamers* (reviewed in Ref. [49]). From conformational analysis of organic molecules, it was predicted long ago [182,183] that protein side chains should attain a limited number of conformations because of steric and dihedral strain within each side chain, and between the side chain and the backbone. Dihedral strain occurs because of Pauli exclusion between bonding molecular orbitals in eclipsed positions [94]. For sp^3–sp^3 hybridized bonds, the energy minima for the dihedral are at the staggered positions that minimize dihedral strain at approximately 60°, 180°, and –60°. For sp^3–sp^2 bonds, the minima are usually narrowly distributed around +90° or –90° for aromatics and widely distributed around 0° or 180° for carboxylates and amides (e.g. Asn/Asp χ_2 and Glu/Gln χ_3).

As crystal structures of proteins have been solved in increasing numbers, a variety of rotamer libraries have been compiled with increasing amounts of detail and greater statistical soundness, i.e. with more structures at higher resolution [12,17,50–52,88,125,132,161,187,212]. The earliest rotamer libraries were based on a small number of structures [12, 17, 88, 161]. Even the widely used Ponder and Richards library was based on only 19 structures, including only 16 methionines [161]. The most recent libraries are based on over 850 structures with resolution of 1.7 Å or better and mutual sequence identity less than 50% between any two chains used.

Most rotamer libraries are backbone-conformation-independent. In these libraries, the dihedral angles for side chains are averaged over all side chains of a given type and rotamer class, regardless of the local backbone conformation or secondary structure. The most recent of these is by Lovell and coworkers [125], who derived a more accurate backbone-independent rotamer library by eliminating side chains of low stereochemical quality, including those with high B-factors, steric conflicts in the presence of predicted hydrogen atom locations, and other factors. The statistical analysis does not rely on a parametric distribution function such as the normal model, and hence can model factors like skew in an unbiased way.

Several libraries have been proposed that are dependent on the conformation of the local backbone [50–52,132,187]. McGregor and coworkers [132] and Schrauber and coworkers [187] compiled rotamer probabilities and dihedral angle averages in different secondary structures We have used Bayesian statistical methods to compile a backbone-dependent rotamer library with rotamer probabilities and average angles and standard deviations at all values of the backbone dihedral angles ϕ and ψ in 10° increments [49–52]. The current version of this library is based on 850 chains with resolution better than 1.7 Å and less than 50% mutual sequence identity.

Finally, there is an alternative form of a rotamer library that includes large numbers of conformations of each side-chain type in the form of Cartesian coordinates. These libraries therefore include variation in bond lengths and bond angles, as well as dihedral angles. They are generally used for fine sampling of side-chain positions in the context of side-chain prediction. For instance, Xiang and Honig [234] produced a library consisting of 7560 conformations for use in their side-chain prediction method from a set of 297 high-resolution structures. The variation in bond angles and dihedrals away from average values is particularly useful for larger side chains for which a small change in an angle near the base of the side chain may cause large motions of atoms at the far end of the side chain. Other groups have also used large rotamer libraries to introduce flexibility about mean dihedral angles of rotamers as well as variation in bond lengths and bond angles [157, 193].

3.2.3 Side-chain Prediction Methods

Side-chain prediction methods can be classified in terms of how they treat side-chain dihedral angles (rotamer library, grid or continuous dihedral angle distribution), bond lengths and bond angles (fixed, variable, sampled from Cartesian conformers), potential energy function used to evaluate proposed conformations, and search strategy.

The potential energy functions in side-chain prediction methods have varied tremendously from simple steric exclusion terms to full molecular mechanics potentials. In most cases, the potential energy function is a standard Lennard–Jones potential:

$$E(r) = 4\varepsilon \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} \right] . \tag{1}$$

In this equation, r is the distance between two nonbonded atoms, and ε and σ are parameters that determine the shape of the potential. This potential has a minimum at the distance $r = 2^{1/6}\sigma$ and a well depth of ε. Different values of σ and ε may be chosen for different pairs of atom types. Some potential energy functions for side chains may also include a hydrogen bond term. Depending on the potential parameters, these potentials may not accurately model the relative energies of rotamers for each side-chain type that are determined from local interactions within each side chain and between the side chain and the local backbone. For instance, in molecular mechanics potentials, interactions between atoms connected by three covalent bonds (atoms i and $i + 3$ in a chain) are not usually treated by van der Waals terms, but rather in torsion terms of the form [127]:

$$E(\tau) = \sum_m K_m \cos(m\tau + a_m) \tag{2}$$

where the sum over m may include 1-, 2-, 3-, 4- and 6-fold cosine terms. The K_m and a_m are constants specific for each dihedral angle and each term in the sum. These torsion terms are included in some side-chain prediction methods, but ignored in others [96].

Electrostatic interactions in the form of a Coulomb potential have been included in methods that rely on full molecular mechanics potentials, usually with a distance-dependent dielectric, $\varepsilon(r) = r$:

$$E = \frac{q_i q_j}{\varepsilon(r) r} \tag{3}$$

Solvent interactions are also usually ignored, since these can be difficult or expensive to model properly (for exceptions, see [120,185,228]).

A number of side-chain methods use an energy term based on the probability of rotamers as a function of backbone conformation. These probabilities are given in the backbone-dependent rotamer library, and the energy function is usually of the form:

$$E_i = -K \ln \left(\frac{p_i(\phi, \psi, R)}{p_{\max}(\phi, \psi, R)} \right) \tag{4}$$

where the energy of rotamer i is expressed as a function of the probability of this rotamer given the backbone dihedrals ϕ and ψ and the residue type R, and the probability of the most common rotamer for the same backbone dihedrals and residue type. The constant K is empirical and can be optimized given the other terms in the energy function.

Side-chain conformation prediction incurs the risk of combinatorial explosion, since there are on the order of n_{rot}^N possible conformations, where n_{rot} is the average number of rotamers per side chain and N is the number of side chains. However, in fact, the space of conformations is much smaller than that, since side chains can only interact with a small number of neighbors, and in most cases clusters of interacting side chains can be isolated and each cluster can be solved separately [22, 212]. Also, many rotamers have prohibitively large interactions with the backbone and are at the outset unlikely to be part of the final predicted conformation. These can be eliminated from the search early on.

Many standard search methods have been used in side-chain conformation prediction, including Monte Carlo simulation [83,109,116,120,137,167], simulated annealing [86], self-consistent mean field calculations [96,133,134], the dead-end elimination (DEE) method [40–42,70,107,123,159], neural networks [99] and graph theory [30,111,236].

Self-consistent mean field calculations represent each side chain as a set of conformations, each with its own probability. Each rotamer of each side chain has a certain probability, $p(r_i)$. The total energy is a weighted sum of the interactions with the backbone and interactions of side chains with each other:

$$E_{\text{tot}} = \sum_{i=1}^{N} \sum_{r_i=1}^{n_{\text{rot}}(i)} p(r_i) E_{bb}(r_i) + \sum_{i=1}^{N-1} \sum_{r_i=1}^{n_{\text{rot}}(i)} \sum_{j=i+1}^{N} \sum_{r_j=1}^{n_{\text{rot}}(j)} p(r_i) p(r_j) E_{\text{sc}}(r_i, r_j) \tag{5}$$

In this equation, $p(r_i)$ is the density or probability of rotamer r_i of residue i, $E_{bb}(r_i)$ is the energy of interaction of this rotamer with the backbone, and $E_{\text{sc}}(r_i,r_j)$ is the interaction energy (van der Waals, electrostatic) of rotamer r_i of residue i with rotamer r_j of residue j. Some initial probabilities are chosen for the ps in Eq. (5) and the energies calculated. New probabilities $p\prime(r_i)$ can then be calculated with a Boltzmann distribution based on the energies of each side chain and the probabilities of the previous step:

$$\begin{aligned} E(r_i) &= E_{bb}(r_i) + \sum_{j=1, j\neq i}^{N} \sum_{r_j=1}^{n_{\text{rot}}(j)} p(r_j) E_{\text{sc}}(r_i, r_j) \\ p'(r_i) &= \frac{\exp(-E(r_i)/kT)}{\sum_{r_i=1}^{n_{\text{rot}}(i)} \exp(-E(r_i)/kT)} \end{aligned} \tag{6}$$

Alternating steps of new energies and new probabilities can be calculated from the expressions in Eq. (6) until the changes in probabilities and energies in each step become smaller than some tolerance.

The DEE algorithm is a method for pruning the number of rotamers used in a combinatorial search by removing rotamers that cannot be part of the global minimum energy conformation [41, 42, 70, 107, 108, 123]. This method can be used for any search problem that can be expressed as a sum of single-residue terms and pairwise interactions. Goldstein's improvement on the original DEE can be expressed as follows [70]. If the total energy for all side chains is expressed as the sum of singlet and pairwise energies:

$$E = \sum_{i=1}^{N} E_{bb}(r_i) + \sum_{i=1}^{N-1} \sum_{j>i}^{N} E_{\text{sc}}(r_i, r_j) \tag{7}$$

then a rotamer r_i can be eliminated from the search if there is another rotamer s_i for the same side chain that satisfied the following equation:

$$E_{bb}(r_i) - E_{bb}(s_i) + \sum_{j=1, j\neq i}^{N} \min_{r_j} \left\{ E_{\text{sc}}(r_i, r_j) - E_{\text{sc}}(s_i, r_j) \right\} > 0 \tag{8}$$

In words, rotamer r_i of residue i can be eliminated from the search if another rotamer of residue i, s_i, always has a lower interaction energy with all other side chains regardless of which rotamer is chosen for the other side chains. More powerful versions have been developed that eliminate certain pairs of rotamers from the search [42,70,123]. DEE-based methods have also proved very useful in protein design, where there is variation of residue type as well as conformation at each position of the protein [37,71,218].

The current SCWRL algorithm [30] uses graph theory to solve the combinatorial problem. In this method, each side chain in the protein is considered a node in an undirected graph. An edge exists between two nodes *i* and *j* if at least one rotamer of residue *i* and one rotamer of residue *j* interact with each other, i.e. have a nonzero interaction energy. This produces a number of separate graphs that are not connected to each other. Each of these graphs can then be solved for the minimum energy conformation of the residues in the graph. To accomplish this, each separate graph is broken up into its biconnected components, as shown in Figure 4(a). Biconnected components are cycles or nested cycles or bridges consisting of two nodes connected by an edge. Two biconnected components share a node called an articulation point, which when removed from the graph breaks the graph into two (or more) connected subgraphs. The global minimum of the energy can be found by beginning on the outside of the graph with biconnected components that have only one articulation point. For each rotamer of the articulation point, the minimum energy of the other rotamers is found and stored with the rotamer of the articulation point. Then the biconnected graph is "collapsed" onto the articulation point residue. This residue now contains information on all the residues in the biconnected component. The procedure continues to collapse biconnected components, until a single component is left, as shown in Figure 4.

Recently, two papers [111,236] have appeared that extend the graph theory algorithm further so that the smallest groups that need to be searched are much smaller than biconnected components. In this method, some nodes can be removed from the graph by collapsing a node or nodes onto an *edge*. This is shown in Figure 4(b), in which a single node that has two neighbors in the graph is collapsed onto an edge between the two neighbors. The new energy of each rotamer pair for residues *i* and *j* is now:

$$E_{\text{pair}}^{\text{new}}(r_i, r_j) = E_{\text{pair}}^{\text{old}}(r_i, r_j) + \min_{r_k} \left\{ E_{\text{self}}(r_k) + E_{\text{pair}}(r_i, r_k) + E_{\text{pair}}(r_j, r_k) \right\} \quad (9)$$

The size of the smallest group that must be solved combinatorially is called the tree width and is related to the size of the largest group of side chains that are all mutually connected to each other.

In most methods, the search is over a well-defined set of rotamers for each residue. As described above, these represent local minima on the side-chain conformational potential energy map. In several methods, however, nonrotamer positions are sampled. Summers and Karplus used CHARMM to calculate potential energy maps for side chains based on 10° grids [203,204]. Dunbrack and Karplus used CHARMM to minimize the energy of rotamers

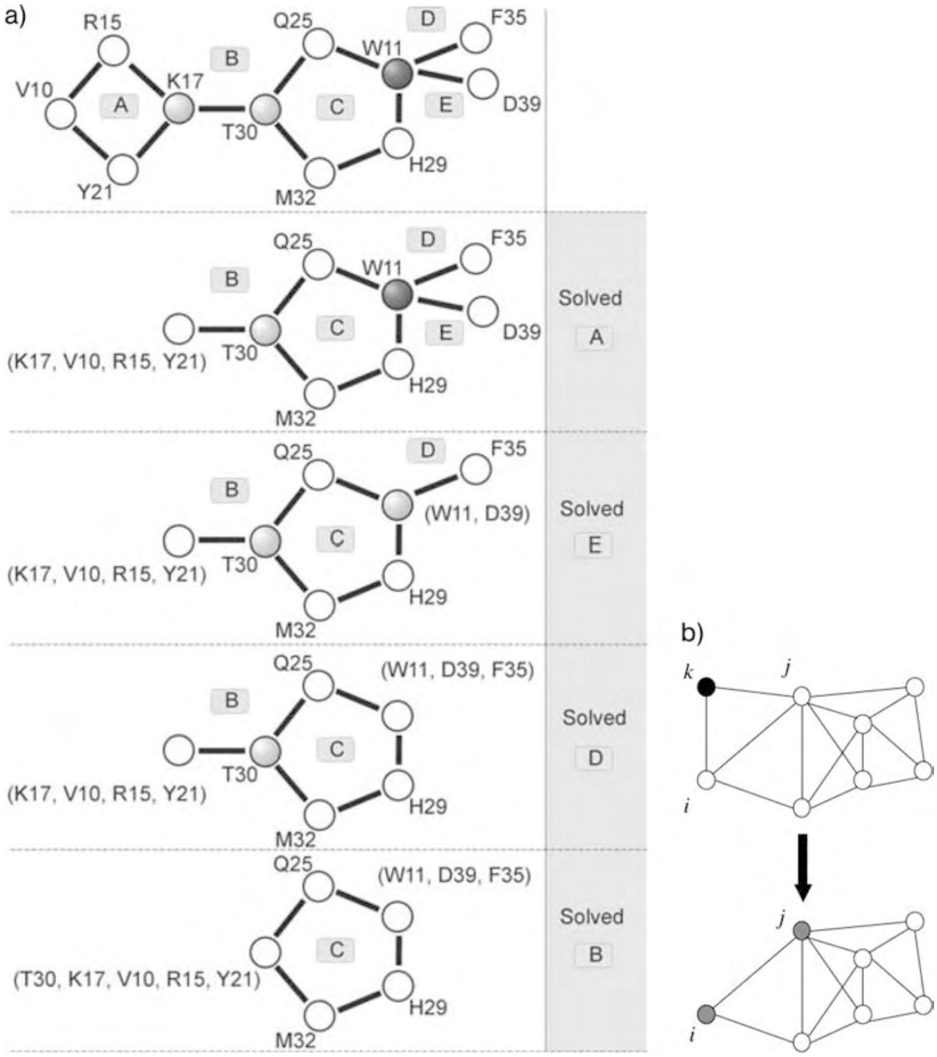

Figure 4 (a) Graph algorithm used in SCWRL3.0, solving a cluster using biconnected components. The minimum energy configuration of the cluster shown in Figure 1 is identified by stepwise solution of biconnected components. Each biconnected component is solved as shown in the right margin and the collapsed component is shown as superresidues in curly brackets. (b) Collapsing a node onto an edge.

from canonical starting conformations (–60°, 180° and +60°) [51]. Vasquez also used energy minimization [213], while Lee and Subbiah used a search over 10° increments in dihedral angles with a simple van der Waals term and a 3-fold alkane potential on side-chain dihedrals [112]. Mendes and coworkers [133, 134] used a mean-field method to sample from Gaussian distributions about the conformations in the rotamer library of Tuffery and coworkers [212].

3.2.4 Available Programs for Side-chain Prediction

While many methods for side-chain prediction have been presented over the years, only a small number of programs are publicly available at this time. Information on obtaining these programs is given in Table 2. We define "available" as either being downloadable (in source or executable form or both) from the Internet or able to be run from a webserver. Some authors will also provide their programs on request, but these programs do not generally have documentation nor are they designed for general use. They are not listed in Table 2.

3.3 Loop Modeling

3.3.1 Input Information

In stepwise construction methods, backbone segments that differ in length between the template and target (according to the sequence alignment) need to be rebuilt. In some situations, even when the sequence length of a coil segment is maintained, it may be necessary to consider alternative conformations to accommodate larger side chains or residues with differing backbone conformational requirements, Gly ↔ non-Gly or Pro ↔ non-Pro mutations. Most such loop construction methods have been tested only on native structures from which the loop to be built has been removed. However, the reality in homology modeling is more complicated, requiring several choices to be made in building the complete structure. These include how much of the template structure to remove before loop building, whether to model all side chains of the core before rebuilding the loops, and whether to rebuild multiple loops simultaneously or serially.

Deciding how much of the template structure to remove before loop building depends on examination of the sequence alignment and the template structure [114, 230]. Sequence alignments with insertions and deletions are usually not unambiguous. Most sequence alignment methods ignorant of structure will not juxtapose a gap in one sequence immediately adjacent to a gap in another sequence, i.e. they will produce an alignment that looks like this alignment:

```
AGVEPMENYKLS
SG---LDDFKLT
```

rather than like this one:

```
AGVEPMEN---YKLS
SGL-----LDDFKLT
```

However, the latter alignment is probably more realistic [1], indicating that a five-amino-acid loop in the first sequence and structure is to be replaced with a three-amino-acid loop in the second sequence. The customary practice is to remove the whole segment between two conserved secondary structures units. Even with this practice, ambiguity remains, since the ends of secondary structures, especially α-helices, are not well determined. If loop-building methods were accurate, then removing more of the segment would be a good idea. However, long loops (longer than seven amino acids) are difficult to rebuild accurately and hence there is cause to preserve as much of the starting structure as possible. Once the backbone has been borrowed from the template in stepwise modeling, one has to decide the order of building the core side chains, the backbone of loops to be built and their side chains. They may be built sequentially or allowed to vary simultaneously. Side chains from the core may guide the building of the loop, but at the same time may hinder correct placement. It is certainly the case that in the final structure there must be a reasonably low-energy conformation that can accommodate all loops and side chains simultaneously. Different authors have made different choices, and there has been little attempt to vary the procedure while keeping the search algorithm and potential energy function used fixed.

3.3.2 Loop Conformational Analysis

Loop structure prediction is always based in one way or another on an understanding of loop conformations in experimentally determined structures. Loop conformational analysis has been performed on a number of levels, ranging from classification of loops into a number of distinct types to statistical analysis of backbone dihedral angles. Loop classification schemes have usually been restricted to loops of a particular size range: short loops of one to four residues, medium loops of five to eight residues and long loops of nine residues or longer.

Thornton and coworkers have classified β-turns, which are short loops of two to five residues that connect two antiparallel β-sheet strands [195, 196, 226, 227]. These loops occur in a limited number of conformations that depend on the sequence of the loop, especially on the presence of glycine and proline residues at specific positions. The backbone conformation can be characterized by the conformations of each amino acid in terms of regions of the Ramachandran map occupied (usually defined as α_R, β_P, β_E, γ_R, α_L and γ_L) [227]. Usually one or more positions in the loops require an α_L conformation and therefore a glycine, asparagine or aspartic acid residue. One useful aspect of this analysis is that if a residue varies at certain positions or there are short insertions at certain positions, the effect on the loop can be predicted [196] since the number of possibilities for each length class is small. The programs BTPRED [192] and BHAIRPRED [103] are available (see Table 3) to predict the locations of specific types of β-turns from protein sequences and secondary structure predictions. Single-amino-acid changes tend to maintain the loop conformations, except when Pro residues substitute for residues with $\phi > 0^\circ$, while insertions change the class of the loop.

In recent years with a larger number of structures available, medium-length loops have also been classified [38,44,56,69,104,115,135,147,149,150,229] by their patterns of backbone conformation residue by residue (α_R, β_P, etc.). A number of regularly occurring classes have been found, depending on length, type of secondary structure being connected and sequence. These classes cover many but by no means all of the loops seen in non-β turn contexts.

Longer loops (with more than eight amino acids) have been investigated by Martin and coworkers [131] and Ring and coworkers [165]. Martin and coworkers found that long loops fall into two classes: those that connect spatially adjacent secondary structures and those that connect secondary structures separated by some distance. Ring and coworkers provided a useful classification of longer loops as either strap (long extended loops), Ω loops (similar to those described by Leszczynski [115] and Pal and coworkers [150]), which resemble the Greek letter, and ζ loops, which are nonplanar and have a zigzag appearance. The different loop types were found to have different distributions of virtual C_α–C_α–C_α–C_α dihedrals to accommodate their shapes.

A number of groups have updated the Ramachandran propensities of the 20 amino acids. Swindells and coworkers [209] have calculated the intrinsic ϕ,ψ propensities of the 20 amino acids from the coil regions of 85 protein structures. The distribution for coil regions is quite different than for the regular secondary structure regions, with a large increase in β_P and α_L conformations, and much more diverse conformations in the β_E and α_R regions. Their results also indicate that the 18 non-Gly,Pro amino acid type are in fact quite different from each other in terms of their Ramachandran distributions, despite the fact that they are often treated as identically distributed in prediction methods [25, 57]. Their analysis was divided into the main broad regions of the Ramachandran map, ignoring the α_L region. The results are intriguing, in that the probability distributions are distinct enough even when calculated from a relatively small protein dataset. More recently Lovell and coworkers [124] and Anderson and coworkers [4] have produced new Ramachandran maps based on stricter criteria for inclusion of amino acids based on resolution, R-factors and B-factors, as well as data smoothing techniques that remove outliers and unpopulated parts of the Ramachandran map. Their results indicate that a stricter adherence to “allowed” regions is called for, since nearly all residues in disallowed regions are based on poor electron density.

3.3.3 **Loop Prediction Methods**

Loop prediction methods can be analyzed for a number of important factors in determining their usefulness: (i) method of backbone construction, (ii) what range of lengths are possible, (iii) how widely is the conformational space searched, (iv) how are side chains added, (v) how are the conformations scored (i.e., the potential energy function) and (vi) how much has the method been tested (length, number, self/nonself).

The most common approach to loop modeling involves using “spare parts” from other (unrelated) protein structures [10, 32, 60, 61, 63, 72, 81, 91, 96, 114, 135, 165, 168, 172, 205, 207, 217, 230, 231]. These database methods begin by measuring the orientation and separation of the backbone segments flanking the region to be modeled, and then search the PDB for segments of the same length that span a region of similar size and orientation. This work was pioneered by Jones and Thirup [91]. They defined a procedure in which C_α–C_α distances were measured among six residues, three on either side of a backbone segment to be constructed. These 15 C_α–C_α distances were used to search structures in the PDB for segments with similar C_α–C_α distances and the appropriate number of intervening residues. Other authors have used the same method for locating potential database candidates for the loop to be constructed [60, 96, 205, 217]. The fragment selection method used in Rosetta *ab initio* modeling [197] is based at least in part on the database approach to loop modeling, and is used in Rosetta for loop construction in homology modeling [167]. In recent years, as the size of the PDB has increased, database methods have continued to attract attention. With a larger database, recurring structural motifs have been classified for loop structures [44, 56, 104, 113, 135, 147, 172], including their sequence dependence.

Although many methods have been published, they have usually only been tested on a small number of loops, and then usually in the context of rebuilding loops onto their own backbones, rather than in the process of homology modeling. A recent exception is that of Fernandez-Fuentes and coworkers [61] who tested the ArchDB database [56] of loops as a predictive tool. They used a “jackknife” test that removed all loops from the same superfamily for each loop in a set of over 10 000 used to construct ArchDB.

The main alternative to database methods is *ab initio* construction of loops by random or exhaustive search mechanisms. These methods are quite varied in their generation and subsequent modification of loop structures to fit the environment of the fitted segment. The initial conformation may be random, starting from the N- or C-terminal anchor, so that the other end of the loop does not connect to the other anchor (the C- or N-terminal anchor, respectively). Such loops can then be closed using energy minimization that places some energetic constraints on a closed loop, or using loop closure methods, such as those based on inverse kinematics in robotics [19, 28, 35]. Other methods have built chains by sampling Ramachandran conformations randomly, keeping partial segments as long as they can complete the loop with the remaining residues to be built [64, 191, 198].

An alternative approach to the loop generation problem is to use a geometrically distorted loop that bridges the two anchors exactly and then to relax the structure into an undistorted protein-like structure. MODELLER starts loop modeling with a linear arrangement of the atoms in the loop, which is then relaxed into a protein-like conformation using energy minimization [65]. Zheng and coworkers used a scaling-relaxation method in which an initially generated or database loop is scaled in size until it fits the anchors [244–246]. This results in very short bond distances and unphysical connections to the anchors. From there, energy minimization is performed on the loop, slowly relaxing the scaling constant, until the loop is scaled back to full size.

One important aspect in the development of a prediction method based on random (or exhaustive) construction of backbone conformations is the free energy function used to discriminate among those conformations that successfully bridge the anchors. Fogolari and Tosatto have found that a free energy function including a molecular mechanics potential energy and a Poisson–Boltzmann solvent-accessible surface area solvation term was able to identify decoys from a large set that were close to the native structure [66]. Jacobson and coworkers recently used the OPLS (optimized potential for liquid simulations) molecular mechanics force field, with improved torsional energy parameters optimized to reproduce quantum-mechanical data and side-chain prediction [87], in combination with a surface-generalized Born/nonpolar (SGB/NP) hydration free energy model [68]. Their search method generated one residue at a time from a 5° resolution backbone model with steric and side-chain checks, from both ends of the loop, followed by clustering and energy minimizations of cluster representatives. Their method was tested on a large set of 833 loops with excellent results for loops up to 12 residues in length.

3.3.4 **Available Programs**

Very few loop modeling programs *per se* are publicly available, although loop modeling is integral to more complete modeling programs. A list of available loop modeling programs is given in Table 3. Some programs that do complete modeling but can be used for loop modeling without further refinement are listed (e.g. MODELLER).

3.4 Methods for Complete Modeling

Homology modeling is a complex process. Automated protocols that begin with a sequence and produce a complete model are few, and the resulting models should be examined with great care (as of course should all models). However, these methods usually allow for (and indeed recommend) some manual intervention in the choice of template structure or structures and in the sequence alignment. In these steps, manual intervention is likely to have important consequences. Later stages of modeling (actual building of the structure) are more easily automated and there are not usually obvious manual adjustments to make.

There are several publicly available programs available for homology modeling that are intended to make complete models from input sequences. These include MODELLER [174, 175, 180, 181], RAMP [176–178] and MolIDE [29]. There are also several webservers that provide homology modeling services, including SWISS-MODEL [74, 153, 154], Esypred [105] and 3D-JIGSAW [11]. Program availability is given in Table 4. Some of these programs provide only BLAST/PSI-BLAST searching followed by model-building with MODELLER (e.g. EsyPRED). We describe some of these programs.

3.4.1 MODELLER

MODELLER takes as input a protein sequence and a sequence alignment to the sequence(s) of known structure(s), and produces a comparative model. The program uses the input structure(s) to construct constraints on atomic distances, dihedral angles, etc., that when combined with statistical distributions derived from many homologous structure pairs in the PDB form a conditional probability distribution function for the degrees of freedom of the protein.

For instance, a probability function for the backbone dihedrals of a particular residue to be built in the model can be derived by combining information in the known structure (given the alignment) and information about the amino acid type's Ramachandran distribution in the PDB. The number of constraints is very large; for a protein of 100 residues there may be as many as 20 000 constraints. The constraints are combined with the CHARMM force field to form a function to be optimized. This function is optimized using conjugate gradient minimization and molecular dynamics with simulated annealing.

3.4.2 **MolIDE: A Graphical User Interface for Modeling**

MolIDE (Molecular Interactive Design Environment) is an open-source, extensible graphical user interface for homology modeling [29]. MolIDE provides a graphical interface for running sequence database searches with PSI-BLAST, searches of the PDB, secondary structure prediction, manual alignment editing, and running loop and side-chain prediction programs. One of MolIDE's main benefits is allowing a user to edit a sequence–structure alignment and to view the positions of insertions and deletions within the template structure in real time. MolIDE also allows manual choice of anchor residues for loop modeling with the assistance of a graphical view of the template protein structure. MolIDE runs on the Windows and Linux operating systems. The use of MolIDE will be illustrated in the next section with an example of comparative modeling of a protein of biological interest.

3.4.3 **RAMP and PROTINFO**

Samudrala and Moult described a method for "handling context sensitivity" of protein structure prediction, i.e. simultaneous loop and side-chain modeling, using a graph theory method [178, 179] and an all-atom distance-dependent statistical potential energy function [176]. These methods are also implemented in the PROTINFO webserver listed in Table 4.

3.4.4 **SWISS-MODEL**

SWISS-MODEL is intended to be a complete modeling procedure accessible via a web server that accepts the sequence to be modeled and then delivers the model by electronic mail [74, 154]. In contrast to MODELLER, SWISS-MODEL follows the standard protocol of homolog identification, sequence alignment, determining the core backbone, and modeling loops and side chains. SWISS-MODEL will search a sequence database of proteins in the PDB with BLAST, and will attempt to build a model for any PDB hits with p-values less than 10^{-5} and at least 30% sequence identity to the target. SWISS-MODEL allows for user intervention by specifying the template(s) and alignments to be used.

If more than one structure is found, the structures will be superimposed on the template structure closest in sequence identity to the target.

SWISS-MODEL determines the core backbone from the alignment of the target sequence to the template sequence(s) by averaging the structures according to their local degree of sequence identity with the target sequence. The program builds new segments of backbone for loop regions by a database scan of the PDB using anchors of four C_α atoms on each end. This method is used to build only the C_α atoms and the backbone is completed with a search of pentapeptide segments in the PDB that fit the C_α trace of the loop. Side chains are now built for those residues without information in the template structure by using the most common (backbone-independent) rotamer for that residue type. If a side chain can not be placed without steric overlaps, another rotamer is used. Some additional refinement is performed with energy minimization with the GROMOS [75] program.

4 Results

4.1 Range of Targets

A very large number of homology models have been built over the years by many authors. Recent targets have included proteins of significant interest in biology and medicine 10- [2, 9, 16, 20, 26, 27, 33, 36, 58, 67, 77, 128, 129, 145, 162, 171, 206, 216, 242]. Several databases of homology models are available on the Internet, including ModBase [158], FAMSBASE [237] and the SWISS-MODEL repository [100]. Their websites are given in Table 4.

4.2 Example: Protein Kinase STK11/LKB1

The protein kinase STK11 is frequently mutated in human cancers and mutations in this gene are strongly associated with Peutz–Jeghers syndrome [79, 89]. Patients with Peutz–Jeghers syndrome often develop dark spots on the lips and inside the mouth as well as near the eyes and nostrils. These patients also develop polyps in the stomach and intestine, and are very susceptible to cancers of the breast, colon, pancreas, stomach and ovary [188]. This disease is inherited in an autosomal dominant manner, so that a mutation in a single copy of the gene is enough to confer risk [110].

One important use of homology modeling is to understand how missense mutations may lead to disease. In general, missense mutations that have deleterious effects lead to amino changes that either affect stability or dynamics of a folded protein, or affect interactions of the protein product with other molecules, including other proteins, DNA or ligands. While most of the mutations associated with the disease lead to a truncated protein, many missense mutations have also been linked to Peutz–Jeghers syndrome [110]. It is therefore of interest to build a model of the STK11 kinase domain and examine the location and likely effects of disease-associated mutations.

As described above, MolIDE [29] assists a user in modeling a protein by providing a graphical interface to the steps involved in basic homology modeling, including sequence database searching, alignment editing, and loop and side-chain modeling. We obtained the sequence of STK11 from the NCBI website in FASTA format, as shown in the middle panel of Figure 5. Once this sequence is input into MolIDE, the user runs PSI-BLAST from the Tools menu. PSI-BLAST is set up to run several rounds of search against the nonredundant protein database from NCBI. The version of PSI-BLAST distributed with MolIDE has been modified to output a profile matrix with a unique name after each iteration of the search so that each matrix can then be used to search the PDB sequence database included with MolIDE (G. Wang and R.L. Dunbrack, Jr., unpublished). These profiles are also used by the secondary structure prediction program PSIPRED [90], included with MolIDE. The secondary structure predictions are shown in the lower panel of Figure 5, where the red and green colors indicate α-helices and β-sheet strands, respectively, and the intensity of the color represents the confidence level of the prediction. As the profile includes more and more sequences remotely related to the query, the secondary structure prediction also changes. For some proteins, the prediction gets better as the signal from the multiple alignment becomes stronger, while for others the prediction may worsen if many sequences with variations in secondary structure (longer loops, shorter or longer secondary structure elements) get aligned or even misaligned to the profile.

As STK11 is a kinase, we have a large variety of structures in the PDB that can be used as a template. It is important to make a good choice, since the quality of the model will depend on the template or templates used. Currently, MolIDE does not model from multiple templates, so we need to select one structure. However, we could make a number of models based on different templates and compare them. A list of hits from the PDB for STK11 is shown in the upper panel of Figure 5. This list was generated from a PSI-BLAST search using the profile generated from the first round of PSI-BLAST on the nonredundant database. Information about each template, including PDB code, experiment type, resolution, *E*-value, sequence identity, length of template, starting positions of alignment and length of alignment, is given. Template choice is facilitated in this table by sorting based on any of the categories by clicking on the column header. Three different sorts of the table are shown in Figure 6, sorted by end query residue of the alignment (top), resolution (middle) and percent gaps in the alignment (bottom).

Figure 5 Screenshot of MolIDE for modeling STK11. Top: hits from a search of the PDB for protein target sequence STK11. Middle: sequence of STK11. Bottom: secondary structure prediction for STK11 using PSIPRED after each of three rounds of PSI-BLAST. Helix predictions are in red and sheet strand predictions are in green, and the intensity of the color is proportional to the confidence levels produced by PSIPRED.

The usefulness of a template depends on many factors. It is not necessarily the case that one should use the highest-sequence-identity hit or the best *E*-value. The number and location of gaps in the alignment should also be considered, as should the presence of desirable ligands and structure quality. For STK11, the majority of template alignments end around residue 310, which is the end of the kinase domain, but obviously it would be useful to model the region C-terminal to the kinase domain (residues 310–433).

By double-clicking on the PDB code, MolIDE opens up a window with the alignment as shown for that PDB entry. This window contains the alignment at the bottom and a rotatable view of the backbone of the template in the top part of the window (Figure 7). Conserved amino acids are indicated between the query (top) and hit (bottom) sequences. Gaps in the alignment are indicated by blue squares as are residues in the template that are missing in the coordinates due to poor electron density. Positions in the template structure where insertions need to be modeled, because the query sequence is longer in

that region, are marked with yellow spheres on the structure view. Deletions from the structure are shown on the protein structure as red spheres.

Figure 7 shows the C-terminal end of the alignment for template 1RDQ (chain E) [238]. It is fairly clear from this view that the extension of the alignment beyond residue 316 of the query shows very little similarity in sequence with the template and includes a very large insertion that would need to be modeled. It is likely that this region is incorrectly aligned. This often happens with PSI-BLAST type alignments, such that alignments extend beyond conserved domains due to chance similarities, especially in regions without significant regular secondary structure.

After examining a number of the other templates that extend well beyond residue 310, it was clear that none of them gave a very good alignment for the C-terminal portion of STK11. While a large number of the templates share similar sequence identity to STK11 on the order of 21–27%, some of them contain substantially fewer gaps in the alignment than others. Sorting by

Figure 7 Template 1RDQ (chain E) as template for STK11. The end portion of the alignment is shown, indicating that the residues after STK11 residue 310 are poorly aligned with little sequence similarity and a large gap. Gaps in the alignment are marked with blue squares, and conserved residues are marked between the query (top) and hit (bottom) sequences. The predicted secondary structure is above the query (red = helix; green = sheet) and the experimental secondary structure of the hit is below the template sequence. In the structure view, residues deleted from the structure are indicated with red balls and points of insertion are marked by pairs of yellow balls. The aligned portion of the template is in green and the unaligned portions are in gray. The last residue of the aligned portion is in spacefill representation (Tyr336).

percent gaps, we find a group of templates that have 2–3% of the alignment as gaps for residues 40–310, as shown in the bottom panel of Figure 6. We chose as template PDB entry 1MQ4, a 1.9-Å structure of aurora-A kinase [143], since this structure was the highest resolution of these and contained ADP in the active site of the kinase.

One of the benefits of MolIDE in user-assisted homology modeling is the ability to edit the sequence with the assistance of a graphical view of the protein with the locations of insertions and deletions. For instance, in Figure 8 the alignments before (left screenshot) and after (right screenshot) editing are shown. In the left figure, the two-residue insertion (residues 123–124 with

Figure 8 Manual editing of sequence alignments based on the structure view of template 1MQ4 for STK11. The alignment before editing is shown at left and after editing at right. The spacefilled residues mark the loop being edited (Ala84 left and His82 right). Note that the positions of the yellow balls marking the position of the insertion move as the alignment is edited. The anchor positions for loop modeling set manually are indicated on the right (Tyr118 and Lys124 of STK11).

sequence QK) occurs inside a β-sheet strand. Ala84 in the middle of the neighboring loop is shown in spacefill representation to mark the location on the structure. After editing the alignment by "ctrl"-clicking and "shift"-clicking to delete the gap and to create it in another location, the alignment appears as it does in the right side of the figure (with the last residue of the sheet strand, His82, in spacefill this time).

Once the sequence alignment is edited, e.g. by moving insertions and deletions into the middle of loop regions as described above, loop and side-chain modeling commands can be called from the menus. Our side-chain modeling program SCWRL is integrated into MolIDE and Loopy is used for loop modeling [235]. To model loops, the positions of left and right anchor residues are set by pointing and "right"-clicking on the query sequence and then calling Loopy from the Tools menu. The anchors for the loop consisting of residues 118–123 are shown in the right screenshot in Figure 8.

After modeling each of the five insertions and adding the coordinates of the ADP and magnesium ions, we can view the structure superposed on its template as shown in Figure 9. MolIDE is not set up to model in the presence

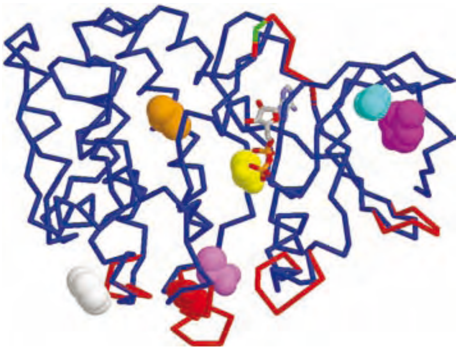

Figure 9 Model of STK11. The template backbone is in blue and the modeled loops for STK11 are in red. The ADP bound in the active site is in stick figure and CPK coloring (carbon = gray; oxygen = red; nitrogen = blue; phosphorus = orange). Several mutations associated with development of cancer are shown in spacefill representation, including Tyr49 (magenta), Val66 (cyan), Leu160 (orange), Asp194 (yellow), Glu199 (violet), Asp208 (red) and Phe231 (white). Gly135 is marked on the backbone in green.

of the ligand, although this can be accomplished for side chains with SCWRL outside of MolIDE. Most of the insertions are some distance away from the active site and four of these are relatively close in space to each other, all on the bottom face of the protein as oriented in Figure 9.

The positions of some missense mutations associated with cancer are marked with spacefill on the structure and three of these mutations are located in the modeled loops at the bottom of the protein. Another one is in the modeled loop at the top. Three mutations are buried in the hydrophobic core, of which two are in the N-terminal domain and one is in the C-terminal domain (colored in cyan, magenta and orange, respectively). These mutations are likely to disturb the hydrophobic cores of these regions, leading to instability of the folded structure. One additional mutation, in yellow spheres, is an Asp residue that binds the magnesium ions which stabilize the binding of ATP to the kinase. Loss of this Asp is likely to result in loss of magnesium and inability to bind ATP. STK11 binds a number of other proteins, and it is possible that one of these proteins binds to the modified loops at the bottom of the structure and that mutations in these loops leads to lack of binding of important interactors of STK11. Mutations which affect binding of the STRAD protein have been analyzed using a homology model of STK11 by Boudeau and coworkers [21]. While STRAD is homologous to kinase domains, none of the available dimeric kinase templates appears to have a binding interface consistent with these mutations, indicating that perhaps STRAD does not bind to STK11 in a manner similar to existing dimer interfaces of kinases.

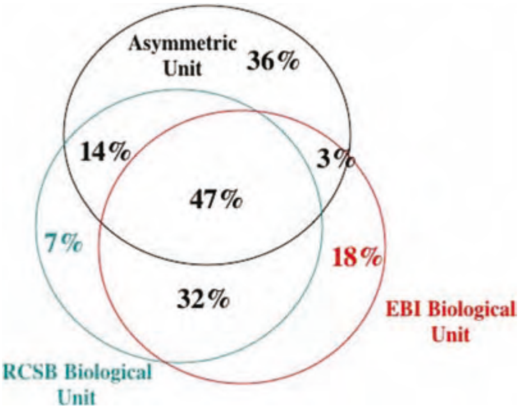

Figure 10 Venn diagram of similarities among asymmetric units, RCSB biological units and EBI (PQS) biological units. Each circle represents 24 000 entries available from both RCSN and PQS sites. Areas are only approximations to percentages marked in each overlapping or nonoverlapping region. For instance, 36% of the 24 000 entries have an asymmetric unit that is different from both RCSB and PQS.

4.3 The Importance of Protein Interactions

The STK11 example points out the importance of incorporating information on protein interactions in homology modeling. As described above, the Research Collaboratory for Structural Bioinformatics (RCSB) provides structures of the asymmetric unit, rather than the biological unit for crystal structures. RCSB also provides separate files that contain the proposed biological unit(s) for each structure, which may be larger or smaller than the asymmetric unit. To quantify this issue, we compared the asymmetric units and the biological units as provided by both the RCSB and the EBI/macromolecular structure database (MSD) [80]. For 23 418 structures available in PQS, Figure 10 shows the similarity of these three sets of units. Figure 10 shows that 53% of asymmetric units are different from either the RCSB or the PQS biological unit or both. This indicates that the standard entry from the PDB is not the biological unit at least half of the time and that the other two sources should be consulted. In addition, RCSB and PQS do not agree on biological units 21% of the time. Unfortunately, there are no automated ways to model homo-multimers, other than to model the sequence on each chain of a known multimer structure. SWISS-MODEL does provide a way to combine models made from different chains of a template biological unit file from PQS.

To illustrate the importance of these interactions, we investigated the large set of mutations in Lac Repressor investigated by Miller and colleagues [130, 148, 202], These authors presented functional data on 4042 mutations of the *Escherichia coil* Lac repressor. The Lac repressor function was evaluated *in vivo* by observing expression levels of β-galactosidase with and without allosteric induction by isopropyl-β-D-galactoside (IPTG). Thus mutations that reduce stability of the Lac repressor monomer, the affinity of monomers in the tetramer, as well as those that affect binding to DNA will produce a visible blue phenotype by the expression of β-galactosidase. Mutations that affect binding of IPTG will not be inducible and thus remain as white colonies, even in the presence of IPTG. This is an ideal system for identifying parameters that can be used to distinguish missense mutations that may cause functional changes in proteins from those that probably would not.

We used two pieces of information to analyze these mutations: (i) the location of residues in the structure of Lac tetramer bound to DNA and (ii) the log-odds scores in a position-specific scoring matrix (PSSM) generated from a multiple sequence alignment of repressor sequences. The PSSM includes two pieces of information: whether a particular site is well conserved in proteins related to Lac repressor and whether a proposed mutation is very different in physical character to residues at that position in proteins related to Lac repressor.

We defined four categories for location of an amino acid: face, buried, edge or surface depending on the value of the relative surface accessibility of a side-chain in the Lac repressor tetramer/DNA structure. Face residues were those that had reduced accessibility of their side-chains in the full complex compared to the Lac repressor monomer alone. Buried residues had less than 5% surface accessibility of their side-chains in the monomers. Edge residues were those with 5–30% accessibility and surface were all others. Surface residues are therefore those that are both on the surface and not in any binding site. The results are shown in Figure 11.

The data indicate that dissimilarity to amino acids in the repressor family as well as a location either buried in the hydrophobic core or in interfaces is sufficient to distinguish levels of "risk", i.e. a mutation with functional consequences. For each category of PSSM log-odds except PSSM = –4, face mutations are more likely to be deleterious than buried mutations and these are much more likely to be deleterious than edge or surface mutations. Interface residues do not tolerate even conservative mutations, so that even for PSSM values of 1 and 2, the proportion of deleterious mutations is 30% or higher. Mutations on the surface but not in an interface are very tolerant to mutations, with less than 1% of 743 mutations on the surface with PSSM of –2 or above having a negative phenotype.

The data in Figure 11 indicate the importance of modeling the biological unit, since all of the mutations in the "face" region would be considered surface or edge residues if the monomer was not present in a dimer complex with DNA.

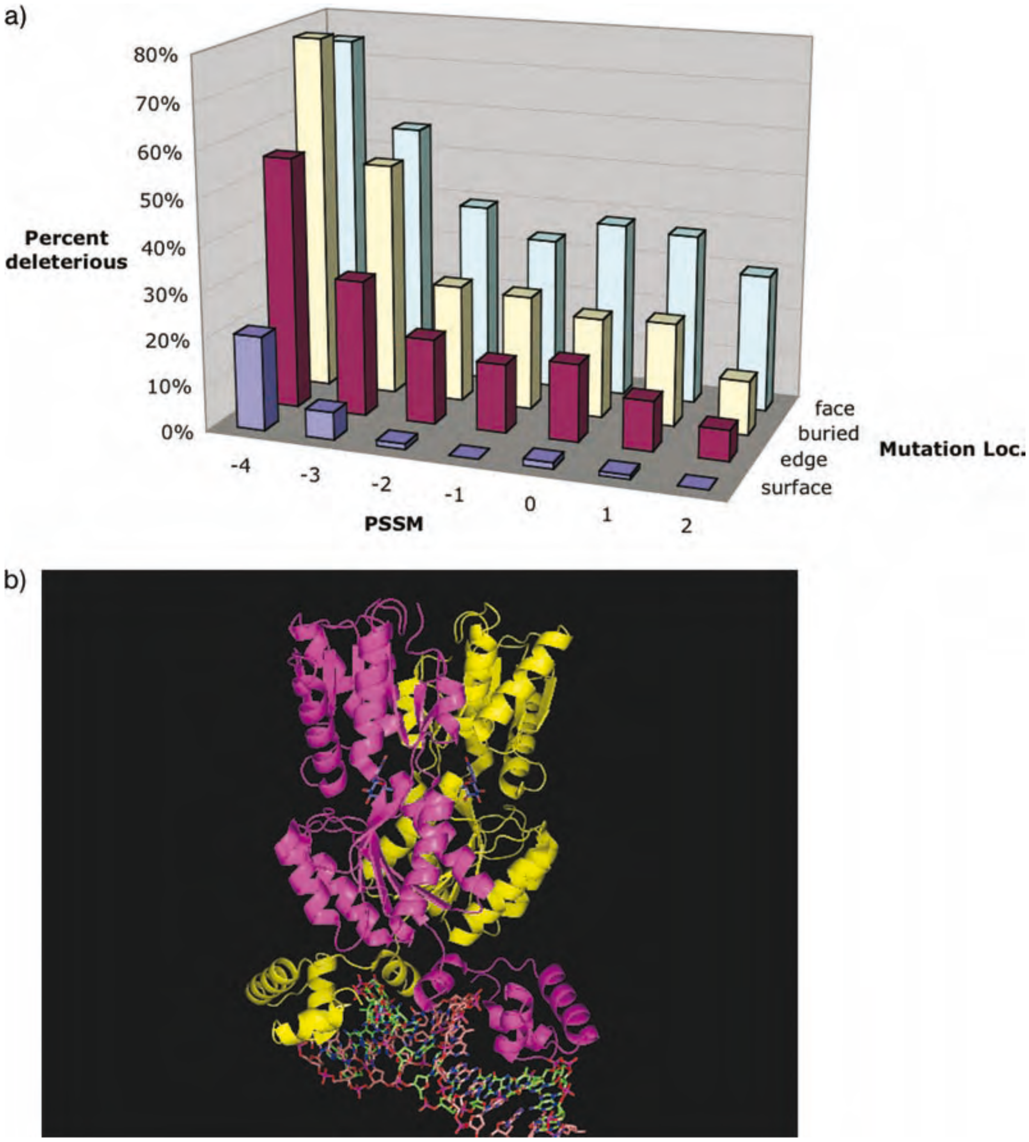

Figure 11 (a) Rates of deleterious mutations based on PSSM score and physical location for 4042 Lac repressor mutants. Face residues are those with lower surface accessibility in the Lac repressor dimer/DNA complex than in the Lac repressor monomer structure. Buried residues have less than 5% surface accessibility in the Lac repressor monomer. Surface residues have greater than 30% accessibility in the Lac repressor monomer or dimer/DNA complex, and "edge" residues have between 5 and 30% accessibility. PSSM is the log-odds score of finding the mutation at each location of the Lac repressor sequence based on a multiple alignment of homologous sequences. (b) Crystal structure of the Lac repressor dimer bound to DNA.

5 Strengths and Limitations

The strengths of homology modeling are based on the insights provided for protein function, structure and evolution that would not be available in the absence of an experimental structure. In many situations, a model built by homology is sufficient for interpreting a great deal of experimental information and will provide enough information for designing new experiments. Homology modeling may also provide functional information beyond the identification of homologous sequences to the target, i.e. a model may serve to distinguish orthologous and paralogous relationships.

The limitations are due to decreasing accuracy as the evolutionary distance between target and template increases. Alignment becomes more uncertain, insertions and deletions more frequent, and even secondary structural units may be of different lengths, numbers, and positions in very remote homologs. Predicting the locations of secondary structure units that are not present in the template structure is a difficult problem and there has been little attention paid to this problem.

The limitations of homology modeling also arise when we have insufficient information to build a model for an entire protein. For instance, we may be able to model one or more domains of a multi-domain protein or a multisubunit complex, but it may not be possible to predict the relative organization of the domains or subunits within the full protein. This remains a challenge for further research. And we are of course limited by structures present in the PDB, which are almost exclusively soluble proteins. Up to 30% of some genomes are membrane proteins, which are at present difficult to model because of the small number of membrane proteins of known structure. Recent structures [119, 146] of the G-protein-coupled receptor (GPCR) rhodopsin at higher resolution than previous structures [151] create new opportunities to model many of these membrane proteins more accurately. A number of GPCRs have been modeled on the bovine rhodopsin structures [33, 58, 136, 144, 152, 243]. In addition, recent structures of bacterial ATP-binding cassette (ABC) transporters at various stages of the transport process [45, 122, 164, 186] also provide opportunities for modeling of a large number of human ABC transporters implicated in drug resistance, such as P-glycoprotein and the multidrug resistance protein (MRP) proteins [160, 190].

Another problem is the quality of data in sequencing and structure determination. There are substantial errors in determining protein sequences from genome sequences, either because of errors in the DNA sequence or in locating exons in eukaryotic genomic DNA [199]. Over 50% of X-ray structures are solved at relatively low resolution, levels of greater than 2.0 Å. Despite progress in determining protein structures by NMR, these structures are of lower resolution than high-quality X-ray structures. While high-throughput structure determination will be of great value to modeling by homology, one concern is the quality of structure determination when the function of the proteins being determined is unknown.

6 Validation

Validation for homology modeling is available in two distinct ways: (i) the prediction rates for each method based on the prediction of known structures given information from other structures and (ii) criteria used to judge each model individually. Most structure prediction method papers have included predictions of known structure, serving as test sets of their accuracy. However, in many cases the number of test cases is inadequate (see Ref. [48]). It is also very easy to select test structures that behave particularly well for a given method and many methods do not stand up to scrutiny of large test sets performed by other researchers. Test sets vary in number of test cases as well as whether predictions of loops or side-chains are performed by building replacements on the template structure scaffold, or in real homology modeling situations where the loops/side-chains are built on nonself scaffolds. The realistic case is more difficult to perform in a comprehensive way, since it requires many sequence–structure alignments to provide the input information on which models are to be built. Another problem is that each method is judged using widely varying criteria, and so no head-to-head comparison is possible from the published papers. The problem of biased test sets and subsequent development of larger benchmarks has a long history in the secondary structure prediction field [170, 239].

While sequence alignment methods have been extensively benchmarked [184], programs that build coordinates from alignments, including the backbone, loops and side chains, have not been extensively compared to one another in large-scale tests. Recently, however, Wallner and Elofsson [220] compared several programs that build coordinates from templates given template-target alignments, including MODELLER [174], SegMod/ENCAD [116], SWISS-MODEL [189], 3D-JIGSAW [11], nest [234, 235], Builder [96, 97] and SCWRL (for side chains without modification of the template backbone) [30]. They found that three of the programs, MODELLER, nest and SegMod/ENCAD, perform better than the others. In particular, SegMod is a very old program and still performs as well as much more recent programs. They also observed that none of the homology modeling programs builds side chains as well as SCWRL.

6.1 The CASP Meeting

Another forum for testing homology modeling methods has been the ongoing series of CASP meetings organized by John Moult and colleagues [138–141, 214,215,240]. In the spring and summer before each meeting held in December 1994, 1996, 1998, 2000, 2002 and 2004, sequences of proteins whose structure was under active experimental determination by NMR or X-ray crystallography were distributed via the Internet. Anyone can submit structure predictions at various levels of detail (secondary structure predictions, sequence alignments to structures and full 3-D coordinates) before specific expiration dates for each target sequence. The models are evaluated via a number of computer programs written for the purpose, and then assessed by experts in each field, including comparative modeling, fold recognition and *ab initio* structure prediction. The organizers then invite predictors whose predictions are outstanding to present their methods and results at the meeting, and to describe their work in a special issue of the journal *Proteins*, published in the following year.

Ordinarily when protein structure prediction methods are developed, they are tested on sets of protein structures where the answer is known. Unfortunately, it is easy to select targets, even subconsciously, for which a particular method under development may work well. Also, it is easy to optimize parameters for a small test set that do not work as well for larger test sets. While the number of prediction targets in CASP is limited to numbers on the order of 10–20 per category, these numbers are still higher than many of the test sets used in testing new methods under development.

6.2 Protein Health

A number of programs have been developed to ascertain the quality of experimentally determined structures and these can be used to determine whether a protein model obeys appropriate stereochemical rules. The two most popular programs are ProCheck and WhatCheck [219]. Recently, the Richardson group has developed MolProbity, which seeks to identify a number of features in protein structures that are statistically unlikely, when compared to a manually curated set of very high-resolution structures [39]. This is a webserver that reports bad rotamer conformations, close contacts, flipped amide side-chains and other potential errors in structures. Although this site is more geared to analysis of new experimental structures, it can also be used on homology models to identify steric clashes or poorly modeled regions of proteins.

These programs check bond lengths and angles, dihedral angles, planarity of sp^2 groups, nonbonded atomic distances, disulfide bonds and other characteristics of protein structures. One of the more useful checks is to see whether backbone geometries are in acceptable regions of the Ramachandran map. Backbone conformations in the forbidden regions are very likely to be incorrect. It should be noted once again that correct geometry is no guarantee of correct structure prediction. In some cases, it may be better to tolerate a few steric conflicts or bad dihedral angles, rather than to minimize the structure's energy. While the geometry may look better, the final structure may be further away from the true structure (if it were known) than the unminimized structure. Chapter 11 discusses the problem of health of protein models and describes the respective Model Quality Assessment Programs (MQAPs).

Acknowledgements

This work was funded in part by grants R01-HG02302 and CA06927 from the National Institutes of Health. I thank Guoli Wang for providing the genome analysis in Figure 2, and Adrian Canutescu for assistance with MolIDE and Figure 3.

Protein Fold Recognition Based on Distant Homologs

Ingolf Sommer

1 Introduction

In the 1960s Anfinsen showed with a rather simple experiment that for many proteins the sequence is the sole determinant for the three-dimensional (3-D) structure [7, 8]. A denaturating substance was added to the solution of a protein, resulting in the loss of native protein structure and function. After removal of the denaturing substance, proteins recovered the functional activity (an enzymatic reaction in Anfinsen's experiment). Thereby, it was concluded that the protein managed to refold itself in the absence of any other agents.

Later, it became evident that some proteins need other proteins to fold and some proteins or parts of proteins remain unfolded (see Chapter 9). Still, the Anfinsen principle has been a guiding force for much research that aims at understanding mechanisms for determining the 3-D structure of proteins given their sequence. Although great improvements of these methods have been achieved, the protein structure prediction problem is still unsolved, in general. The folding process that determines the structure is not known to enough detail to serve as a basis for modeling. Instead, prediction methods have to rely on heuristic inductive inferences.

One very successful approach to the prediction of protein structures today models the protein structure based on another structurally resolved protein as a structural template. We call this approach template-based modeling. The protein whose structure is to be predicted is called the target. In addition to the target sequence, the method requires the input of a database of resolved protein structures, the so-called template structures. Rather than modeling the protein structure *de novo*, we repeatedly ask the question whether the protein structure of the target sequence is similar to a template structure. This leaves us with a set of candidates for templates after which we can model the structure of the target sequence.

This chapter deals with the question how likely it is that a target protein sequence attains a structure similar to a given template structure. In principle

one can compare the sequence itself to the sequences of the template structures (sequence–sequence comparison, Section 3.1), additionally take evolutionary information into account (profile methods, Sections 3.2 and 3.3) or thread the sequence onto the given 3-D template structure taking physico-chemical properties of the template structure into account (Section 4). The problem of identifying suitable templates typically becomes harder the more distant the target sequence is related to its most similar sequences in the template database. More similar sequences are easier to identify when looking at sequence information only; typically, they also have a more similar structure within a chemically more similar environment.

Traditionally, protein structure prediction has been divided into homology modeling (also called comparative modeling; see Chapter 10), fold recognition (this chapter) and prediction of novel folds (Chapter 12) [97]. In homology modeling, closely homologous templates are available affording very precise models for the protein structure. In fold recognition, identifying a suitable template becomes a challenge. Once a template is obtained, a prediction of the 3-D arrangement can be made, whereas a constructed full-atom model is not reliable, in general. In contrast, in the new fold category no suitable template is available and fragment assembly or *de novo* methods need to be applied.

The basic pipeline exercised is identical in the first two categories, in principle. Thus, today homology modeling and fold recognition are merging. The focus in homology modeling is more on obtaining detailed models with high resolution. The focus of fold recognition is more on the identification of suitable templates.

2 Overview of Template-based Modeling

2.1 Key Steps in Template-based Modeling

The input to template-based modeling is a target sequence and a database of previously resolved template structures. The output is a 3-D model for the target sequence, constructed according to the template.

2.1.1 Identifying Templates

How do we decide how likely the sequence of a target protein attains a given template structure? We perform a pairwise alignment of the target sequence with the sequences of the template structures. Here, different techniques can be used: the target sequence can be aligned with the amino acid sequences of the templates. If evolutionary information on the target sequence is available (see Chapters 3 and 4), a multiple alignment of related sequences can be used to construct a position-specific scoring matrix (PSSM or, similarly, a frequency profile, see Section 3.2.1). A PSSM represents the preferences of a residue in the target sequence to be matched with a residue in the template structure (Section 3.2.1). This kind of evolutionary information can also be used on the template side or on both target and template sides. One can enhance this approach by introducing additional information, e.g. stemming from secondary structure predictions (Section 5.1.1). Sequence–structure alignment methods using the 3-D structure information on the template sides during the template identification process are presented in Section 4.

2.1.2 **Assessing Significance**

The score of the alignment tells us the propensity of the target sequence to attain the template structure. Ideally, the template that can be aligned to the target sequence with the highest alignment score should provide the structural model for the target protein. However, since alignment scores reflect structural preference only inadequately, this model selection procedure is fallible. Thus, the score has to be accompanied with a confidence value that rates how much we can trust the prediction. Often, a confidence score is based on theoretical statistical significance which rates how unlikely it is to obtain the alignment by chance. In addition, empirical choices of confidence values have also proven effective (Section 6.1).

2.1.3 **Model Building**

Aligning the target sequence to a template protein is only the first step of producing a full-atom protein structure model for the target protein. While it is the critical step for the similarity range of below about 40% sequence identity between target and template sequence, it is less difficult in high similarity ranges (see Chapter 10). An incorrect alignment invariably leads to a wrong protein model.

The alignment maps residues of the target onto the template. An initial model is constructed by copying coordinates of the template structure and changing the template residue types according to the target sequence. This model only provides a part of the structure of the target protein's backbone. Gaps in the alignment represent parts of the target sequence that we cannot map onto the template structure (if gaps occur in the template sequence) or tears and rips in the backbone model of the target sequence (if gaps occur in the target sequence). The former gaps mostly coincide with loops in the target protein that have no counterpart in the template structure. These loops have to be modeled in a separate loop modeling step by inserting loop fragments from a database of protein structures, or by using energy optimization methods. Rips in the backbone of the target protein have to be mended and, finally, the sidechains of the target protein have to be attached to the backbone. Here, the variants are to use a database of side chain rotamers or to do energy optimization. Similarity-based protein modeling tools combine these steps in different ways and using different algorithmic procedures (see Chapter 10) [32, 129, 133].

2.1.4 Evaluation

The performance of fold recognition methods is typically assessed by benchmarks [20, 37, 71, 171]. Here, the objective is to retrieve the template structure that is most similar to the structure of the target protein. The performance can be quantified in terms of the number of correctly assigned folds or, in a more detailed fashion, by rating the quality of the alignment, on which the fold assignment is based. The accuracy of protein sequence–structure alignment methods depends highly on the sequence similarity between the target and the template protein. It is low in the case of low sequence similarity and high in the case of high sequence similarity. Over the whole protein structure database we can today achieve an accuracy of above 70% correctly assigned folds [165]. Starting 1994, the Critical Assessment of Protein Structure Prediction (CASP) experiment, a biannual blind test for protein structure prediction methods was established to measure progress in the field [98].

While similarity-based modeling is quite successful, this approach cannot discover yet unseen protein structures. Rather, it can only rediscover structures that have been seen before as attained by different protein sequences. As we can only assume to have uncovered about one half of all protein folds used by nature [72, 178], this approach has strong limitations.

2.2 Template Databases

Typically the structures serving as templates are experimentally determined by X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy.

X-ray crystallography determines structures of macromolecules by analyzing their diffraction patterns when irradiated by X-rays. In order to obtain a diffraction pattern a protein has to be crystallized. During crystallization many instances of the same protein are symmetrically arranged along a lattice. Even when crystallized, proteins frequently display biological activity indicating that the crystallization process captured them in the biologically active form. Some proteins are very hard to crystallize (e.g. membrane proteins). When the protein crystal is properly irradiated with X-rays, diffraction patterns result that are captured on film or digital media. From these patterns the electron density of the protein is computed and from the density information the atomic structure of the protein is derived [13, 14, 120].

NMR spectroscopy is the second prominent method for structure determination. It can be applied to smaller proteins (up to around 40 kDa) in highly concentrated solution. Some atomic nuclei, e.g. protons in hydrogen, display an intrinsic magnetic property called spin. By applying an external varying magnetic field the state of the spin may change, provided resonance takes place. A resonance spectrum can be obtained. The surrounding local environment of nuclei may cause a shift of the peaks in the resonance spectrum. Peaks in the spectrum are associated with residues in the protein sequence in a sequential assignment step and a list of distance constraints can be deduced. Applying distance geometry techniques to these data, atom coordinates can be estimated [13, 14, 162].

The most frequently used public resource for coordinates of protein structures determined with NMR spectroscopy or X-ray crystallography is the Protein Data Bank (PDB). Quality of structures deposited in the PDB can be judged with a number of programs (Procheck [94], Whatcheck [55]). The ASTRAL compendium for structure and sequence analysis conveniently combines the output of several of these programs with additional manual annotation into a joint AEROSPACI score [16, 24].

Most proteins are globular. Larger proteins often fold into several independent folding units or domains. Domains are compact regions of structure often capable of folding on their own in aqueous solution. Domains can be defined as folding units, as units of structural similarity, or as evolutionary units [115]. Several resources describe the domain composition within proteins and classify the identified domains hierarchically: most prominent are SCOP, CATH and FSSP. SCOP, (structural classification of proteins [99]) is a human-curated database organized hierarchically into classes, folds, superfamilies and families. CATH (class, architecture, topology and homologous superfamily [106]) is a semi-automated procedure. The FSSP (families of structurally similar proteins [54]) relies on a fully automatic procedure.

Since domains are recurring folding units, often domains are chosen as templates for structure prediction. For the construction of template databases, reasonably different templates with high quality structures are favored. Representative sets of templates can be constructed limiting the maximal percentage of sequence identity while choosing structures with a high SPACI score for example. Choosing SCOP domains with at most 40% (95%) sequence identity results in a set of 7290 (12 065) structures for SCOP version 1.69 of July 2005.

3 Sequence-based Methods for Identifying Templates

3.1 Sequence–Sequence Comparison Methods

The simplest method for assigning a fold to a target sequence is to compare the target sequence to sequences of proteins with known structures. In order to compare the sequences they are aligned (see Chapter 3, [34]).

Scoring the similarity of an individual pair of amino acids amounts to comparing the likelihoods of generating this pair from two alternative stochastic models. One model, the model of related amino acids, describes the distribution of amino acid pairs originating from related positions in pairwise alignments of homologous sequences. The second model is a null model which describes the distribution of unrelated amino acid pairs. The amino acid pair is denoted by a pair of random variables (X, Y) both with values in $\{1, \ldots, 20\}$. The distribution of (X, Y) under the related model is defined as $p_{\mathrm{rel}}(i, j)$. Note that the background distribution of amino acids can be computed as $p_i = \sum_{j=1}^{20} p_{\mathrm{rel}}(i, j)$. The log-likelihood ratios of all pairs of amino acids are stored in an amino acid similarity matrix: $M_{i,j} = \lambda \log \left(\frac{p_{\mathrm{rel}}(i,j)}{p_i p_j} \right)$, with constant scaling factors λ. Different factors were introduced by different authors: Dayhoff and coworkers [29] use $\lambda = 10/\log 10$, the BLOSUM series [51] uses $\lambda = 2/\log 2$.

Introducing an additional penalty for inserting and extending gaps, two sequences of unequal length can be aligned. For arbitrary sequences, the Needleman–Wunsch algorithm [100], aligns two sequences using dynamic programming. It is appropriate, when sequences are expected to be similar from beginning to end, computing a so-called *global* alignment. In cases where only limited patches of the sequences share similarity, *local* alignment is used, which is computed using the Smith–Waterman algorithm [145]. When searching for similarity of a complete subsequence within a sequence, as is the case for example when identifying domains within longer sequences, *free-shift* alignments are appropriate (domain identification is also discussed in the context of Chapter 12).

The runtime of alignment algorithms is measured in terms of (sum of the) length of the aligned sequences. Using the Needleman–Wunsch algorithm, alignments can be computed in cubic time for general gap cost functions. For affine gap-cost functions, alignments can be computed in quadratic time using the Gotoh algorithm [48]. Since these dynamic programming programming algorithm can be slow for high-throughput applications fast heuristics like BLAST [5] and FASTA [113] were developed which approximate the optimal alignment algorithms.

The parameters of sequence alignment methods have to be calibrated for the intended application, e.g. Pearson details a protocol for searching genomes with these methods [111]. The major disadvantage of these pairwise sequence comparison methods is that conserved and variable positions are treated indifferently and contribute equally to the final alignment score. This limits the ability to identify distant homologs.

Sequence–sequence comparison methods like the Smith–Waterman algorithm [145] and the BLAST [5] or FASTA [113] tools can assign a fold to approximately 20–30% of the proteins coded by genes in a microbial genome [45, 173].

3.2 Frequency Profile Methods

Exploiting evolutionary information in addition to the plain sequence information, frequency profile methods are powerful tools for detecting distant relationships between amino acid sequences, often picking up signals even when other methods fail [170]. In this section we define frequency profiles, and describe why one would use them, how they are generated and different ways of comparing profiles to sequences and profiles to other profiles.

3.2.1 Definition of a Frequency Profile and PSSM

A frequency profile (or profile for short) is a sequence of position-specific frequencies of amino acids, which can be used for sequence alignments instead of a sequence containing individual amino acids at each position [49, 150].

Starting with an alignment of several related sequences (a multiple sequence alignment), for each position in that multiple alignment the occurrences of the types of amino acids are counted (for an example, see Figures 1 and 2). This yields an estimate of the likelihood of different types of amino acids occurring at different positions along the sequence. By counting gap characters in an alignment column, information on the likelihood of insertions at individual positions along the sequence can be gathered. Before counting, each sequence can be given a weight, which is a useful debiasing procedure if several of the sequences are very similar [49, 52, 91, 134].

Formally, a frequency profile matrix $(F_{p,a})$ is composed of at least 20 columns and N rows. The row p corresponds to the sequence position in the multiple alignment of length N and the column a to the type of amino acid. The first 20 columns of each row specify the relative frequencies of the types of amino acids at that position [123, 167, 185]. Some scoring schemes require additional columns containing penalties for insertions or deletions at that position [49], or unexpected characters in the sequences [18].

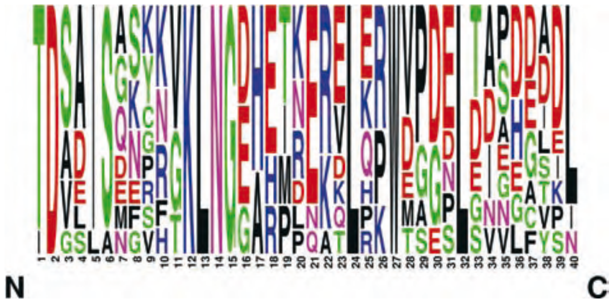

Figure 1 Sequence logo corresponding to the first 40 sequence positions of Pfam [11] multiple alignment of the Ataxin-2 N-terminal region. The figure is produced with WebLogo [28]. The overall height of the stack at each sequence position indicates the sequence conservation at that position, while the height of symbols within the stack indicates the relative frequency of each amino acid at that position.

Figure 2 First 20 sequence positions of the frequency profile matrix corresponding to the sequence logo depicted in Figure 1. All sequences are weighted identically.

Originally, Gribskov [49] combined the frequency profile matrix directly with amino acid substitution matrices [29,51], yielding

$$(S_{p,a}) = \left(\sum_{b=1}^{20} F_{p,b} \cdot M_{a,b} \right),$$

where $(M_{a,b})$ is Dayhoff's substitution matrix. This construct is referred to as a PSSM. In contrast to a frequency profile, a PSSM is a frequency profile multiplied with substitution preferences.

Other authors also use the word *profile* in the context of structure-based template identification methods to describe the sequence-based information extracted from protein structures, as discussed in Sections 4 and 4.3, in particular.

3.2.2 Generating Frequency Profiles

For constructing a profile one needs a multiple alignment of related sequences. Such alignment can be readily available, e.g. as in Pfam [11]. If not, one can start generating a profile from a single sequence by searching related sequences and multiply aligning them. Once a few sequences are found, a profile can be constructed from them and employed to search more sequences. This iterative approach for searching homologs is implemented in the popular PSI-BLAST program [6, 131], for example. In practice, the number of sequences identified by this search matters. This number is controlled by the BLAST parameters "number of iterations" and "E-value" for inclusion into the PSSM. The multiple alignment can be taken directly from the BLAST output, iteratively optimized [136], or improved with tools for multiple sequence alignment like ClustalW [156] or T-Coffee [101, 107]. The process of profile generation is illustrated in Figure 3.

If one particular sequence is the seed for searching further sequences, the multiple sequence alignment can be cropped by deleting the columns which contain gaps in the master sequence (master–slave alignment in BLAST terminology). Such an alignment can be used to construct a profile specifically reflecting that sequence. In the matrix notation above, this results in a frequency profile matrix F with rows eliminated until the N remaining rows correspond to the N residues of the master sequence.

Profiles calculated from multiple alignments that originate from similarity searches are subject to a bias introduced by the composition of the sequence databases that are searched [3]. An example is a case such that a search yields a large number of hits of mammalian origin and only few distantly related plant sequences. If a frequency profile from such a multiple alignment were calculated by simply taking the relative frequencies of the amino acids, this would reflect a strong emphasis on the mammalian sequences. This effect is not desirable, since the goal is to present all sequences of the family in an unbiased manner in the profile. To tackle this problem, it is generally assumed that only a fraction of the sequences of the family to be modeled is available in the databases and many sequences have not been observed, so far. A number of methods has been developed to estimate the size of the sequence families from the available sample. The most important are Dirichlet mixture models [17], pseudocounts [153], minimal-risk estimation [180] and sequence weighting models [52,74,89,123,125,134,150]. For a discussion of sequence weighting models, see Ref. [171].

3.2.3 Scoring Frequency Profiles

Frequency profiles can be aligned using the same algorithms as in sequence alignment. Whereas in plain sequence alignments two individual amino acids are matched, here profile vectors are compared. Profile vectors can be matched to individual amino acids or to other profile vectors. Different schoring schemes exist for both approaches .

3.2.4 Scoring Profiles Against Sequences

Let α be a row-vector at a certain sequence position p in a profile F and let $a_i = F(p,i)$ be the frequency observed for amino acid number i at position p. In the following, we will investigate ways of scoring α against an individual amino acid of type j (profile–sequence), or against another row-vector β from another profile F' (profile–profile).

The average score was the first profile–sequence score used in bioinformatics [22,49]. It is defined as

$$\text{score}_{\text{avg}}(\alpha, j) = \sum_{i=1}^{20} \alpha_i M_{i,j}.$$

Its basic idea is to compute the expected value of the sequence–sequence score under the profile distribution. Later, we will see an extension of this idea to profile–profile scoring. This scoring system has several drawbacks which led to further development.

The previously mentioned iterative PSI-BLAST program [6] starts with a round of BLAST using sequence–sequence alignment techniques to identify related sequences. From the sequences found, a profile is constructed which is used to identify further sequences using essentially the average scoring scheme. No position-specific gap costs are used, instead for each iteration the same gap costs that are used in the initial BLAST run are applied. In contrast to PSI-BLAST, the related tool IMPALA [131] implements the opposite sequence–profile direction and compares a single target sequence to a database of PSSMs previously generated with PSI-BLAST. This method can be used to quickly compare a sequence to a database of template structures with precomputed PSSMs.

Log-likelihood profile–sequence scoring (e.g. Ref. [27]):

$$\text{score}_{\text{lq}}(\alpha, j) = \log \frac{\alpha_j}{p_j},$$

is an optimal (in the sense that the likelihood ratio guarantees the lowest error of type II of all tests at the same level of significance) test statistic according to the Neyman–Pearson lemma from statistical test theory for deciding whether the amino acid j is a sample from the distribution α or rather from the background distribution p. The values summed up over all aligned positions provide a direct measure of the likelihood of the amino acid sequence being a sample from the profile.

Evolutionary profile–sequence scoring [27,50] is defined as

$$\text{score}_{\text{ev}}(\alpha, j) = \log \sum_{i=1}^{20} \alpha_i \frac{p_{\text{rel}}(i, j)}{p_i p_j}.$$

This score summed up over all aligned positions in an alignment is an optimal means of deciding whether the sequence occurs by chance or is more likely to be the result of sampling from the profile having undergone evolutionary transition.

3.2.5 Scoring Profiles against Profiles

Since profiles have been invented, several ways of comparing profiles to profiles have been developed and tested. These scoring schemes perform differently in their abilities for searching templates and in the quality of the alignments produced.

A simple, fast and heuristic way of comparing two profile vectors independently of any substitution matrix is the dot product scoring, which is the summation of the products of the frequencies per type of amino acid [117,123,124]:

$$\text{score}_{\text{dotprod}}(\alpha, \beta) = \sum_{i=1}^{20} \alpha_i \beta_i .$$

Average or cross-product profile–profile scoring is a straightforward extension of the approach used in profile–sequence scoring. The products of the frequencies are multiplied with the corresponding log–odds elements of the substitution matrix:

$$\text{score}_{\text{avg}}(\alpha, \beta) = \sum_{i=1}^{20} \sum_{j=1}^{20} \alpha_i \beta_j \log \frac{p_{\text{rel}}(i, j)}{p_i p_j} .$$

Though not called profile–profile alignment, this approach has been used in ClustalW [155, 156], where two multiple alignments are aligned using the average over all pairwise scores between residues.

The log-average scoring multiplies the products of the frequencies by the corresponding probabilities in the substitution matrix and then takes the logarithm [165, 167]:

$$\text{score}_{\text{logavg}}(\alpha, \beta) = \log \sum_{i=1}^{20} \sum_{j=1}^{20} \alpha_i \beta_j \frac{p_{\text{rel}}(i, j)}{p_i p_j} .$$

This scoring is symmetric and scores zero against the background distribution. For the special case of profile–sequence alignment, i.e. for one of the profiles corresponding to just one sequence, log-average scoring reduces to score_{ev}. For the special case of both profiles corresponding to one sequence, log-average scoring reduces to the scoring in normal sequence–sequence alignment.

The Jensen–Shannon divergence $D^{\text{JS}}_{\lambda}(\alpha, \beta) = \lambda D^{\text{KL}}(\alpha, \gamma) + (1 - \lambda) D^{\text{KL}}(\beta, \gamma)$, with $\gamma = \lambda\alpha + (1 - \lambda)\beta$ for $0 \leq \lambda \leq 1$ is based on the information theoretic Kullback–Leibler distance $D^{\text{KL}}(\alpha, \beta) = \sum_{k=1}^{20} \alpha_k \log_2 \frac{\alpha_k}{\beta_k}$. With p as amino acid background distribution, Yona and Levitt developed the score [185]:

$$\text{score}_{\text{JensenShannon}}(\alpha, \beta) = \frac{1}{2}(1 - D^{\text{JS}}(\alpha, \beta))(1 + D^{\text{JS}}(\gamma, p)).$$

Given two profile vectors α and β, the corresponding row vectors of the PSI-BLAST PSSMs S and T, and the effective number of observations n and m, the Panchenko score [108] is computed as:

$$\text{score}_{\text{Panchenko}}((\alpha, S, m), (\beta, T, n)) = \frac{m\,\alpha \cdot T + n\,\beta \cdot S}{n + m} .$$

The LogOddsMultin score used in the COMPASS tool for comparison of multiple protein alignments [125] is an extension of the scoring that PSI-BLAST uses:

$$\text{score}_{\text{LogOddsMultin}} = c_1 \sum_{i=1}^{20} n_i^{(1)} \log \frac{q_i^{(2)}}{p_i} + c_2 \sum_{i=1}^{20} n_i^{(2)} \log \frac{q_i^{(1)}}{p_i} ,$$

where $n_a^{(1)}$ and $n_a^{(2)}$ are the effective counts for each amino acid in columns 1 and 2, and where $c_1 = \frac{n^{(2)}-1}{n^{(1)}+n^{(2)}-2}$, $c_2 = \frac{n^{(1)}-1}{n^{(1)}+n^{(2)}-2} = 1 - c_1$ and $n^{(k)} = \sum_{j=1}^{20} n_j^{(k)}$.

These scoring schemes are extensively discussed and experimentally compared in Refs. [164, 171]. Both studies compare and analyze the searching abilities as well as the quality of the alignments produced with these scorings schemes. Alignment quality can be monitored with measures like Q_{Modeler} as fraction of correctly aligned positions in the profile–profile alignment [130], $Q_{\text{Developer}}$ as fraction of correctly aligned positions in the structural alignment [130], or similarly Q_{Combined} that penalizes sequence alignments that are either too long or too short [185]. Measuring alignment quality with Q_{Combined}, the above profile–profile scoring functions perform similarly, while displaying differences in Q_{Modeler} and $Q_{\text{Developer}}$ [171]. The Jensen–Shannon and LogOddsMultin functions produce shorter, more accurate alignments [171]. The Jensen–Shannon scoring produces better alignments for closely related sequences [164]. Of the scoring functions above, in terms of search specificity and sensitivity the LogOddsMultin and log-average perform significantly better [171].

3.3 Hidden Markov Models (HMMs)

3.3.1 Definition

HMMs (see Chapter 3 or Ref. [34]) can be regarded as a generalization of profiles and have become an important tool in fold recognition. Introduced in the late 1960s and 1970s, and popular in speech recognition [118], HMMs made it into computational biology in the late 1980s [26] and have been used as profile models since the mid-1990s [73, 151]. For an introduction to HMMs, see Chapter 3 or Refs. [9, 118]; for review articles in the context of computational biology, see Refs. [25, 35].

HMMs are probabilistic models that are applicable to signals, time series or linear sequences. An HMM is a system characterized by the following: It has a set of hidden states $S = \{S_1, S_2, \ldots, S_N\}$. The system is in state q_t at time t and has a number M of distinct observation symbols per state, i.e. a discrete alphabet $V = \{v_1, v_2, \ldots, v_M\}$. The system randomly evolves according to a state transition probability distribution matrix $A = (a_{ij})$, where $a_{ij} = P(q_{t+1} = S_j | q_t = S_i)$ for $1 \leq i, j \leq N$ and emits characters from the alphabet V according to an emission probability matrix $E = (e_{ik})$, $1 \leq i \leq N, 1 \leq k \leq M$. When the system is in a given state i, it has a probability a_{ij} of moving to state j and a probability e_{ik} of emitting letter v_k. Biological relevance is attached to the hidden states of the Markov model. Transition and emission probabilities depend on the current state only and not on the past. This property is called the first-order Markov assumption. Only the emitted symbols can be observed, not the underlying random walk from state to state.

3.3.2 Profile HMM Technology

When applying HMMs to model families of protein sequences one speaks of profile HMMs. In this case, mainly an alphabet of 20 amino acid letters is used, but also other alphabets exist such as 64-letter alphabets for codon triplets, three-letter alphabets (helix, sheet and coil) for secondary structure prediction and Cartesian products of these alphabets. If necessary, meta-characters such as gap symbols can be added to the alphabets, as well.

In a standard architecture for protein sequence HMMs there are three classes of states [9], besides the *start* and *end* state: the *match*, *insert* and *delete* states. Thus $S = \{start, m_1, \ldots, m_N, i_1, \ldots, i_{N+1}, d_1, \ldots, d_N, end\}$. Typically, the length of the model N is the average length of the sequences in the family. The *match* and *insert* states always emit amino acid symbols, whereas the delete states never do. The basic path of state transitions is *start* $\rightarrow m_1 \rightarrow m_2 \rightarrow \ldots \rightarrow m_N \rightarrow$ *end*. Each *match* state m_j has an outgoing edge to succeeding *match*, *delete*, and *insert* states, m_{j+1}, d_{j+1} and i_{j+1}, respectively. Each *delete* state d_j has outgoing edges to the succeeding *delete*, *match* and *insert* states d_{j+1}, m_{j+1} and i_{j+1}. The *insert* state i_j is connected to the succeeding *match* and *delete* states m_{j+1} and d_{j+1}, and has a loop to itself allowing for multiple insertions.

There are three typical questions associated with HMMs in this context [118]. Given an observation sequence of emission characters and a model, how likely is that sequence for the particular model? Given the observation, i.e. target, sequence and a model, what is the underlying sequence of states? How to adjust the model parameters so that the model best describes a multiple alignment of amino acid sequences?

With profile HMMs [73], sequence families can be characterized. For a profile HMM, the first question addresses the likelihood of a given amino acid sequence to be a member of the given family.

For computing the likelihood of a sequence being emitted by a model, the forward procedure [9, 118] is used. Probabilities of states are propagated through the model from the *start* to the *end* states. From the state probabilities, the probabilities of a certain letter being emitted at a certain time can then be computed.

The most likely path of states is computed with the Viterbi algorithm [9, 118]. The path consists of a sequence of matches, insertions and deletions, and thus corresponds to an alignment of the target sequence with the sequence family.

Commonly, with a given multiple alignment the parameters of the standard architecture are initialized prior to learning as follows: The *match* state is assigned to any column of the alignment that contains less than 50% gaps. *Delete* states are associated with columns that contain any gaps. Columns with more than 50% gaps are assigned to corresponding *insert* states. Emissions of *match* and *insert* states can be initialized from the frequency counts of the corresponding columns in the multiple alignment. These counts need to be regularized with Dirichlet distributions or Dirichlet mixtures in order to avoid emissions associated with zero counts [9]. In a subsequent *learning* phase, the HMM parameters are optimized. Various algorithms are available for that, including the expectation maximization (EM or Baum–Welch) algorithm and different generalizations of it as well as gradient descent methods [9, 10, 30, 118]. This learning process corresponds to the generation of a profile in the previous section on profile–profile scoring.

3.3.3 HMMs in Fold Recognition

HMMs have been used for a number of years in fold recognition [25, 35, 66–68] and have been extensively tested (e.g Ref. [110]). One approach [66] is to iteratively add homologous sequences to a HMM (like the PSI-BLAST approach does for sequence alignments). Similar to profile methods, HMMs can turn multiple sequence alignments into position-specific scoring systems suitable for searching databases for remotely homologous sequences [35].

3.3.4 HMM–HMM Comparisons

Similar to the scoring schemes described in the section on frequency profile scoring, there are several ways to score profile HMMs against sequences or against other profile HMMs. Whereas the standard HMM approach was to compare an HMM to one sequence, Lyngsø and coworkers developed an algorithm for the alignment of two HMMs based on the maximization of the coemission probabilities [90]. Recently, Edgar and Sjölander proposed an approach to align two multiple alignments by constructing a profile HMM from one of the alignments and aligning the other to that HMM [36]. Söding has generalized the log-likelihood score maximized in HMM sequence alignments to the case of HMM–HMM alignments [146].

3.4 Support Vector Machines (SVMs)

3.4.1 Definition

SVMs are a state-of-the-art machine learning method for classification problems. SVMs have been succesfully applied for fold recognition.

Conceptually, SVMs map the data points to be classified into a high-dimensional space called feature space, in which an optimally separating hyperplane is sought that separates the two classes of points to be distinguished by the (binary) classification [132]. Technically, the transformation into the high-dimensional space can be avoided and only inner products in that space, called kernels, need to be computed. While the SVM machinery is fairly standardized, kernel functions are highly problem specific. One problem for protein sequences is to map the sequences of typically differing lengths into a space with a constant dimensionality. Several kernel functions exist for the protein classification problem.

3.4.2 **Various Kernels**

Jaakkola and coworkers suggest the Fisher kernel function, which is specific to a protein family [57]. An HMM is trained from positive samples of the family. The so-called Fisher score is the gradient of the log likelihood score for an arbitrary sequence X with respect to the HMM parameters. This score maps the sequence X into a fixed length vector. The Fisher kernel function is then computed on the basis of Euclidean distances between the Fisher score vector for X and the score vectors for known positive and negative examples of the protein family.

Another example, the SVM-pairwise kernel, uses the Smith–Waterman algorithm to align a new protein sequence X against all n sequences in the training set. The feature vector corresponding to protein X is $F_X = f_{x1}, f_{x2}, \ldots, f_{xn}$, where f_{xi} is the E-value of the Smith–Waterman score between sequence X and the ith training set sequence [81].

There are numerous other kernels to treat protein sequences, e.g. mismatch kernels [79], string kernels [126] or motif kernels [12].

3.4.3 **Experimental Assessment**

Machine learning methods need sufficient training data, which imposes some restrictions on the experiments. The typical problem tackled by the machine learning community is the protein classification problem, as described by Jaakkola and coworkers in 1999 [56]. The protein classification problem is to predict the SCOP structural class of a protein given its amino acid sequence. Two sequences with the same superfamily are considered as related by homology and two domains from different folds are considered as unrelated. Proteins from different superfamilies within the same fold have an uncertain relationship, and are not considered in experiments. The classification question then is to decide whether a protein belongs to a certain superfamily.

In the standardized experimental setup defined by Jaakkola and coworkers, and typically used, for each family the protein domains outside the family, but within the same superfamily are taken as positive training samples. Positive test samples are the members of the family. Negative samples are taken from outside the fold to which the family belongs. The set of negative samples is randomly split into training and test samples.

Jaakkola suggests to use only families with at least five family members (positive test) and 10 superfamily members outside the family (positive train). Liao and coworkers [81] suggest using only families with at least 10 family members and five superfamily members outside the family. Both restrictions imply a drastic reduction of the number of families considered at all.

A distincion is made whether all the training data are labeled (supervised learning) or not (semi-supervised learning). The additional data in semi-supervised learning can help to better structure the space around the labeled points. Typically, semi-supervised learning is more expensive and experimentally performs better than supervised learning [177].

Despite the promising developments, it has to be clearly pointed out that SVMs operating directly on the amino acid sequence with kernels like the ones mentioned above currently are not actively used to identify suitable templates. The machine learning methodology requires a certain amount of data for training. Therefore, the protocols used for testing SVMs on the fold recognition problem vary slightly, but significantly, from protocols used to evaluate other current methods. For instance, in CASP6 (see Section 6.3) there was no prediction group relying on kernel methods for template identification.

4 Structure-based Methods for Identifying Templates

Often proteins share similar structure while showing very little (15% or less) sequence identity [62]. Sequence similarity is not necessary for structural similarity, instead extreme divergences of sequences are observed as well as convergent evolution where similar 3-D folds are adopted several times.

Starting in the 1990s, methods were developed for template identification based on structural information such as secondary structure, burial patterns or side-chain pair-interactions. These methods are often referred to as inverse folding, sequence–structure alignment or threading methods. Note, that the term “threading” is widely used to label any method which attempts to tackle the problem of aligning two protein sequences the structure of one of which is known. Originally invented by Jones and coworkers [62] and also frequently used is an alternative definition, according to which “threading” is the alignment of a sequence with a protein structure in 3-D without regard to the sequence associated with the structure [58].

Sequence–structure alignment methods should be able to recognize not only homologous proteins but also analogous proteins sharing the same fold [15, 62]. Most of these methods employ inverse Boltzmann statistics: the frequencies of observed findings are converted into a pseudo-energy function which is optimized in order to find a good sequence–structure alignment (see Section 4.1).

Basically there are two ways of scoring a sequence against a structure. One is to score the interactions of pairs of amino acids of the target sequence within the template structure using pair-interaction potentials as energy functions. Unfortunately, finding a global optimum for this kind of problem has been shown to be NP-hard [77]. There are several approaches to tackle this and we will present four conceptually important ones in Section 4.2.

Alternatively, locations of residues may be evaluated with respect to their placement inside the original template structure afforded by sequence alignments of target and template protein. In this case the global optimum sequence–structure alignment can be found using dynamic programming methods. Standard methods for this are reviewed in Section 4.3.

Today, hybrid algorithms, combining sequence frequency profile methods with sequence–structure methods, are common practice. Either profiles can be integrated into the threading process or methods are exercised separately and the results are merged afterwards. Reviews can be found in Refs. [59, 70, 149, 160]; however, we will first focus on the basic principles.

4.1 Boltzmann's Principle and Knowledge-based Potentials

In protein kinetics, the topography of the landscape of free energies is often described as a funnel [31]. Typically, the energy is assumed to decrease as the folding process proceeds. This organization of the energy landscape is not characteristic of random polypeptides, but is a result of evolution. A common assumption is that the native structure is the one with the lowest free energy. However, many factors contribute to the free energy of the system. Not all factors are known and neither is their interplay completely understood. Therefore, energy landscapes cannot be determined exactly [105].

In addition, in threading we are actually dealing with two structures, i.e. the one to be identified and the one serving as template. The environments of the two structures can be substantially different, making it difficult to apply the same detailed energy potentials to both structures. In spite of these problems, knowledge-based potentials have been employed successfully in threading [19]. Information on different levels of abstraction can be extracted from databases of known structures, with the help of inverse Boltzmann statistics converted into empirical energy potentials.

According to the law of Boltzmann [137, 187] a particular state x of a physical system in equilibrium is occupied with probability $f(x)$:

$$f(x) = \frac{1}{Z} \mathrm{e}^{-\frac{E(x)}{kT}}, \quad \text{where} \quad Z = \int \cdots \int \mathrm{e}^{-\frac{E(x)}{kT}} \mathrm{d}x,$$

k is the Boltzmann's constant, T is the absolute temperature and Z is called the partition function. In a discrete state space, the integrals are replaced by sums. If the energies of all states x are known, the probability densities $f(x)$ can be computed.

Conversely, if the probability density functions f of a system are given [138], the energy can be calculated as:

$$E(x) = -kT \ln(f(x)) - kT \ln(Z).$$

This is frequently referred to as the inverse Boltzmann principle. Z cannot be evaluated by measuring the densities and therefore the energy can be only determined up to the additive constant $-kT \ln(Z)$.

Originally, Boltzmann's equation assumes that the system is in equilibrium. Also, the principle can only be applied to complete systems not to their parts. However, Finkelstein and coworkers showed that a Boltzmann-like distribution arises naturally from low energy conformations of random heteropolymers and similarly of proteins [38, 187]. This suggests that the Boltzmann model can be applied to derive empirical energy functions from ensembles of protein structures even though they are not systems in equilibrium.

4.2 Threading Using Pair-interaction Potentials

Different types of potentials are used in threading. The more accurate potentials rely on pair-interactions of residues (many-body interactions are not considered at all in threading due to their complexity). Most often, distances between pairs of residues, considering their amino acid side-chain types, are condensed into pair-interaction potentials using knowledge-based inverse Boltzmann approaches. Commonly used choices of interaction centers are the C_α atoms, the C_β atoms, the side-chain centers of mass, specially defined interaction centers or any side-chain atom [142].

Finding the globally optimum threading involving a pair-interaction scoring function is NP-hard if variable-length gaps and interactions between neighboring amino residues are allowed [77]. This means that, in order to find an optimal solution, an algorithm requires an amount of time that, in the worst case, is exponential in the size of the protein. Several strategies have been developed to tackle this.

Jones and coworkers [62] use a double dynamic programming algorithm in conjunction with potentials that do not require explicit modeling of all side-chain atoms. They use a set of knowledge-based potentials which are derived from a statistical analysis of known protein structures, according to the inverse Boltzmann principle [137]. For a given pair of atoms, a given residue sequence separation and a given interaction distance these potentials provide a measure of pseudo-energy, which relates to the probability of observing the proposed interaction in native protein structures. By providing different empirical potentials for different ranges of sequence separation, specific structural significance is conferred on each range. The short-range terms predominate in the matching of secondary structural elements. By threading a sequence segment onto the template of an α-helical conformation and evaluating the short-range potential terms, the probability of the sequence folding into an α-helix is evaluated. In a similar way, medium-range terms mediate the matching of super-secondary structural motifs, and the long-range terms the tertiary packing. Around each residue in turn, their algorithm uses dynamic programming as in sequence alignment to optimize the threading of the sequence onto the structure. It finally computes the best threading through the whole structure by means of a shortest-path algorithm.

Lathrop and Smith use core structural models to derive a branch and bound algorithm for threading [78]. A core structural model consists of several core segments. Each position of each core element is occupied by a single amino acid residue from the threaded sequence. Typically core segments correspond to secondary structure elements, i.e. helices or strands. They are connected by a set of loop regions. Neighboring positions are computed, where positions are defined to be neighbors if they contribute a pair-interaction term to the energy-score function. This often but not always requires that they lie close in space, that is make a noncovalent interaction. The use of core elements as larger building blocks reduces the problem size drastically.

Recursive dynamic programming (RDP) [154] is another approach to addressing the full threading problem using heuristics and without restriction to core elements. It is based on the "divide-and-conquer" paradigm and maps the target sequence onto the known backbone structure of a template protein in a stepwise fashion – a technique that is similar to computing local alignments but utilizing different cost functions. It starts by mapping parts of the target onto the template that show statistically significant similarity with the template sequence. After mapping, the template structure is modified in order to account for the mapped target residues. Then significant similarities between the yet unmapped parts of the target and the modified template are searched, and the resulting segments of the target are mapped onto the template. This recursive process of identifying segments in the target to be mapped onto the template and modifying the template is continued until no significant similarities between the remaining parts of target and template are found. Those parts which are left unmapped by the procedure are interpreted as gaps. The RDP method is robust in the sense that different local alignment methods can be used, several alternatives of mapping parts of the target onto the template can be handled and compared in the process, and the cost functions can be dynamically adapted to biological needs.

Xu and coworkers, in their RAPTOR (RApid Protein Threading by Operation Research technique) method, use a linear programming approach to do protein 3-D structure prediction via threading [181–183]. Based on the contact map graph of the protein 3-D structure template, the protein threading problem is formulated as a large-scale integer programming problem. This formulation is then relaxed to a linear programming problem, and solved by a branch-and-bound method. The final solution is globally optimal with respect to their energy functions. The energy function includes pairwise interaction preferences and allows variable gaps.

4.3 Threading using Frozen Approximation Algorithms

The alternative to using full pair-potentials in threading is to evaluate a target sequence with respect to the template structure's original native sequence. While threading the target onto the structure, the interaction partners in the potentials or a set of local environmental preferences are taken from the template protein. With these frozen approximation approaches [47,142], a globally optimum threading – of a problem with reduced complexity compared to the threading problem using full pair-interaction potentials – can be found using dynamic programming methods.

Bowie and coworkers [15] start with a known template structure and describe the environments of its residues by three types of properties: (i) the area of the residues buried in the protein and inaccessible to solvent, (ii) the fraction of side-chain area that is covered by polar atoms, and (iii) the local secondary structure. Based on these parameters each residue is categorized into an environment class. In this manner, a 3-D protein structure is converted into a 1-D string, like a sequence, which represents the environment class of each residue in the folded protein structure. With a sequence-alignment-like algorithm they then seek the most favorable alignment of a protein sequence to this environment string. An alignment column now aligns a residue in the target sequence with an environment class in the template structure. Using inverse Boltzmann statistics, knowledge-based scoring functions have been derived for this kind of match. Later the method was extended to also incorporate secondary structure predictions (helix, strand, coil) on the sequence side to be matched to the secondary structure of the templates [121].

Flöckner and Sippl base their method to determine a sequence to structure alignment on the Needleman–Wunsch algorithm [43,140]. While in sequence comparison the similarity of amino acids is measured directly, Flöckner and

Sippl evaluate the fitness of an amino acid of the query sequence within the template structure by using the energy field generated by the original template structure, while mutating that single residue to the type observed within the query sequence. For this mutated structure a knowledge-based energy function, composed of pairwise atom–atom interactions is evaluated for C_β–C_β interactions.

Also starting from known structures, Alexandrov and Zimmer [2] describe the environments of residues by counting the number of contacts that each amino acid makes in a structure. This information can be matched with sequence information by previously counting the so-called contact capacities, i.e. is the normalized number of contacts that each type of amino acid makes in an ensemble of proteins. Given the number of contact counts per sequence position in the structure and the number of counts a type of amino acid prefers, for each position in the structure's sequence certain types of amino acids are preferable. This information can be aligned to the target sequence with dynamic programming just as in sequence alignment.

5 Hybrid Methods and Recent Developments

5.1 Using Different Sources of Information

Secondary structure prediction and disorder prediction are methods for predicting additional structural features of amino acid sequences (see Chapter 9). Such methods can be used as stand-alone tools to learn more about a target sequence. Alternatively, they can be directly integrated into template identification methods by incorporating the additional sources of information into the scoring functions. In the context of this section, the focus is on the integration of these methods into sequence comparison.

5.1.1 Incorporating Secondary Structure Prediction into Frequency Profiles and HMMs

Often, one of the first steps in structure prediction is to predict the secondary structure of the target protein, that is to annotate each of a sequence's residues with a probability of being contained in a helix, coil or sheet (see Chapter 9). As a result, the field of secondary structure prediction has received considerable attention and is reaching a mature state [1,61,83,92,179].

Predicted secondary structure can be incorporated into other fold recognition methods, e.g. profile–profile, HMM or threading methods [39,88]. In the frequency profile case, the profile matrix with 20 columns for each type of amino acid is extended with an additional profile matrix with three columns for helix, coil and sheet. Both profile matrices are scored against other profile matrices of the same type and the results is merged to a joint score [46, 166]. Wang and Dunbrack state that incorporation of secondary structure information improves alignment accuracy slightly [171] and improves the search capabilities of the average score mentioned in Section 3.2.5 significantly.

Secondary structure information was also used to extend the HMM principle [64, 67]. Karchin and Karplus incorporated predicted local structure into so-called two-track profile HMMs. They did not rely on a simple helix–strand–coil definition of secondary structure, but experimented with a variety of local structure descriptions, and established which descriptions are most useful for improving fold recognition and alignment quality. On a test set of 1298 nonhomologous proteins, HMMs incorporating a three-letter alphabet improved fold recognition accuracy by 15% over HMMs using amino acids only. Comparing two-track HMMs to HMMs operating on amino acids only, on a difficult alignment test set of 200 protein pairs, Karchin found that HMMs with a six-letter secondary track improved alignment quality by 62%, relative to DALI [53] structural alignments.

5.1.2 Intrinsically Disordered Regions in Proteins

While the analysis and prediction of secondary structure is a matured subject, the interest in intrinsic disorder of proteins (see Chapter 9) has grown tremendously over the last couple of years [33, 63, 84, 102, 104, 119, 157, 158, 174].

Intrinsically disordered proteins do not fold into stable 3-D structure; instead, in solution they exist as an ensemble of interchanging conformations. There are examples of proteins which are disordered completely and others where only part of the amino acid sequence does not fold stably. In a recent study [103] based on six genomes, roughly 5% of proteins in bacteria, 7% in archea and 25% in eukaryotes were estimated to be mostly disordered. Ward and coworkers [174] predict an average of 2% of archaean, 4% of eubacteria and 33% of eukaryotic proteins to contain more than 30 residues of disorder. Thus, proteins with disordered regions seem to be especially common in eukaryotic cells. Often, proteins with disordered regions perform a function: they are involved in protein–protein [76, 82, 85] or protein–nucleic acid [148] interactions. Under certain conditions disordered fragments become structured during the process of interaction. In the electron density maps of X-ray crystallographic studies, disordered regions frequently do not appear; in NMR experiments, they appear highly flexible.

As stretches of amino acids that do not fold into a stable structure should not be predicted to have a structure, disorder prediction (see Chapter 9) has become important in structure prediction. Methods have been developed which annotate each residue of an amino acid sequence with a value of predicted disorder. These methods are based on machine learning techniques like neural nets or support vector machines and employ training sets of disordered regions to learn to discriminate ordered from disordered stretches of sequence [63, 84, 103, 104, 119, 168].

To the best of our knowledge such methods have not yet been incorporated into fold recognition methods as has been done with secondary structure prediction, but this should only be a matter of time.

5.1.3 Incorporating 3-D Structure into Frequency Profiles

Frequency profiles can be derived from sequences alone, as reviewed in Section 3.2.2. Alternatively, structure-based multiple alignments can be used for the generation of profiles. For this, multiple structure superposition is performed on the available structures to create a multiple alignment of their sequences which is then used to generate a frequency profile as described in Section 3.2.2 above [23, 69, 107, 114, 152, 184]. There are actually two aspects to this. First, using structure superposition to create multiple alignments even for cases where sequence alignment is not feasible. This potentially results in an increase of coverage at a loss of precision. Second, using available structures to generate more reliable seed alignments, increasing precision.

5.2 Combining Information

Recent contributions to the field of fold recognition have been integrative, collecting information from many sources. The GenTHREADER program [60, 93] for automatic fold recognition consists of a neural net which was trained to combine sequence alignment score, length information and energy potentials derived from threading into a single score representing the relationship between two proteins [60]. An improved version incorporates PSI-BLAST searches and also makes use of predicted secondary structure [93].

Another competitive example for the combination of information is the TASSER/PROSPECTOR suite of programs developed by Skolnick and coworkers. PROSPECTOR_3 is an iterative approach to search for diverse templates using a variety of pair potentials and scoring functions [143, 188]. Different frequency profiles are used in a first round to identify templates. These targets are further evaluated in subsequent evaluations of pair interactions. The scoring functions include a quasi-chemical based pair potential [141], a protein-specific, orientation-independent pair potential based on local sequence fragments [144] and a pair potential that depends on the orientation of the side-chains [144]. With the templates identified by PROSPECTOR, the TASSER program performs tertiary structure assembly via the rearrangement of continuous template fragments [189].

Another example is the SPARKS method (Sequence, secondary structure Profiles and Residue-level Knowledge-based energy Score) [191], in which Zhou and Zhou use a knowledge-based energy function for fold recognition.

Being a residue-level frozen approximation potential, the dynamic programming method can be used for alignment optimization. The potential contains a backbone torsion term, a buried surface term and a contact-energy term. With sequence profile and secondary structure information it is combined into a joint fold recognition method. Taking advantage of sequence and structure methods it was highly competitive in the latest CASP experiment.

Like this one, there are a number of other approaches integration information from programs running locally or collecting information from web services [166].

5.3 Meta-servers

Meta-servers collect and analyze results from individual web servers and combine them into a joint result. Benchmarking results obtained in the last years indicate that, on average, meta-servers are more accurate than individual methods.

One first successful attempt to benefit from a number of distributed information sources was the PCONS meta-server, which concentrates on a number of reliable servers at different locations and selects the most abundant fold among their high-scoring models [86]. It translates the confidence scores reported by each server into uniformly scaled values corresponding to the expected accuracy of each model. The translated scores as well as the similarity between initial models is used as input to a neural network in charge of the final selection.

Several other meta-methods followed soon afterwards. Current methods differ in how the initial models are compared, whether scores provided by the individual methods are used and how the final model is generated.

The 3D-Jury system uses the rationale that the high-scoring models which are produced by several servers are closer to the native structure than the single model with highest score. Thus, models occurring with higher than expected frequencies are are taken for the preferred conformation [44, 163].

The 3D-SHOTGUN meta-predictor employs techniques of so-called cooperative algorithms from computer vision. As input it takes the models with their confidence scores. The result is a hybrid model, which is spliced from fragments of the input models. It has the potential of covering a larger part of the native protein than any template structure alone. Thus, 3D-SHOTGUN entails the first fold recognition meta-predictor attempt to go beyond the simple selection of one of the input models [40].

6 Assessment of Models

Once a template is identified it can be assessed in a number of ways. (i) The significance of the selection of the template can be estimated. (ii) After a model has been constructed on the basis of the template, the quality of the 3-D model can be scored. (iii) If the native structure for which the prediction was made becomes known later, the quality of the model can be evaluated, in terms of how faithfully it represents the true structure. Thus, conclusions about the method producing the prediction can be drawn.

6.1 Estimating Significance of Sequence Hits

Essentially, methods for template identification compute a list of candidate templates for a target sequence. The method typically employs a scoring system or (virtual) energy function according to which the list is sorted and the maximum scoring candidate is selected as template. Before using a template to build a model the question how reliably the template is related to the target needs to be addressed.

The classic approach to this is to calculate the probability of obtaining a maximum score greater than the observed score assuming that the protein sequences compared with the scoring system are unrelated. This probability is called p-value. To compute it one needs to know the distribution of maximal scores for unrelated sequences for the particular scoring scheme. The E-value is a similar concept, additionally taking the size of the database of templates into account [5,6].

For some template identification methods the score distributions are known, thus scores can be readily converted into p-values (see Section 4 in Chapter 3). For other methods empirical confidence scores have been developed.

For optimal local gapless sequence alignments of independent random sequences the score distributions are known to be of an asymptotically extreme-value or Gumbel form [65]: $P(score > t) \approx 1 - \mathrm{e}^{-K\mathrm{e}^{-\lambda t}}$, where λ depends only on the scoring system and K depends on the scoring system and the sequence lengths, such that the distribution reflects the fact that the chance of spurious high scores increases with sequence lengths. The dependence of the parameters on the scoring system and sequence lengths is known.

For local alignments with gaps of unrelated biological sequences no general theory is available. However, there is considerable evidence that the distribution is still of extreme-value form and parameters can be fitted experimentally [4,75,80,95,112,175]. Local alignments using frequency profile sequences were also shown to follow an extreme-value distribution [95].

For optimal global alignments, whether with plain sequences or sequence profiles, theoretically neither the family of distributions nor the dependence of the expected score (or of other parameters) on the sequence lengths is known. However, there exist approaches for experimentally fitting distributions to scores [109, 176].

For frozen approximation sequence–structure alignment the situation is similar to sequence alignment: the local threading scores of sample sequence–structure pairs often can be fitted to a Gumbel distribution [147]. In the global threading case the distribution is unknown.

For the methods for which no theory is available, heuristic approaches exist for estimating reliability of the predictions. One generic approach is to derive a function of target and template which is reasonably associated with reliability, and then statistically test it on a set of proteins to estimate the probability for an identified target being correct (e.g. Ref. [147]). One such target–template comparison function is, for example, the difference of the score of the target sequence aligned to the template and the reversed target sequence aligned to the template. This is much faster than repeatedly evaluating the score relative to that of a randomized sequence [66, 143].

For a more detailed discussion, see Ref. [34], where the classical statistical assessment of significance of scores is also compared to Bayesian approaches.

6.2 Scoring 3-D Model Quality: Model Quality Assessment Programs (MQAPs)

The template identification methods discussed above compute suggestions for templates. With a target-template alignment, a model can be computed. MQAPs serve to distinguish near-native structures (i.e. "good" predictions) from decoys (i.e. "bad" predictions). MQAPs are programs that receive as input a 3-D model of a protein structure and produce as output a real number representing the quality of the model (http://www.cs.bgu.ac.il/∼dfischer/CAFASP4/mqap.html). MQAPs only use the model as input, not the native structure, and thus stand in contrast to methods that evaluate the quality of a model when comparing it to the native structure.

In contrast to scoring functions in sequence–structure alignment and to physical energy functions, MQAPs operate on an intermediate level – they are more flexible than a sequence–structure alignment function as the dynamic programming paradigm used in alignment imposes the requirement of prefix optimality which is not required in MQAPs. On the other hand, MQAP functions are not sensitive to ruptures in the sequences in contrast to physical energy functions. MQAPs target at scoring the quality of predicted models. Typically, MQAPs use one or more different statistical potentials, representing information coded in protein structures [87, 116, 139, 159]. For example, the FRST method uses a combination of pairwise, solvation, hydrogen bond and torsion angle potentials [159]. An intuitive test for a scoring function is picking the native structure among a set of decoys. A number of decoy sets have been made available [127] and are used for training.

In 2004, CAFASP4 [42] provided infrastructure to perform a fully automated blind test of MQAPs on the CASP target proteins and the structure predictions made during CASP. In this test the five following programs were rated as most reliable: FRST [159], Verify3-D [87], RAPDF [128], ProsaII [139] and ProQ [169].

Generating different alignments between target and template using various alignment methods and then employing an MQAP to pick out the best one can potentially lead to an improved overall alignment result.

6.3 Evaluation of Protein Structure Prediction: Critical Assessment of Techniques for Protein Structure Prediction

The performance of methods like the ones reviewed above needs assessment. The performance of sequence–structure alignment methods can be assessed either by testing their fold recognition performance [20, 37, 71] or by benchmarking their alignment quality [130, 171]. For assessing fold recognition performance, classification performance of different methods is tested versus a standard like the SCOP database for structure classification. For measuring alignment quality, the sequence–structure alignments produced by threading methods are compared to high-quality alignments as produced by structure superposition methods. CASP, a blind testing experiment, has had a large impact on the community and is therefore summarized in the following.

CASP was started in 1994 [98]. The idea was to establish a clearinghouse between experimental and predicted protein structure. Protein sequences whose structure is currently being analyzed experimentally are made available to structure prediction groups. Structural models are predicted by a number of participating groups and submitted to the CASP organizers before the release of the crystal structures. After the release of the crystal structures, the predicted models are compared with them by a number of human experts – the CASP assessors. Typically, the structures are categorized according to their difficulty into homology modeling, fold recognition and *de novo* targets. CASP has been held biannually. The number of targets has been growing from 33 (CASP1 in 1994) to 42, (CASP2), 43 (CASP3), 43 (CASP4), 67 (CASP5) and 64 (CASP6 in 2004), as well as the number of participating prediction groups from 35 (CASP1) to 152 (CASP2) to 201 human groups and 65 servers in CASP6.

Within the original setup of CASP humans can interact with computer programs to generate protein models. In this setting, it is hard to discriminate between the contribution of the human and the program, respectively. This issue was resolved by introducing CAFASP [41], where the additional FA in the acronym stands for fully automated. In CAFASP, server programs are directly contacted by the clearinghouse and have to respond within a short timeframe (usually 48 h) and without human intervention.

In order to perform the comparisons of predicted models and experimental structures, different assessors have chosen different approaches. Some completely relied on manual inspection (which is a tremendous amount of work). Due to the number of participating groups, computerized preprocessing of the results is becoming the standard procedure. Different distance measures for measuring the fractional similarity between the experimental and the predicted structure have been employed. Currently the GDT_TS score is used for CASP and the MaxSub score in CAFASP. The GDT_TS score is computed by the LGA program which simultaneously optimizes for local structure and global RMSD superposition using different cutoffs [186]. MaxSub aims at identifying the largest subset of C_α atoms of a model that superimpose "well" over the experimental structure [135]. Both measures produce a single normalized score that represents the quality of the model. Both measures differ in details, but correlate on concrete examples [190].

CASP5 (2002) results for fold recognition methods are summarized in Ref. [70], results of CASP6 (2004) are in press at the time of writing [96, 161, 172]. While there is an obvious danger of overtraining to the experiment, the CASP community has been eager to pick up new trends and find ways to evaluate them. Examples are the evaluation of predicted intrinsic disorder at CASP5 and CASP6 or the assessment of prediction of domain boundaries and model quality assessment programs at CASP6.

Continuous experiments, LiveBench and EVA, are performed by weekly extracting newly published structures from the PDB and submitting them to automated servers. Based on automated measures like MaxSub, the quality of the predictions of participating servers can be measured online [21, 122].

7 Programs and Web Resources

The web resources for protein structure prediction are extensive. Since search engines have a tendency to be more up-to-date and practical than link lists in books, we give an overview and further pointers here only. Good starting points for fold recognition via the Internet are meta-servers and the CASP experiment. Meta-servers provide functionality for unproblematically exercising a number of servers simultaneously in order to perform structure predictions. The CASP experiment provides a list of the best performing methods today; although some of these might not be as easily accessible or very compute intensive to exercise.

Bioinfo/3D-Jury	http://bioinfo.pl/meta
PredictProtein	http://www.embl-heidelberg.de/predictprotein/predictprotein
CASP	http://predictioncenter.org
CAFASP	http://www.cs.bgu.ac.il/∼dfischer/CAFASP4

For high-throughput experiments as well as confidentiality reasons one may want to install fold recognition software locally. Unfortunately, this software tends to depend on a number of libraries (templates, profiles, potentials, motifs, etc.) which need to be up-to-date in order to be performant and which have a tendency to be cumbersome to install. An obvious starting point for downloadable software is PSI-BLAST. Some HMM software is freely available. Most profile software is available through contacting the respective authors only. URLs of BLAST and two HMM libraries are:

BLAST	http://www.ncbi.nlm.nih.gov/BLAST
HMMer	http://hmmer.wustl.edu
SAM	http://www.cse.ucsc.edu/compbio/sam.html

Links to key databases are:

PDB	http://www.rcsb.org/pdb
SCOP	http://scop.mrc-lmb.cam.ac.uk/scop
Entrez DB Collection	http://www.ncbi.nlm.nih.gov/gquery/gquery.fcgi

Also Kevin Karplus provides an up to date link list, related to this chapter:

http://www.soe.ucsc.edu/∼karplus/compbio_pages

Acknowledgments

This work was funded in part by grant Le 491/14 of the Deutsche Forschungsgemeinschaft. I thank my colleagues at the Max-Planck-Institut for Informatics for their support. I am particularly grateful to Mario Albrecht, Francisco S. Domingues, Andreas Kaemper, Lars Kunert, Oliver Sander and Thomas Lengauer for critically reading the manuscript and improving it considerably.

De Novo Structure Prediction: Methods and Applications

Richard Bonneau

1 Introduction

1.1 Scope of this Review and Definition of *De Novo* Structure Prediction

This review will focus on the questions: (i) what are the features common to methods that represent the current state of the art in *de novo* structure prediction and (ii) how can these methods benefit biologists whose primary aim is a systems-wide description of a given organism or system of organisms. The role and capabilities of *de novo* structure prediction as well as the relationship of *de novo* structure prediction to other sequence and structure-based methods is far from simple. The literature on this subject is rapidly evolving; for balance in coverage and opinion the reader is also referred to recent reviews of *de novo* structure prediction methods [11,27,32,39,50].

Many methods that are today referred to as *de novo* have alternately or previously been referred to *ab initio* or "new folds" methods. For the purpose of this review I will classify a method as *de novo* structure prediction if that method does not rely on homology between the query sequence and a sequence in the Protein Data Bank (PDB) to create a template for structure prediction. *De novo* methods, by this definition, are forced to consider much larger conformational landscapes than fold recognition and comparative modeling techniques that limit the exploration of conformational space to those regions close to the initial structural template or templates.

Another common pedagogical distinction between structure prediction methods has been the distinction between methods based on statistical principles, on the one hand, and physical or first principles, on the other hand. I will not discuss this distinction here at great length except for noting that one of the shortcomings of this artificial division is that most effective structure prediction methodologies are in fact a combination of these two camps. For example, several methods that are described as based on physical or first-principles employ energy functions and parameters that are statistical approximations of data (e.g. the Lennard–Jones representation of van der

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

Waals forces is often thought of as a physical potential, but is a heuristic fit to data). Most current successful *de novo* structure prediction methods fall into the statistics camp. A more useful distinction may be the distinction between reduced complexity models and models that use atomic detail. Throughout this chapter I will discuss low-resolution (models containing drastic reductions in complexity such as unified atoms and centroid representations of side-chain atoms) and high-resolution methods (methods that represent protein and sometimes solvent in full atomic detail) focusing on this practical classification/division of methods in favor of distinctions based on a given method's derivation or parameterization.

1.2 The Role of Structure Prediction in Biology

What is the main application of structure prediction to biology? At present this is an open question that will take many years to develop, as the answer relies on the relative rate of progress in several fields. In short, I will argue that the main current application of structure prediction in biology lies in understanding protein function. Structure predictions can offer meaningful biological insights at several functional levels depending on the method used to generate the structure prediction, the expected resolution and the comprehensiveness or scale on which predictions are available for a given system.

At the highest levels of detail/accuracy (comparative modeling) there are several similarities between the uses of experimental and computational/predicted protein structure and the types of functional information that can be extracted from models generated by both methods [4]. For example, experimentally determined structures and structures resulting from comparative modeling can be used to help understand the details of protein function at an atomic scale, map conservation and mutagenesis data onto a structural framework, and explore detailed functional relationships between protein with similar folds or active sites.

At the other end of the prediction resolution spectrum, *de novo* structure prediction and fold recognition methods produce models of lower resolution than comparative models (see Chapter 10). These models can be used to assign putative functions to proteins for which little is known [15]. At the most basic level we can use structural similarities between a predicted structure and known structures to explore possible distant evolutionary relationships between query proteins of unknown function and other well-studied proteins for which structures have been experimentally determined. A query protein is likely to share some functional aspects with proteins in the PDB that show strong structure–structure matches to a high confidence predicted structure for that protein. This is based on the assumption that detectable structure relationships are conserved across a greater evolutionary distance than are detectable sequence similarities. This assumption is well supported by multiple surveys of the distributions of folds and their related functions in the PDB [48, 68, 76, 83]. The relationship between fold and function, however, is by no means a simple subject, and I refer the reader to several works that discuss this relationship in greater detail [56, 70, 84, 107]. Another way of exploring the functional significance of high confidence predicted structures is to use libraries of three-dimensional (3-D) functional motifs to search for conserved active site or functional motifs on the predicted structures [33, 72, 103]. Both basic methods, fold–fold matching and the use of small 3-D functional motif searches, can in principle be combined to form the basis for deriving functional hypothesis from predicted structure, thereby extending the completeness of genome annotations based only on primary sequence. For more details on how to infer protein function from protein structure, see Chapter 34.

1.3 *De novo* Structure Prediction in a Genome Annotation Context, Synergy with Other Methods

To date, the annotation of protein function in newly sequenced genomes relies on a large array of tools based ultimately on primary sequence analysis [3, 9, 19, 100]. These tools have afforded great progress in genome annotation including large improvements in gene detection, sequence alignment and detection of homologous sequences across genomes as well as the creation of databases of common protein families and primary sequence functional motifs. Comparative modeling methods have been highly successful on many fronts, creating large databases of highly accurate structure predictions for many organisms, but are based on primary sequence matches between PDB and query sequences [87] (see Chapter 10). Primary sequence methods also exist for the prediction of basic local structure qualities (some of these patterns being lower complexity patterns) of sequences such as the location of coiled-coil, transmembrane and disordered regions [52, 80, 99, 104]. Efforts to use *de novo* structure prediction (and/or fold recognition) must employ these sequence-based methods, as these methods provide a solid foundation on which all *de novo* methods discussed herein are reliant (see Figure 1). Any organization of these methods into an annotation pipeline must properly account for the fact that the accuracy/reliability is quite different between sequence and structure-based methods. One approach is to use structure prediction as part of a hierarchy where methods yielding high-confidence results are exhausted prior to computationally expensive and less accurate *de novo* structure prediction and fold recognition [12] . I will describe some early results from these approaches/pipelines that include structure prediction, the

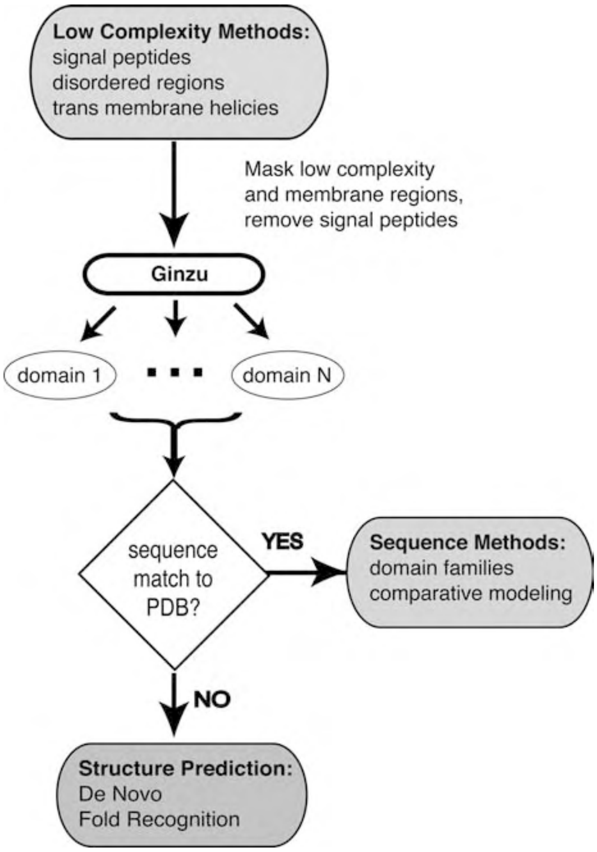

Figure 1 Idealized proteome structure annotation pipeline. Low-complexity regions such as transmembrane helices, signal peptides and disordered regions are masked, and domains dominated by these low-complexity or transmembrane sequence are treated separately. Remaining sequences are parsed to separate regions into structural domains to the degree that such domains are detectable (here, Ginzu is shown as the domain parsing algorithm, see Figure 4). Domains that do not have strong sequence matches to the PDB or other matches to well-annotated domains (Pfam, COG) are forwarded to structure-based methods. The use of structure prediction methods is positioned within this hierarchy of methods to increase comprehension of the resulting annotation without compromising the results obtained by sequence-based methods.

details of these pipelines and the technical and research challenges that remain in applying these pipelines to genome annotation [6,45,86].

The need for methods for predicting transmembrane proteins and understanding membrane–protein interactions is not discussed in this work (see Chapter 9 for this topic), the focus here is instead on soluble domains (including soluble domains excised from proteins containing transmembrane regions). Part of the difficulty in predicting transmembrane protein structure lies in the paucity of membrane protein structures deposited in the PDB

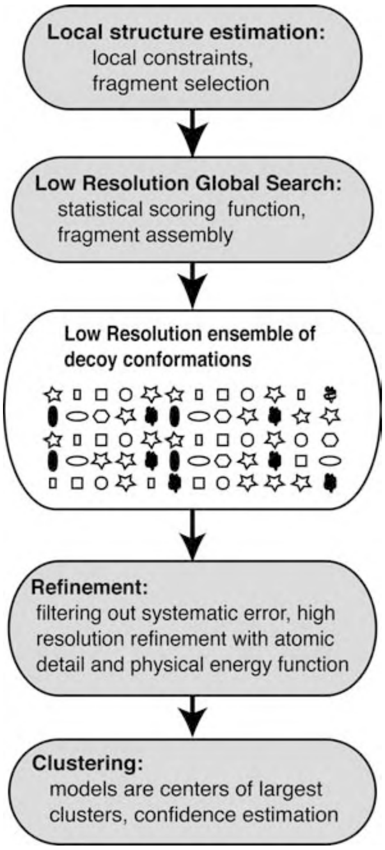
[28, 99]. It is only with access to the PDB, an ideal and comprehensive gold standard, by many criteria, that we can approach the problem of predicting soluble protein structure.

2 Core Features of Current Methods of *De Novo* Structure Prediction

We will now discuss core concepts that are common to multiple successful current *de novo* methods. This review is not intended to be encyclopedic and will invariably fail to mention several methods that are innovative and/or accurate in its attempt to focus on core concepts instead of distinct methodologies. The omission of any specific method should not be interpreted as commentary on the relative accuracy of the omitted method, but is simply due to the scope of this work and the state of rapid development in this field.

2.1 Rosetta *De Novo*

Throughout this work I will use examples of key concepts in *de novo* structure prediction with several examples drawn from the Rosetta *de novo* structure prediction protocol and will thus provide a brief overview of Rosetta before continuing to discuss key elements of the procedure in greater detail [13, 90, 97, 98] (see Figures 2 and 3). Results from the fourth and fifth Critical Assessments of Structure Prediction (CASP4, CASP5 and CASP6; see also Chapter 11) have shown that Rosetta is currently one of the best methods for *de novo* protein structure prediction and distant fold recognition [16, 18, 26, 65]. Rosetta was initially developed as a computer program for *de novo* fold prediction, but has been expanded to include design, docking, experimental determination of structure from partial datasets, protein–protein interaction and protein–DNA interaction prediction [25, 41, 42, 57, 59, 60, 88, 89]. When referring to Rosetta in this work I will be primarily referring to the *de novo* or *ab initio* mode of the Rosetta code base. Early progress in high-resolution structure prediction has been achieved via combinations of low-resolution approaches (for initially searching the conformational landscape) and higher-resolution potentials (where atomic detail and physically derived energy functions are employed). Thus, Rosetta structure prediction is carried out in two phases: (i) a low-resolution phase where overall topology is searched using a statistical scoring function and fragment assembly, and (ii) an atomic-detail refinement phase using rotamers and small backbone angle moves, and a more physically relevant (detailed) scoring function. The algorithms for searching the landscape are Monte-Carlo-type in both phases.



Local structure estimation:

clusters, confidence estimation

Figure 2 Schematic outline of Rosetta structure prediction protocol. Single sequences enter at the top of this schematic and confidence-ranked structure predictions are produced by the last/bottom step.

In the first phase, Rosetta *de novo* (Rosetta) uses information from the PDB to estimate the possible conformations for local sequence segments. The procedure first generates libraries of local sequence fragments excised from the PDB on the basis of local sequence similarity (three- and nine-residue matches between the query sequence and a given structure in the PDB). See Figure 1 for a schematic overview of the low-resolution (or fold prediction) phase of the Rosetta method, and see Tables 1 and 2 for a complete description of the Rosetta score. Rosetta fragment generation works well even for sequences that have no homologs in the known sequence databases; the structures in the PDB cover possible local sequence well at the three- and nine-residue length according to the current method. Rosetta then assembles these pre-computed local structure fragments by minimizing a global scoring function that favors hydrophobic burial/packing, strand pairing, compactness and highly proba-

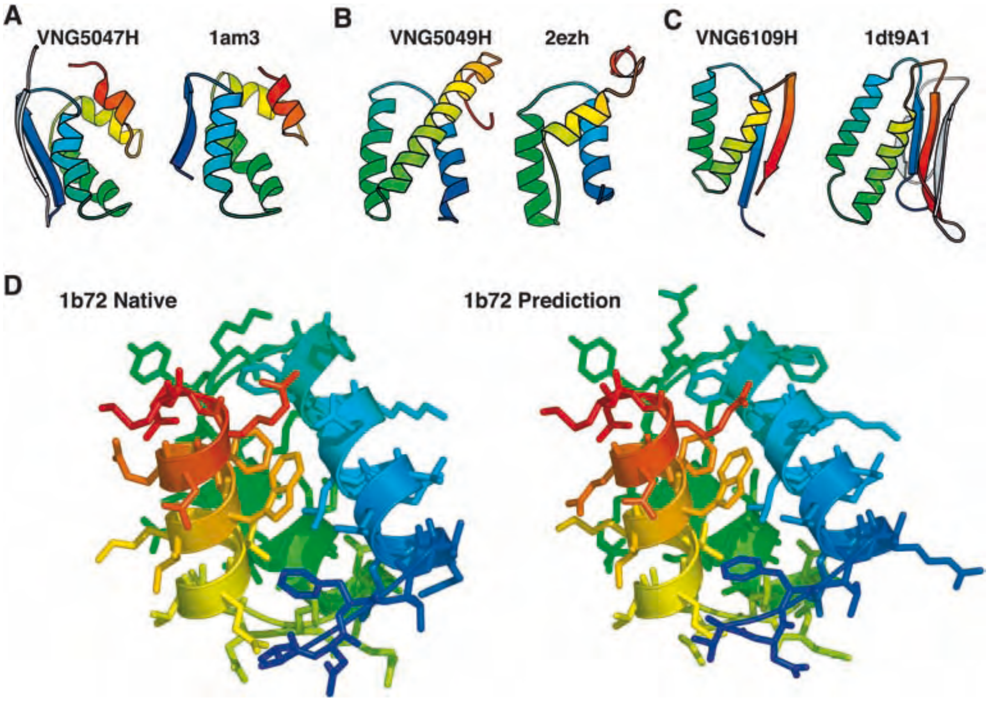

Figure 3 Examples of *de novo* structure predictions generated using Rosetta. (A–C) Examples from our genome-wide prediction of domains of unknown function in *Halobacterium* NRC-1 [12]. In each case the predicted structure is shown next to the correct native. For (A–C) only the backbone ribbons are shown, as these predictions were not refined using the all-atom potential and are examples of the utility of low-resolution prediction in determining function. (D) A recent prediction where high-resolution refinement subsequent to the low-resolution search produced the lowest energy conformation, a prediction of unprecedented accuracy (provided by Phil Bradley) [17].

ble residue pairings. The Rosetta score for this initial low-resolution stage is described in its entirety in Table 1. For the second, refinement, stage centroid representations of amino acid side-chains are replaced with atomic detail (rotamer representations). The scoring function used during this refinement phase includes solvation terms, hydrogen bond terms and other terms with direct physical interpretation. See Table 2 for a full description of the all-atom Rosetta score. Features of the high- and low-resolution phases of the Rosetta method are described below as I discuss key components of *de novo* structure prediction universal to all successful methods.

Using Rosetta generated structure predictions we were able to recapitulate many functional insights not evident from sequence based methods alone [14, 15]. We have reported success in annotating proteins and protein families without links to known structure with Rosetta [8, 14]. Various aspects of this

Table 1 Low-resolution, centroid-based Rosetta scoring function[a]

Name	Description (physical origin)	Functional form	Parameters (values)
env[b]	residue environment (solvation)	$\sum_i - \ln[P(aa_i \vert nb_i)]$	i = residue index aa = amino acid type nb = number of neighboring residues[c] (0, 1, 2, ..., 30. >30)
pair[b]	residue pair interactions (electrostatics, disulfides)	$\sum_i \sum_{j>i} - \ln \left\lfloor \frac{P(aa_i, aa_j \vert s_{ij} d_{ij})}{P(aa_i \vert s_{ij} d_{ij}) P(aa_j \vert s_{ij} d_{ij})} \right\rfloor$	i, j = residue indices aa = amino acid type d = centroid–centroid distance (10–12, 7.5–10, 5–7.5, <5 Å) s = sequence separation (>8 residues)
vdw[g]	steric repulsion	$\sum_i \sum_{j>i} \frac{(r_{ij}^2 - d_{ij}^2)^2}{r_{ij}^2}; \quad d_{ij} < r_{ij}$	i, j = residue (or centroid) indices d = interatomic distance r = summed van der Waals radii[h]
rg	radius of gyration (van der Waals attraction; solvation)	$\sqrt{\langle d_{ij}^2 \rangle}$	i, j = residue indices d = distance between residue centroids
cbeta	C_β density (solvation; correction for excluded volume effect introduced by simulation)	$\sum_i \sum_{sh} - \ln \left\lfloor \frac{P_{\text{compact}}(nb_{i,sh})}{P_{\text{random}}(nb_{i,sh})} \right\rfloor$	i = residue index sh = shell radius (6, 12 Å) nb = number of neighboring residues within shell[f] $P_{compact}$ = probability in compact structures assembled from fragments P_{random} = probability in structures assembled randomly from fragments

overall protocol will be reviewed in greater detail below. We also encourage the reader to refer to several prior works where the Rosetta method is described in its entirety.

2.2 Evaluation of Structure Predictions

In general the most effective methods for predicting structure *de novo* depend on parameters ultimately derived from the PDB. Several methods use the PDB directly to estimate local sequence and even explicitly use fragments of local sequence from the PDB to build global conformations. These uses of the PDB require that methods be tested using structures not present in the sets

Table 1 continued

Name	Description (physical origin)	Functional form	Parameters (values)
SS[d]	strand pairing (hydrogen bonding)	Scheme A: $\mathrm{SS}_{\phi,\theta}$ + SS_{hb} + SS_{d} Scheme B: $\mathrm{SS}_{-\phi,\theta}$ + SS_{hb} + $\mathrm{SS}_{d\sigma}$ where $SS_{\phi,\theta} = \sum_{m} \sum_{n>m}$ $- \ln[P(\phi_{mn}, \theta_{mn} \vert d_{mn}, sp_{mn}, s_{mn})]$ $SS_{hb} = \sum_{m} \sum_{n>m}$ $- \ln[P(hb_{mn}, \vert d_{mn}, s_{mn})]$ $SS_{d} = \sum_{m} \sum_{n>m}$ $- \ln[P(d_{mn}, \vert s_{mn})]$ $SS_{d\sigma} = \sum_{m} \sum_{n>m}$ $- \ln[P(d_{mn}, \sigma_{mn} \vert \rho_{m}, \rho_{n})]$	m, n = strand dimer indices; dimer is two consecutive strand residues $\hat{V}$ = vector between first N and last C atom of dimer $\hat{m}$ = unit vector between $\hat{V}m$ and $\hat{V}n$ midpoints $\hat{x}$ = unit vector along carbon-oxygen bond of first dimer residue $\hat{y}$ = unit vector along oxygen-carbon bond of second dimer residue ϕ, θ = polar angles between $\hat{V}m$ and $\hat{V}n$ (10, 36° bins) $hb = dimertwist,$ $\sum_{k=m,n} 0.5(\vert\hat{m} \cdot \hat{x}_k\vert + \vert\hat{m} \cdot \hat{y}_k\vert)$ (<0.33, 0.33–0.66, 0.66–1.0, 1.0–1.33, 1.33–1.6, 1.6–1.8, 1.8–2.0) d = distance between $\hat{V}m$ and $\hat{V}n$ midpoints (<6.5 Å) σ = angle between $\hat{V}m$ and $\hat{M}$ (18° bins) sp = sequence separation between dimer-containing strands (<2, 2–10, >10 residues) s = sequence separation between dimers (>5 or >10) ρ = mean angle between vectors $\hat{m}$, $\hat{x}$ and $\hat{m}, \hat{y}$ (180° bins)
sheet[e]	strand pair arrangement into sheets	$- \ln[P(n_{\mathrm{sheets}} n_{\mathrm{lone\_strands}} \vert n_{\mathrm{strands}})]$	n_{sheets} = number of sheets $n_{\mathrm{lone\_strands}}$ = number of unpaired strands n_{strands} = total number of strands
HS	helix-strand packing	$\sum_{n} \sum_{n} - \ln[P(\phi_{mn}, \psi_{mn} \vert sp_{mn} d_{mn})]$	m = strand dimer index; dimer is two consecutive strand residues n = helix dimer index; dimer is central two residues of four consecutive helical residues $\hat{V}$ = vector between first N and last C atom of dimer ϕ, θ = polar angles between $\hat{V}m$ and $\hat{V}n$ (36° bins) sp = sequence separation between dimer-containing helix and strand (binned <2, 2–10, >10 residues) d = distance between $\hat{V}m$ and $\hat{V}n$ midpoints (<12 Å)

of protein structures used to train these methods (or present in the sets of structures used to predict local structure fragments). The first such evaluation of structure prediction, CASP (see Chapter 11 for a more detailed description), showed that published estimates of prediction error were smaller than prediction error measured on a set of novel proteins outside the training set (this is not surprising given the difficulties of avoiding overfitting in as complex a data space as protein structure) [64]. Indeed, early experiments showed that no methods for *de novo* structure prediction were effective outside of carefully chosen benchmarks containing only the smallest proteins. Spurred on by these early evaluations the field returned to the drawing board and two years later produced multiple methods with much higher accuracies in the new folds or *de novo* category (CASP3) [73,75,82]. Thus, the CASP experiments proved to be invaluable to the field at that point in the development of the field, provoking a renewed interest in the *de novo* structure prediction and properly realigned interest in techniques according to effectiveness.

Arguably, CASP has the flaw that predictors are allowed to intervene and manually curate their predictions prior to submission to the CASP evaluators. Thus, the results of CASP are a convolution of: (i) the art of prediction (each group's intuition and skill using their tools) and (ii) the relative performance

Footnotes to Table 1:

[a] The individual components in the Rosetta score (the score used by Rosetta during low-resolution/centroid mode *de novo* structure prediction) are given as described originally in Simons [96–98].

[b] Binned function values are linearly interpolated, yielding analytic derivatives.

[c] Neighbors within a 10 Å radius. Residue position defined by C_β coordinates (C_α for glycine).

[d] Interactions between dimers within the same strand are neglected. Favorable interactions are limited to preserve pairwise strand interactions, i.e. dimer m can interact favorably with dimers from at most one strand on each side, with the most favorable dimer interaction ($SS_{\phi s\theta}$ + SS_{hb} + SS_{d}) determining the identity of the interacting strand. $SS_{d\sigma}$ is exempt from the requirement of pairwise strand interactions. SS_{hb} is evaluated only for m, n pairs for which $SS_{\phi,\theta}$ is favorable. $SS_{d\sigma}$ is evaluated only for m, n pairs for which $SS_{\phi,\theta}$g and SS_{hb} are favorable. A bonus is awarded for each favorable dimer interaction for which $|m \; - - n| > 11$ and strand separation is more than eight residues

[e] A sheet is comprised of all strands with dimer pairs less than 5.5 Å apart, allowing each strand having at most one neighboring strand on each side. Discrimination between alternate strand pairings is determined according the most favorable dimer interaction. Probability distributions fitted to $c(n_{\text{strands}}) - 0.9n_{\text{sheets}} - 2.7n_{\text{lone\_strands}}$ where $c(n_{\text{strands}}) = (0.07, 0.41, 0.43, 0.60, 0.61, 0.85, 0.86, 1.12)$.

[f] Residue position defined by C_β coordinates (C_α for glycine).

[g] Not evaluated for atom (centroid) pairs whose interatomic distance depends on the torsion angles of a single residue.

[h] Radii determined from (i) 25th closest distance seen for atom pair in pdbselect25 structures, (ii) the fifth closest distance observed in X-ray structures with better than 1.3-Å resolution and less than 40% sequence identity or (iii) X-ray structures of less than 2 Å resolution, excluding i, i + 1 contacts (centroid radii only).

of the core methods (the performance of each method in an automatic setting). Although this convolution reflects the reality when workers aim to predict proteins of high interest, such as proteins involved in a specific function or proteins critical to a given disease or process being experimentally studied, it does not reflect the demands placed on a method when trying to predict whole genomes, where the shear number of predictions does not allow for much manual intervention. Several additional tests similar to CASP (in that they are blind tests of structure prediction) have been organized in response to the concerns of many that it is important to remove the human aspects of CASP. The Critical Assessment of Fully Automatic Structure Prediction (CAFASP) is an experiment running parallel with CASP that aims to test fully automated methods' performance on CASP targets, mainly testing servers instead of groups [35, 36]. Several groups have also raised concerns that there are problems associated with the small numbers of proteins tested in each CASP experiment, and thus EVA and LiveBench were organized to test methods using larger numbers of proteins [20, 92, 94]. Both use proteins that have structures that are unknown to the participating prediction groups, but that have been recently submitted to the PDB and are not open to the public at the time their sequences are released to those participating in LiveBench or EVA. The participating groups then have the time it takes for the new PDB entries to be validated to predict the structures. Although groups with amazing computer-hacking skills could in principle access this information, these efforts effectively create a CAFASP equivalent for a larger number of proteins.

All four of these tests of prediction methods, as well as benchmarks carried out by authors of any methods in question, are valuable ways of judging the performance of *de novo* methods. The methods, and elements of methods, I describe herein are generally accepted to be the best performers by the five above measures (four blind tests and author benchmarks). I will not focus on the details of the CASP, CAFASP, EVA and LiveBench methods, as they are described in detail elsewhere and instead attempt to focus on common elements of top performing methods.

2.3 Domain Prediction is Key

As the size of a protein increases, so to does the size of the conformational space associated with that protein. Thus, *de novo* methods, which must sample this space, have run times that increase dramatically with sequence length. Current *de novo* methods are limited to proteins and protein domains less than 150 amino acids in length (with Rosetta the limit is around 150 residues for α/β proteins, 80 for β-folds and more than 150 residues for α-only-folds). This limit means that roughly half of the protein domains seen so far in the

ref	unfolded state reference energy	$\sum_{aa} n_{aa}$	aa = amino acid type n = number of residues	Kuhlman, 2000 [59]

PDB are within the size limit of *de novo* structure prediction. Two approaches to circumventing this size limitation are: (i) increasing the size range of *de novo* structure prediction and (ii) dividing proteins into domains prior to attempting to predict structure. Dividing query sequences into their smallest component domains prior to folding is one straightforward way to dramatically increase the reach of *de novo* structure prediction. For many proteins domain divisions can be easily found (as would be the case for a protein where one domain was unknown and one domain was a member of a well-known protein family) while several domains remain beyond our ability to correctly detect them. The determination of domain family membership and domain boundaries for multi-domain proteins is a vital first step in annotating proteins on the basis of primary sequence and has ramifications for several aspects of protein sequence annotation; multiple works describe methods for detecting such boundaries. In short, most protein domain parsing methods rely on hierarchically searching for domains in a query sequence with a collection of primary sequence methods, domain library searches and matches to structural domains in the PDB [26,55,66].

Some notable works use coarse-grained structural simulations/predictions coupled with methods for assigning structural domain boundaries to 3-D structures to detect protein domains from sequence. The guiding principle behind this approach is that very low-resolution predictions will pick up overall patterns of the polypeptide packing into distinct structural domains. Another recent work attempted to use local sequence signals to detect structure domain boundaries under the assumption that there would be detectable differences in local sequence propensities at domain boundaries [37]. As of yet these

Footnotes to Table 2:

[a] All binned function values are linearly interpolated, yielding analytic derivatives, except as noted.

[b] Three-state secondary structure type as assigned by DSSP.

[c] Not evaluated for atom pairs whose interatomic distance depends on the torsion angles of a single residue.

[d] Well depths taken from CHARMm19 parameter set (Neria 1996 [77]).

[e] Radii determined from fitting atom distances in protein X-ray structures to the 6–12 Lennard–Jones potential using CHARMm19 well depths.

[f] Evaluated only for donor acceptor pairs for which $1.4 \leq d \quad \leq 3.0$ and $90^\circ \leq \psi, \theta \quad \leq 180^\circ$. Side-chain hydrogen bonds in involving atoms forming main-chain hydrogen bonds are not evaluated. Individual probability distributions are fitted to eighth-order probability distributions and analytically differentiated.

[g] Secondary structure types for hydrogen bonds are assigned as helical ($j \; - - \; i = 4$, main-chain), strand: ($|j \; - - \; i| \quad > 4$, main-chain) or other.

[h] Values taken from Lazaridis and Karplus [62].

[i] Residue position defined by C_β coordinates (C_α of glycine).

* Also described in Rohl 2005 [90].

Figure 4 Schematic outline of an ideal hierarchical approach to domain parsing. Methods with higher reliability are used first, with sequence matches to the PDB being the highest-quality information. As higher-reliability/interpretability methods are exhausted, noisier methods are used (such as parsing multiple sequence alignments, step 4, and guessing domain boundaries based on the distribution of domain sizes in the PDB). Sequence regions hit by higher confidence methods (represented as gray rectangles) are masked and the remaining sequence (represented by white rectangles) are forwarded onto the remaining methods. Steps 1–4 and 6 are currently implemented in the Ginzu program; step 5 (adding sequence homolog independent methods such as structure-based domain parsing from sequence to the procedure) represent future work. Although we recognize domains in this schematic from left to right this direction is merely schematic, and Ginzu recognizes and parses domains in a fully general (discontinuous, depending on where the strong hits are at any given level) manner.

methods have unacceptably high error rates and are far too computationally demanding for use in genome wide predictions (David Kim, personal communication) [38]. In spite of the limitations mentioned above, these methods (that are not dependent on detecting sequence homologs for a given query sequence) are attractive for proteins that have no detectable homologs or matches to protein domain families and future work on this front could increase the number of proteins within reach of *de novo* methods considerably. It is likely that a method which successfully combines these coarse structure-based methods with existing sequence-based methods into a hierarchically organized domain detection program (e.g. Ginzu) will eventually outperform any existing method at domain parsing and greatly increase the accuracy of downstream structure prediction. Figure 4 shows a schematic domain detection program (this schematic is implemented as the program Ginzu).

2.4 Local Structure Prediction and Reduced Complexity Models are Central to Current *De Novo* Methods

Several methods for reducing the combinatorial complexity of the protein folding problem have been employed including lattice models (confining possible special coordinates to a predefined 3-D grid) and several discrete-state off-lattice models (e.g. reducing degrees of freedom along the backbone to a set of discrete angles). For a more exhaustive description of these methods and their reduced-complexity move sets I refer the reader to earlier reviews of *de novo* structure prediction methods [11, 27].

Instead, I will focus on the use of local structure information to constrain global structure prediction simulations to only conformations consistent with local structure prediction. Local sequences excised from protein structures often have stable structures in the absence of their global contacts, demonstrating that local sequences can have a strong, sequence-dependent, structural bias towards one or more well defined structures [10, 24, 69, 74, 106]. This experimental observation is a result of the fact that the polypeptide chain is heavily constrained by local structure bias in a sequence dependent manner. The strength of this local, sequence-dependent, structure bias can vary from strong (a local sequence that exhibits a single well defined local structure) to weak (local sequences that are disordered or completely determined by their global environment) with most protein sequences falling into some intermediate regime (local sequences that fold into multiple well-defined local structures depending on their global environment) [21, 46]. Prediction methods that accurately predict the type, strength and possible multiplicity of local structure bias for any given query sequence segment drastically reduce the size of the available conformational landscape. Using either fragment substitution (assembling fragments of local structure) as a move set or local structure constraints derived from predicted local structure also has the advantage that the subsequent global search is limited to protein-like regions of the conformational landscape (helices, correct chirality of secondary strand packing, strands and sheets with correct twist, etc.).

There are two main ways to use local structure prediction as an overriding/hard constraint on the global search: (i) using fragments to build up global structures (local structure defining the moveset) and (ii) using local structure as a hard constraint (local structure heavily modifying the objective function).

Rosetta explicitly uses fragments of three and nine residues of local structure to build global structures via fragment assembly. Prior to a Rosetta simulation a library of local structure fragments is generated such that several fragments (25–200) of different local structure are pre-computed for every possible three- and nine-residue window along the query. The simulation (the search for low-energy conformations given the Rosetta scoring function) consists primarily of randomly selecting three- and nine-residue windows along the query and replacing torsion angles at that three- or nine-residue window with torsion angles taken from a different fragment for that position. These fragments are pulled from a nonredundant version of the PDB on the basis of local sequence similarity to the query sequence [97]. This work was inspired by careful studies of the relationship between local sequence and local structure [46], that demonstrated that this relationship was highly variable on a sequence-specific basis and that there is a great deal of sequence-specific local structure that could be recognized even in the absence of global homology. The selection of fragments of local structure on the basis of local sequence matches dramatically reduces the size of the accessible conformational landscape. In practice we see that, as desired, for some local sequence segments there is a strong bias towards a single local structure in the computed local structure fragments, while other local sequences exhibit a wide range of local conformations in the fragment library. Using fragment substitution as a moveset to optimize Rosetta's objective function has one major drawback: as the structure collapses (forms many contacts favorable according to the energy function) late in the simulation the acceptance rate of fragment moves becomes unworkably small. This is due to the fact that the substitution of six or 18 backbone dihedral angles creates large perturbations to the Cartesian coordinates of parts of the protein distant along the polypeptide chain. The likelihood that such large perturbations cause steric clashes and break energetically favorable contacts late in a given simulation is exceedingly large. To recover effective minimization of the Rosetta score after initial collapse several additional move types have been added to the Rosetta moveset. The simplest move type consists of small angle moves (within populated regions of the Ramachandran map). Additional moves, descriptively named "chuck", "wobble" and "gunn" moves, aim to perform fragment insertions that have small effects far from the insertion. These additional move types are also critical to the modeling of loops in homology modeling and are described in detail elsewhere [89].

The TASSER method smoothly combines fragments of aligned protein structure (from threading runs) with regions of unaligned proteins (represented on a lattice for computational efficiency) to effectively scale between the fold recognition and *de novo* regime [108]. Other notable uses of local structure fragments include the use of I-sites to select fragments that are then fed to Rosetta as described by Bystroff and Shao [22]. I-sites is a hidden Markov model (HMM) method designed to detect strong relationships between sequence and structure as defined by a library of local structure–sequence relationships. One potential advantage of this method is that the I-sites method is not constrained to fragments of a fixed length (Rosetta is constrained to three- and nine-length fragments) [23]. Thus larger patterns of local structure bias are expected to be detected better by this method. Karplus and coworkers also use a similar approach to detecting fragments of local structure (a two-stage HMM) as part of their *de novo* method [53]. These methods have the primary advantage of better performance when local sequence–structure bias is high (e.g. when local structure is strongly and/or uniquely determined by sequence).

2.5 Clustering as a Heuristic Approach to Approximating Entropic Determinants of Protein Folding

Several protein structure prediction methods are effectively two-step procedures involving the generation of large ensembles of conformations (each being the result of a minimization or simulation) followed by the clustering of the generated ensemble to produce one or more cluster centers that are taken to be the predicted models. Regardless of how one justifies the use of clustering as a means of selecting small numbers of predictions or models from ensembles of decoys conformations, the justification is indirectly supported by the efficacy of the procedure and the resultant observation that clustering has become a central, seemingly required, feature of successful *de novo* prediction methods. Starting with CASP3 the field has witnessed a proliferation of clustering methods as post-simulation processing steps in protein structure prediction methods [14, 51, 96, 108].

Prediction of protein structure *de novo* using Rosetta relies heavily on a final clustering stage. In the first step a large ensemble of potential protein structures is generated, each conformation being the result of an extensive Monte Carlo search designed to minimize the Rosetta scoring function (see Figure 1). We then apply clustering to find the centers of the largest clusters. These cluster centers are ranked by the size of their originating cluster in the ensemble. The tightness of clustering in the ensemble is also used as a measure of method success (larger tighter clusters indicate a higher probability that the method produced correct fold predictions for a given protein). Each Rosetta simulation/Monte Carlo run can be thought of as a fast quench starting from a random point on the conformational landscape (defined by the local structure estimation/fragments). Many of these fast quenches (individual simulations) results in incorrect conformations that score nearly as well as any correct conformations generated in the full ensemble of decoy conformations, as judged by the Rosetta score (a number of other potentials tested also lack discriminative power at this stage). This lack of discrimination by *de novo* scoring functions is partially the result of inaccuracies in the scoring function, limitations in our ability to search the landscape and the fact that entropic terms are a major contributor to the free energy of folding. In any case, this lack of discrimination is mitigated by a final clustering step and it has been shown that the centers of the largest clusters in a clustered Rosetta decoy ensemble are in most cases the conformations closest to native. The ubiquitous use of clustering can be justified in several ways: clustering can be thought of as (i) a heuristic way to approximate the entropy of a given conformation given the full ensemble of decoy conformations generated for a given protein, (ii) a signal averaging procedure, averaging out errors in the low-resolution scoring function, or (ii) taking advantage of foldable-protein specific energy landscape features such as broad energy wells that are the result of proteins evolving to be robust to sequence and conformational changes from the native sequence or structure (a mix of sequence and configurational entropy) [95].

An interesting alternative to the strategy of clustering ensembles of results from independent minimizations is the use of replica exchange methods. Replica exchange methods employ large numbers of simulations spanning a range of temperatures (defined physically if one uses a physical potential or simply as a constant in the exponent of the Boltzmann equation (see Chapter 11) for probabilistic scoring functions). These independent simulations are carried out in parallel and are allowed to exchange temperatures throughout the run. This simulation strategy ideally allows for a random walk in energy space (and thus better sampling) and can be used to calculate entropic term *post facto*. Replica exchange Monte Carlo has been used successfully in the simulation and prediction of protein structure, and is interesting due to its explicit connection to a physical description of the system and its ability to search low energy states without getting trapped [81].

2.6 Balancing Resolution with Sampling, Prospects for Improved Accuracy and Atomic Detail

Every *de novo* structure prediction procedure must strike a delicate balance between the computational efficiency of the procedure and the level of physical detail used to model protein structure within the procedure. Low-resolution models can be used to predict protein topology/folds and sometimes suggest function [15]. Low-resolution models have also been remarkably successful at predicting features of the folding process such as folding rates and phi values [1, 2]. It is clear, however, that modeling proteins (and possibly bound water and other cofactors) at atomic detail and scoring these higher resolution models with physically derived, detailed potentials is a needed development if higher-resolution structure prediction is to be achieved.

Early progress has focused on the use of low-resolution approaches for initially searching the conformational landscape followed by a refinement step where atomic detail and physical scoring functions are used to select and/or generate higher-resolution structures. For example, several studies have illustrated the usefulness of using *de novo* structure prediction methods as part of a two-stage process in which low-resolution methods are used for fragment assembly and the resulting models are refined using a more physical potential and atomic detail (e.g. rotamers) [31] to represent side-chains [18, 71, 102]. In the first step, Rosetta is used to search the space of possible backbone conformations with all side-chains represented as centroids. This process is well described, and has well-characterized error rates and behavior. High-confidence or low-scoring models are then refined using potentials that account for atomic detail such as hydrogen bonding, van der Waals forces and electrostatics.

One major challenge that faces methods attempting to refine *de novo* methods is that the addition of side-chain degrees of freedom combined with the reduced length scale (reduced radius of convergence; one must get much closer to the correct answer before the scoring function recognizes the conformation as correct) of the potentials employed require the sampling of a much larger space of possible conformations. Thus, one has to correctly determine roughly twice the number of bond angles to a higher tolerance if one hopes to succeed. An illustrative example of the difference in length scale (radius of convergence) between low-resolution methods and high-resolution methods is the scoring of hydrogen bonds. In the low-resolution Rosetta procedure backbone hydrogen bonding is scored indirectly by a term designed to pack strands into sheets under the assumption that correct alignment of strands satisfies hydrogen bonds between backbone atoms along the strand and that intra-helix backbone hydrogen bonds are already well accounted for by the local structure fragments. This low-resolution method first reduces strands to vectors, and then scores strand arrangement (and the correct hydrogen bonding implicit in the relative positions/arrangement of all strand vector pairs) via functions dependent on the angular and distance relationships between the two vectors. Thus, the scoring function is robust to a rather large amount of error in the coordinates of individual electron donors and acceptors participating in backbone hydrogen bonds (as large numbers of residues are reduced to the angle and distance between the two vectors representing a given pair of strands). In the high-resolution, refinement mode of Rosetta an empirical hydrogen bond terms with angle and distance dependence between individual electron donors and acceptors is used [88]. This more-detailed hydrogen bond term has a higher fidelity and a more straightforward connection to the calculation of physically realistic energies (meaningful units), but requires more sampling, as smaller changes in the orientation of the backbone can cause large fluctuations in computed energy.

Another major challenge with high-resolution methods is the difficulty of computing accurate potentials for atomic-detail protein modeling in solvent; with electrostatic and solvation terms being among the most difficult terms to accurately model. Full treatment of the free energy of a protein conformation (with correct treatment of dielectric screening) is complicated by the fact that some waters are detectably bound to the surface of proteins and mediate interactions between residues [34]. Another challenge is the computational cost of full treatment of electrostatic free energy by solving the Poisson–Boltzmann or linearized Poisson–Boltzmann equations for large numbers of conformations. In spite of these difficulties several studies have shown that refinement of *de novo* structures with atomic-detail potentials can increase our ability to select and or generate near native structures [78]. These methods can correctly select near native conformations from these ensembles and improve near native structures, but still rely heavily on the initial low-resolution search to produce an ensemble containing good starting structures [63,71,102]. Some recent examples of high-resolution predictions are quite encouraging and an emerging consensus in the field is that higher resolution *de novo* structure prediction (structure predictions with atomic-detail representations of side-chains) will begin to work if sampling is dramatically increased.

Progress in high-resolution structure prediction will invariably be carried out in parallel with methods including, but not limited to, predicting protein–protein interactions, designing proteins and distilling structures from partially assigned experimental data sets. Indeed, many of the scoring and search strategies that high-resolution *de novo* structure refinement methods employ were initially developed in the context of homology modeling and protein design [61,90].

3 Applying Structure Prediction: *De Novo* Structure Prediction in a Systems Biology Context

Sequence databases are growing rapidly, with new genomes being deposited at a phenomenal pace. A large portion of each of these newly sequenced genomes can be expected to contain proteins that have no detectable homologs or only homologs of unknown function. It can be expected that even with the continued progress of large experimental structural biology efforts there will remain a large number of proteins for which *de novo* structure prediction and distant fold recognition methods are the only options.

3.1 Structure Prediction as a Road to Function

The relationship between protein structure and protein function is discussed in detail in Chapter 33, but will be reviewed briefly here in the context of *de novo* structure prediction. One paradigm for predicting the function of proteins of unknown function in the absence of homologs, sometimes referred to as the "sequence-to-structure-to-structure-to-function" paradigm, is based on the assumption that 3-D structure patterns are conserved across a much greater evolutionary distance than recognizable primary sequence patterns [33]. This assumption is based on the results of several structure–function surveys which show that structure similarities (fold matches between different proteins in the PDB) in the absence of sequence similarities imply some shared function in the majority of cases [48,67,70,84,101]. One protocol for predicting protein function based on this observation is to predict the structure of a query sequence of interest and then use the predicted structure to search for fold or structural similarities between the predicted protein structure and experimentally determined protein structures in the PDB or a nonredundant subset of the PDB [49,76,83,85]. There are several problems associated with deriving functional annotation from fold similarity, e.g. old similarities can occur through convergent evolution and thus have no functional implications. Also, aspects of function can change throughout evolution leaving only general function intact across a given fold superfamily [43, 56, 91]. Fold matches between the predicted structures and the PDB are thus treated as sources of putative general functional information, and are functionally interpreted primarily in combination with other methods such as global expression analysis and the predicted protein association network. To circumvent these ambiguities one can (i) use *de novo* structure prediction and/or fold recognition to generate a confidence ranked list of possible structures for proteins or protein domains of unknown function, (ii) search each of the ranked structure predictions against the PDB for fold similarities and possible 3-D motifs, (iii) calculate confidences for the fold predictions and 3-D motif matches, and, finally, (iv) evaluate possible functional roles in the context of the other systems biology data, such as expression analysis, protein interactions, metabolic networks and comparative genomics.

3.2 Initial Application of *De Novo* Structure Prediction

To date there have been few studies using *de novo* structure prediction as a method for genome annotation, due primarily to the computational expense of the calculations and the relative novelty of the methods. These studies have been carried out in combination with a variety of fold recognition and sequence-based methods for gene annotation, and have provided preliminary results that highlight several successes. It is based on these studies that we argue that *de novo* structure prediction is a viable option for exploring genes of unknown function.

The first emergence of *de novo* structure prediction methods for large-scale structure prediction was heavily limited by available computer resources. These studies were essentially pilot studies to evaluate the potential worth of genome-wide *de novo* structure predictions. In one early study workers were limited to generating predictions for 85 proteins in *Mycoplasma genitalium*, producing around 24 correct fold predictions [54]. Another study approached the computational limitation by folding representatives of Pfam protein families of unknown structure and function [14]. Using this method we were able to generate high confidence fold/structure predictions for around 60% of the 510 protein families for which Rosetta predictions were attempted, covering an additional roughly 12% of the sequences available at that time. Subsequent experimental determination for several of these protein families has shown our computed confidence values to be good estimates of our predictive performance, with success rates (rates of correct fold identification) on internal benchmarks and success rates from blind tests (CASP results and recently solved structures) nearly indistinguishable. Alas, the results of this study were not widely used by biologists due partially to the fact that at the time methods for integrating the resultant low-resolution structure predictions with other data types were not in place. The results of these early studies suggested, however, that whole-genome application of *de novo* structure prediction would result in usable annotations if presented to biologists properly, i.e. integrated with other available data types.

3.3 Application on Genome-wide Scale and Examples of Data Integration

Genome-wide measurements of mRNA transcripts, protein concentrations, protein–protein interactions and protein–DNA interactions generate rich sources of data on proteins, both those with known and those with unknown functions [5, 7]. These systems-level measurements seldom suggest a unique function for a given protein of interest, but often suggest their association with or perhaps their direct participation in a previously known cellular process. Investigators using genome-wide experimental techniques are thus routinely generating data for proteins of hitherto unknown function that appear to play pivotal roles in their studies.

The first full-genome application of *de novo* structure prediction was to the genome of *Halobacterium* NRC-1 [12]. This archaeon is an extreme halophile that thrives in saturated brine environments such as the Dead Sea and solar salterns. It offers a versatile and easily assayed system with several well-coordinated physiologies that are necessary for survival in its harsh environment. The completely sequenced genome of *Halobacterium* NRC-1 (containing around 2600 genes) has provided insights into many of its physiological capabilities; however, nearly half of all genes encoded in the halobacterial genome had no known function prior to our re-annotation [29, 30, 79, 93]. A multi-institutional effort is currently underway to study the genome-wide response of *Halobacterium* NRC-1 to its environment, elevating the need for applying improved methods for annotating proteins of unknown function found in the *Halobacterium* NRC-1 genome. Rosetta *de novo* structure prediction was used to predict 3-D structures for 1185 proteins and protein domains (less than 150 residues in length) found in *Halobacterium* NRC-1. Predicted structures were searched against the PDB to identify fold matches [85] and were analyzed in the context of a predicted association network composed of several sources of functional associations, such as predicted protein interactions, predicted operons, phylogenetic profile similarity and domain fusion. This annotation pipeline was also applied to the recently sequenced genome of *Haloarcula marismortui* with similar rates of correct fold identification.

An application of *de novo* structure prediction to yeast has also been described. This study focused on the application and integration of several methods (ranging from experimental methods to *de novo* structure prediction) to 100 essential open reading frames (ORFs) in yeast [47]. For these 100 proteins the group applied affinity purification followed by mass spectrometry (to detect protein binding partners), two-hybrid analysis, florescence microscopy (to localize proteins) and *de novo* structure prediction (Ginzu to separate domains [26, 55] and Rosetta to build structures for domains of unknown function). Due to the cost of experiments and the computational cost of Rosetta *de novo* structure prediction, the group was initially able to prototype the method on just these 100 proteins. Function was assigned to 48 of the proteins (as defined by assignment to Gene Ontology categories). In total, 77 of the 100 proteins were annotated (had confident hits) by on of the methods employed. Given that the starting set represented a difficult set of ORFs of no known function this represents a significant milestone. Scaling this sort of approach up to whole genomes (including large eukaryotic genomes) is still a significant challenge. A grid computing solution (Section 3.4) is currently being employed to complete this study (fold the remaining ORFs in the genome) and, due to the wide use of yeast as a model organism, we can expect this complete resource to be a major step in crossing the social and technical barrier that has so far prevented the wide application of *de novo* structure prediction to biology. A similar approach has also been applied to the Y chromosome of *Homo sapiens* [40]. By integrating fold recognition with *de novo* structure prediction folds were assigned to around 42 of the 60 recognized domains examined (these 60 domains originated from the 27 proteins thought to be encoded on this chromosome at the time of the study). In both of these application, yeast and human, careful thought was put into reducing the set of proteins examined and scaling-up *de novo* structure prediction remains a critical bottleneck (the introduction of all-atom or high-resolution refinement of these predicted structures will only exacerbate this critical need for computing).

3.4 Scaling-up *De Novo* Structure Prediction: Rosetta on the World Community Grid

There are several strategies one can use to limit the number of protein domains for which computationally expensive *de novo* structure prediction needs to be carried out, allowing for the calculation of useful *de novo* structure predictions for only the most relevant subsets of larger genomes, as discussed above. In spite of these strategies, finding the required compute resources has been a constant challenge for the application of *de novo* structure prediction to functional annotation and has limited the application of the method. To circumvent this problem we are currently applying a grid, distributed computing, solution to folding over 100 000 domains with the full Rosetta *de novo* structure prediction protocol (www.worldcommunitygrid.org). These domains were chosen by applying Ginzu [26,55] to over 60 complete genomes as well as several other appropriate sequences in public sequence databases. The results will be integrated with data types that are appropriate/available for a given organism in collaboration with several other groups [12, 47]. This work is ongoing in collaboration with David Baker, Lars Malmstroem (University of Washington) Rick Alther, Bill Boverman and Viktors Berstis (IBM), and United Devices (Austin, TX). Currently (11:10 AM, pacific coast time, 14 April 2005), there are over 1 million volunteers (people who have downloaded the client to run grid-Rosetta) comprising a virtual grid of over 3 million devices. Interested parties wishing to participate (donate idle CPU time on your desktop computer to this project) can download the grid-enabled Rosetta client at www.worldcommunitygrid.org. This amount of computational power will enable us to remove the barrier represented by the computational cost of *de novo* methods.

4 Future Directions

4.1 Structure Prediction and Systems Biology: Data Integration

Even with dramatically improved accuracy we still face challenges due to the ambiguities of the relationship between fold and function seen for many fold families (indeed, even close sequence homology is not always trivial to interpret as functional similarity, see also Chapter 30). Thus, the full potential of *de novo* structure prediction in a systems biology context can only be realized if structure predictions are integrated into larger analysis, and subsequently made accessible to biologists through better data integration, analysis and visualization tools. One clear example of this is provided by the bacterial transcription factors, for which even strong sequence similarity can imply several possible functions and system-wide information is required to determine a meaningful function (the target of a given transcription factor).

4.2 Need for Improved Accuracy and Extending the Reach of *De Novo* Methods

Although I have argued that data integration is as critical a bottleneck as any other and that there are current applications of *de novo* structure prediction, it is clear that improved accuracy is also essential for progress in the field and for the acceptance of *de novo* structure methods by the end users of whole-genome annotations. There is still a significant amount of error in predictions generated using current structure prediction and domain parsing methods. Extending the size limit of protein folding methods is a promising area of active research as is the development of higher-resolution refinement methods. *De novo* structure prediction requires large amounts of CPU time compared to sequence-based and fold recognition methods (although the use of distributed computing and Moore's law continue to make this less of a bottleneck). Integrating *de novo* predictions with orthogonal sources of general and putative functional information, both experimental and computational, will likely facilitate the annotation of significant portions of the protein sequences resulting from ongoing sequencing efforts, as well as proteins in currently sequenced genomes.

Acknowledgments

I would like to thank Viktors Berstis, Rick Alther and Bill Boverman of IBM for their critical work on the World Community Grid, and Phil Bradley, Lars Malmstroem, David Kim, Dylan Chivian and David Baker for myriad comments, opinions, structure prediction, preprints etc.

Structural Genomics

Philip E. Bourne and Adam Godzik

1 Overview

1.1 What is Structural Genomics?

Inspired by the success of the genome-sequencing projects, particularly the Human Genome Project [41], research-funding bodies in the US, Japan and Europe decided to embark on an equally ambitious project of large-scale macromolecular structure determination. Looking at biology in terms of increasing complexity and scale, this made sense – from the sequence of genomes comes structure from which molecular function can be derived. Individual functions define processes that occur in different parts of the cell, different cell types make up an organism and so on. Thus, the next logical step in understanding living systems was large-scale macromolecular structure determination. These efforts, weakly correlated and distributed over several institutions on several continents, became collectively known as structural genomics. The hope was that structural genomics would continue an explosive growth in raw data, knowledge and technology [32,35]. This chapter describes structural genomics on its fifth anniversary. Where representative examples of the work being undertaken are needed, they are taken from the Joint Center for Structural Genomics (JCSG), one of the US structural genomics centers that is close to the authors both in space (it is located in San Diego) and in spirit (one of us, A. G., leads the bioinformatics core at JCSG).

1.2 What are the Motivators?

Whereas the goal of the human genome project was straightforward, i.e. determine the 3 billion nucleotides that comprise the specific genome (human), the goal of structural genomics is less so. The most often stated goal was to provide "structural coverage" of protein space, by solving enough structures that all known proteins could be accurately modeled [7, 42]. Other goals, such as targeting disease-relevant genes, were also listed [8]. Last, but

not least, structural genomics aimed to develop new structure determination technologies that would lower the costs and time needed to solve protein structures. Without a formal definition of its goals, structural genomics was adopted as a broad research goal by a loose coalition of researchers from around the world. A list of the current projects is given in Table 1 and up-to-date information is available from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) [4] which tracks all projects (http://sg.pdb.org/target_centers.html) [10,22].

In the US, structural genomics efforts resulted in the launch of the National Institutes of Health (NIH) Protein Structure Initiative (PSI), which in time developed its own goals and milestones [30] that partly overlapped the original overall goals of structural genomics. The same could be said of developments in other parts of the world. Recently, the PSI initiatives in the US have received their second round of 5-year funding and goals and milestones are being further refined. Table 1 indicates major US centers from round 1 as PSI-1 and the subset of those with major funding in round 2 as PSI-2. Regardless of the stated objectives, structural genomics already accomplished (or perhaps coincided with) a major paradigm shift in structural biology – moving from a strictly functionally driven endeavor to a genomically driven endeavor. As we discuss subsequently, this both requires and is driven by contributions from a variety of communities. From the perspective of bioinformatics research, this includes problems in defining the universe of protein structures, recognition of natural units of protein evolution (domains), understanding the complex relationship between protein function(s) and sequence and structure, development of protein structure prediction in general, and homology modeling in particular, and many others.

1.2.1 Fold Coverage as a Motivator

The often repeated goal of structural genomics is "coverage of protein structural space". However, there are at least two levels on which this goal can be achieved. On one level, solving at least one example of all possible folds would provide some information about how large and complex is protein fold space. On another level, many structures from each fold would have to be solved to provide structural templates for possible comparative modeling for every existing protein. The first level, coarse-grained coverage of fold space, seems to be tractable in terms of number of structures that need to be solved, with a total number of folds estimated to be in the 5000–10 000 range. However, choosing structures that would have to be solved would be a formidable task, as it is difficult to predict from sequence which proteins would have a new fold – once the sequence identity drops below 25% the relationship to an existing structure may not be detected, yet folds are often the same below 10% sequence identity [31] (see Chapters 10 and 12). This

Table 1 Structural genomics projects worldwide

Project	Major objectives (as described on their website)
Protein structure initiative centers US	
Berkeley Structural Genomics Center (BSGC) PSI-1	two minimal genomes, *Mycoplasma genitalium* and *Mycoplasma pneumoniae*
Center for Eukaryotic Structural Genomics (CESG) PSI-2	variety of eukaryotic targets
Joint Center for Structural Genomics (JCSG) PSI-2	targets from all superkingdoms with emphasis on *T. maritima*, mouse and yeast
Midwest Center for Structural Genomics (MCSG) PSI-2	various
NorthEast Structural Genomics Consortium (NESG) PSI-2	coverage of fold space
New York Structural Genomics Research Consortium (NYSGRC) PSI-2	technology development
Southeast Collaboratory for Structural Genomics (SECSG) PSI-1	*Caenorhabditis elegans*, *Homo sapiens* and homologs from *Pyrococcus furiosus*
Structural Genomics of Pathogenic Protozoa Consortium (SGPP) PSI-1	various diseases
Mycobacterium tuberculosis Structural Genomics Consortium (TB) PSI-1	study of tuberculosis
Structural genomics projects in Europe and environs	
Bacterial Targets at IGS-CNRS, France (BIGS)	rickettsia, ORFan targets from *Escherichia. coli*, antibacterial gene targets
deCode – decode Genetics, Iceland	various diseases
Israel Structural Proteomics Center (ISPC)	various
Marseilles Structural Genomics Program, France (MSGP)	unknown
NWSGC – North West Structural Genomics Centre, UK	tuberculosis
Oxford Protein Production Facility, England (OPPF)	technology development
Protein Structure Factory, Germany (PSF)	various
Structural Proteomics in Europe, England (SPINE)	structures related to human health and disease
Mycobacterium Tuberculosis Structural Proteomics Project, Germany (XMTB)	tuberculosis
Paris-Sud Yeast Structural Genomics, France (YSG)	relevant proteins with homologs in *Schizosaccharomyces pombe*
Structural genomics projects in North America	
Montreal-Kingston Bacterial Structural Genomics Initiative, Canada (BSGI)	various
OCSP – Ontario Centre for Structural Proteomics, Canada	various
Project CyberCell, Canada	various

Table 1 continued

Project	Major objectives (as described on their website)
SGC – Structural Genomics Consortium, Canada, UK	various proteins of medical relevance
Structure 2 Function Project, US (S2F)	*Haemophilus influenzae*
Structural genomics projects in Asia	
KSPRO – Korean Structural Proteomics Research Organization, Korea	*Helicobacter pylori* and human cancer genes
RIKEN Structural Genomics Initiative, Japan (RSGI)	various
SGCGES – Structural Genomics Consortium for Research on Gene Expression System, Japan	proteins associated with protein synthesis

difficulty is illustrated in Figure 1, where the growth in the number of new folds is shown not to have increased significantly since the advent of the structural genomics projects in 2000. The picture is complicated by how one defines a new fold. Figure 1 is based upon the Structure Classification of Proteins (SCOP) [1], but other definitions exist as will be described subsequently. Further, proteins not homologous to already crystallized proteins are significantly more difficult to handle and have lower success rates at almost every stage of the structure determination process. On the second level, covering protein space at a fine-grained level requires a number of potential targets counted in hundreds of thousands, thus making the goals of structural genomics essentially unattainable. It is clear that the practical strategy must steer clear from both these extremes and, as we will discuss below, this is indeed what most structural genomics centers have been doing in practice.

Despite improvements in structure determination technology, it is clear that we have not achieved a breakthrough that could be compared to, for example, what shotgun sequencing did for accelerating genome-sequencing projects. Automation and streamlining have been applied at every step, but overall improvements have been incremental rather than dramatic, and as of today even the best centers do not produce more than 10–15 structures a month at a cost of US$50 000–$60 000 per structure. While this is impressive by the standards of structural biology from even a few years ago, at this rate and cost it is clear that fine-grained coverage of protein structural space is impossible to attain. Therefore, the ultimate goal of structural genomics could only be achieved by combining experimental and theoretical approaches, and improvements in comparative modeling are necessary to improve the convergence radius of successful model building.

Another means of defining a goal for structural genomics is to consider that goal from a biological perspective.

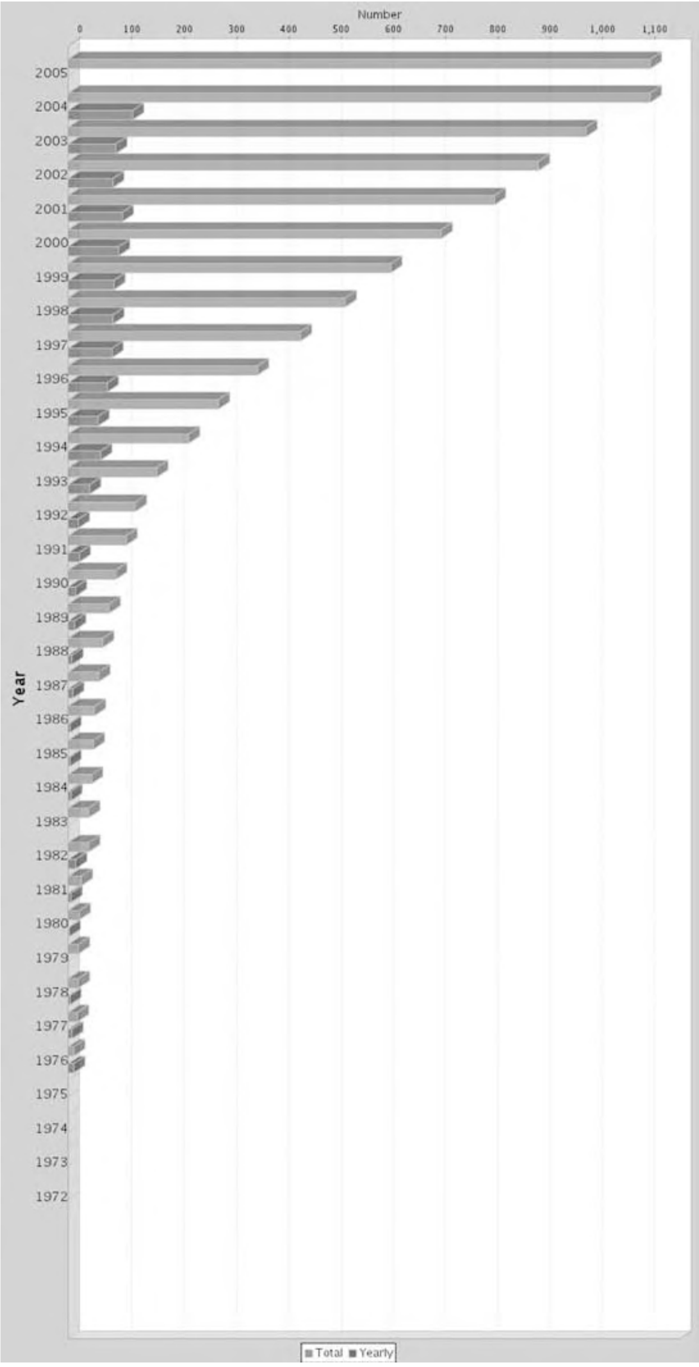

Figure 1 Growth in the number of folds per year as defined by SCOP.

1.2.2 Structural Coverage of an Organism as a Motivator

One stated and ambitious goal of structural genomics is to provide an understanding of an entire organism at the molecular level. Some structural genomics centers focused on single organisms, e.g. the JCSG cloned and attempted the expression of 1777 of the predicted 1877 open reading frames from *Thermotoga maritima* leaving aside some of the putative genes with obvious problems in predicted boundaries, etc. From a predicted 1377 soluble proteins, 705 were expressed and 581 made it to crystallization trials. To date, JCSG have solved 155 *T. maritima* structures, which, when combined with structures of *T. maritima* proteins solved at other centers, gives direct structural coverage of 25% of the expressed soluble proteins and around 12% of this organism's proteome. After taking into account structures that can be modeled through homology and fold recognition, this percentage rises to over 70% (over 90% of predicted crystallizable proteins). Thus, we are only a few dozens structures away from having complete structural coverage of an entire organism. However, as we shall see subsequently, based on a detailed discussion of the coverage of the human genome, what constitutes genome coverage by models is open to interpretation. Beyond that, Brenner and colleagues have pointed out [9] that even the determination of several complete archaeal or bacterial proteomes would still leave many protein families structurally uncovered.

1.2.3 Structure Coverage of Central Metabolism Pathways as a Motivator

Here we consider a specific example. Structures solved at JCSG and other PSI centers allow us to take a structure-based view of the metabolic pathways in *T. maritima*. In collaboration with the SEED project (http://theseed.uchicago.edu/FIG/index.cgi), an integrated *T. maritima* annotation project was initiated combining structural, functional and genomic annotations (Figure 2). Results of this effort, which will soon be available on the *T. maritima* annotation website, will provide a unique genome annotation resource. At this point, all *T. maritima* metabolic pathways can be covered by experimental or modeled structures, providing a first of its kind structural view of an organism's metabolome. Structure determination has resolved many outstanding issues in what seemed to be incomplete or redundant pathways and identified novel aspects of *T. maritima* metabolism. For instance, *T. maritima* is one of only four known organisms that do not depend on biotin decarboxylase for fatty acid metabolism. About 40% of all JCSG-solved *T. maritima* structures had their functional annotations changed or significantly updated after their structures were determined.

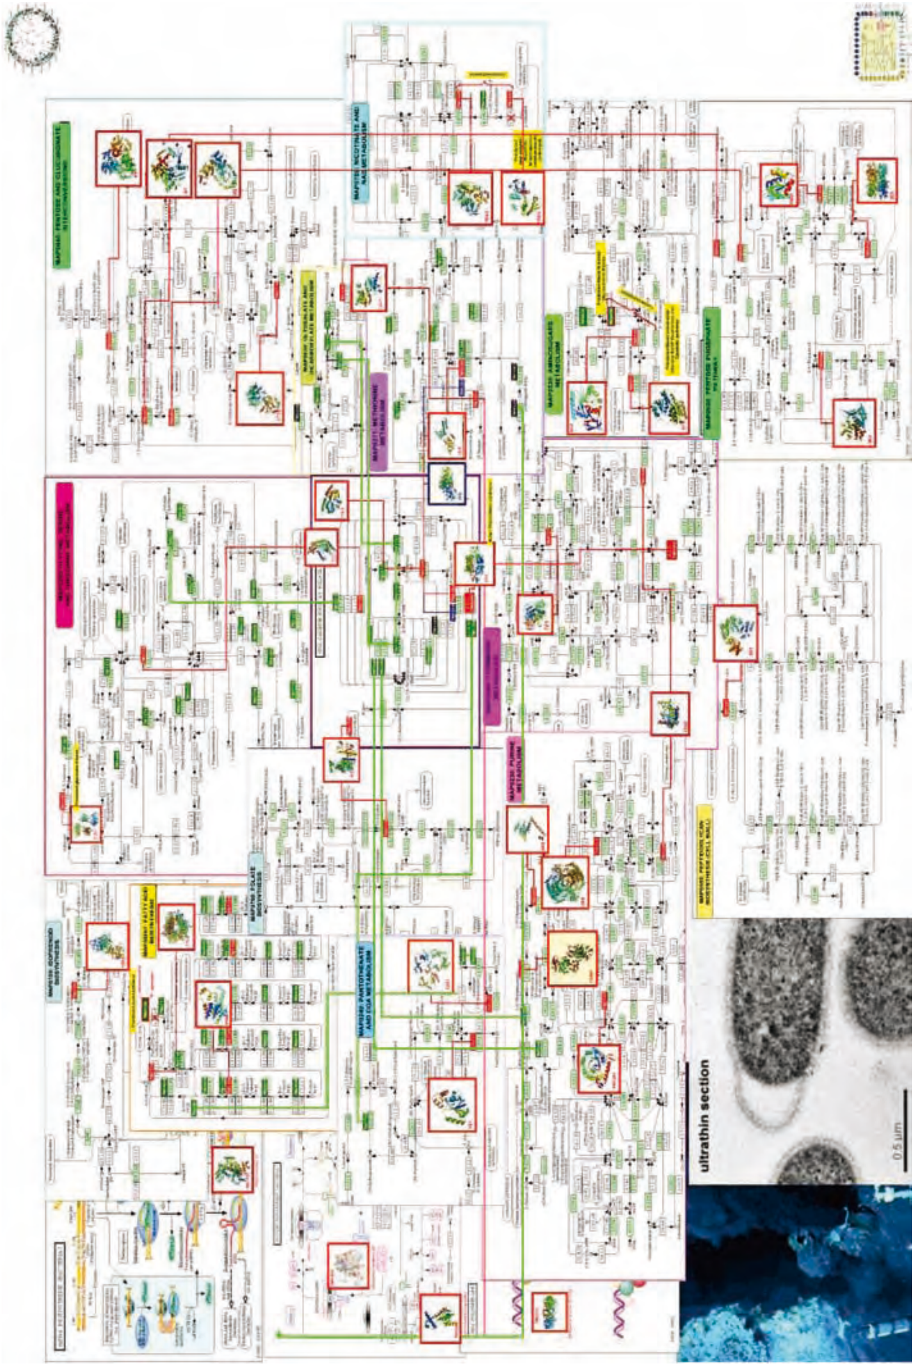
1.2.4 Disease as a Motivator

According to a recent study [45] the PDB currently covers approximately 70% of the human disease categories described by the Online Mendelian Inheritance in Man (OMIM) resource [15], but that coverage is not even. For example, diseases of the central nervous system have a disproportionately large number of solved structures and structural genomics targets relative to the number of proteins associated with this class of disease in the human genome. Blood- and lymph-based diseases have a disproportionately large number of solved structures in the PDB, yet an appropriate underrepresentation of structural genomics targets being attempted. Diseases of the ear, nose and throat, which are currently structurally underrepresented in the PDB, have few targets being attempted and yet there are a significant number of proteins identified as being responsible for this class of disease in the human genome [45]. Some structural genomics projects (Table 1) are targeting specific diseases, e.g. *Mycobacterium tuberculosis*, Chagas' disease and malaria, and a more balanced coverage of proteins associated with human diseases is expected in the next 5 years.

1.3 How Does Structural Genomics Relate to Conventional Structural Biology?

What should be apparent from the above discussion of motivators is that structural genomics changes the conventional paradigm of "I know something about the function of this protein from biochemical evidence, let me determine the single structure of this protein to better elucidate the mechanism" to an almost reverse approach at a different scale of biology, "I see a protein that seems to be important – it is conserved, essential, sits on a virulence island, but its function is unknown, lets solve a structure to start the functional characterization process". One outcome of this paradigm shift is that, for the first time, we are seeing a number of structures which have yet to be functionally characterized offering new challenges for computational biologists to determine function from sequence and structure, not necessarily a trivial undertaking, but success is possible.

Taking a specific example, for 42 of the *T. maritima* structures solved by the JCSG, structural analysis provided strong indications for the possible functions of proteins which were previously listed as "hypothetical proteins". Further, by incorporating structural information into the annotation process, functional annotations of 90 out of 122 structures have been modified, usually by making the function annotation more specific and occasionally by correcting it. Importantly, for some proteins even knowledge of their three-dimensional (3-D) structure did not help to elucidate their function. For instance, TM0875 (a specific JCSG target), with a unique fold and no known homologs, remains uncharacterized a few years after structure determination.



ultrathin section
0.5 µm

Currently, over 900 proteins in PDB are classified as "structural genomics unknown function".

Interestingly, while the value of structural genomics was questioned by some structural biologists at the outset, the consensus opinion now seems to be that advances made in structure determination through structural genomics have fed back to impact conventional structural biology laboratories through, for example, improved software, streamlined procedures at the synchrotron beamlines, and improved techniques for expression, purification and crystallization. We now consider some of these advances.

2 Methodology

Structural genomics employ a variety of methods – X-ray crystallography, nuclear magnetic resonance (NMR), electron microscopy, neutron diffraction, mass spectrometry, etc. It is beyond the scope of this chapter to describe all of these. Rather, we consider X-ray crystallography as the most prevalent of the methods (85% of structures in the PDB to date) to illustrate the impact that structural genomics is having on the methods employed to solve structures by single crystal X-ray diffraction. Figure 3 is a schematic of the basic process. We consider each step and demonstrate what has been achieved by one project, the JCSG, as an example of progress that is being made.

2.1 Target Selection

The motivation for selecting targets was introduced above. The goal of target selection is to ascertain that the sequence of the protein meets the criteria defined for the anticipated structural outcome. That could be biological, i.e. it has a particular function usually determined by identification of homology to another protein known to have this function (see Chapters 30–35), or methodological, i.e. a specific globular domain can be identified which is likely to be amenable to crystallization. Neither recognizing distant homologs nor domains from sequence is a solved problem, although these are active areas of endeavor. See, for example, Ref. [20] for the latest on domain recognition from the Sixth Critical Assessment of Structure Prediction (CASP) [39].

←

Figure 2 Fragment of the metabolic map of *T. maritima* with experimental structures identified by ribbon diagrams and models identified by a green highlight of the enzyme name. Most of the pathways have complete structural coverage and the remaining proteins are being targeted in the fifth year of JCSG.

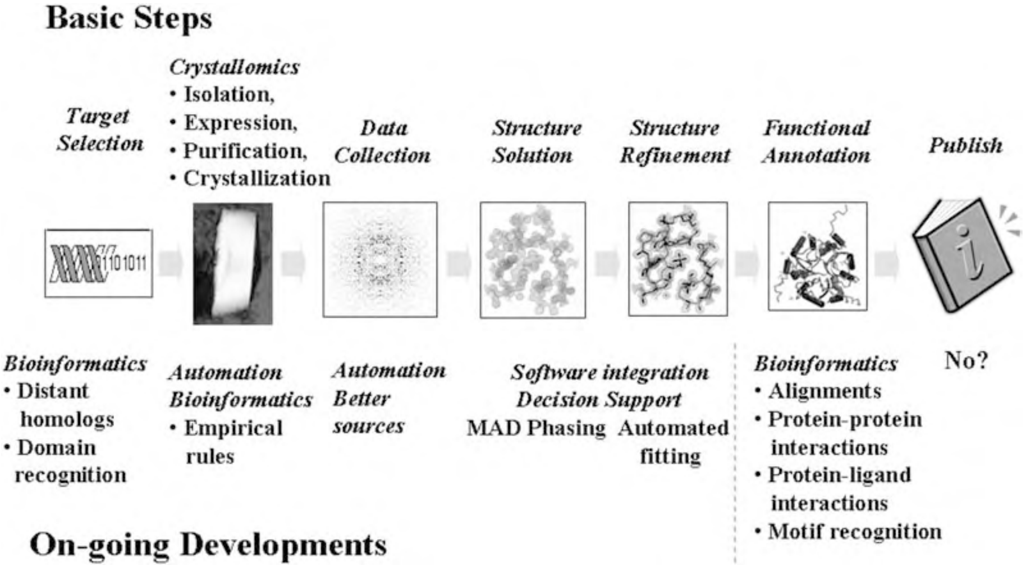


Figure 3 The basic steps in a single-crystal X-ray diffraction experiment (top) and associated on-going developments (bottom) being catalyzed by structural genomics efforts worldwide.

2.2 Crystallomics

Crystallomics is a term to collectively define the steps of protein isolation, expression, purification and crystallization. The initial phase of structural genomics has yielded great progress here. Large-scale, fully automated facilities for protein production have been developed by all structural genomics centers and, increasingly, many commercial solutions are available. Structural genomics centers cloned over 56 000 targets, expressed over 30 000 targets, purified over 10 000 targets and crystallized about 4000 targets in the period since program inception in 2000 to October 2005 (Figure 4). Additional constantly updated statistics are available at http://targetdb.pdb.org/. Consider the approach of JCSG. Many options for creating expression systems were evaluated to maximize flexibility and minimize cost. Ultimately the JCSG team chose to automate a conventional cloning approach. They developed a robotic platform and were able to provide up to 384 validated clones per week. To date, over 2500 clones have been generated and expressed with this system from over 30 000 attempts. The system is efficient, needing only a single person to operate. *Escherichia coli* has been used as the expressions system. To purify the expressed protein, a two-process system has been adopted, both processes being controlled by robotics. Together, they can produce 48–96

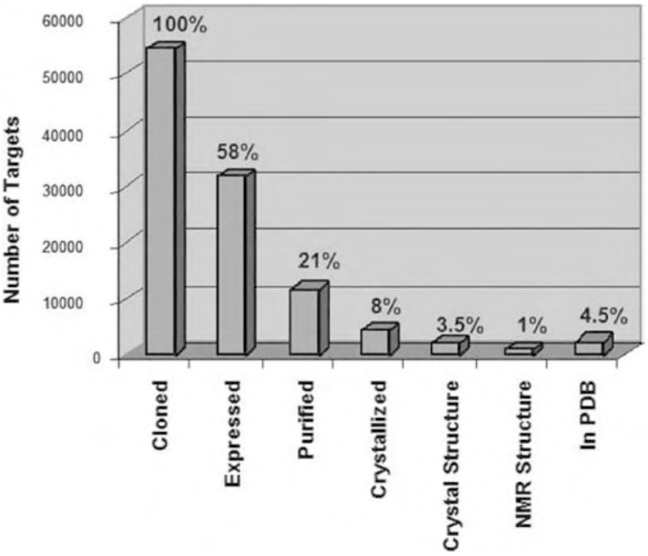

Figure 4 Progress within the structural genomics initiative worldwide as of 17 November 2005.

proteins a week on a 10–50 mg scale. Further details on this process can be found at http://www.jcsg.org/scripts/prod/technologies1.html.

Crystallization strategies vary but are high throughput involving multiwell robotic systems. The JCSG system includes an automated system for shooting digital images of each well and automatic recognition of crystalline samples. To date over 3 million images have been taken and analyzed. Once a sample is identified a prescreening is undertaken to determine if the crystal is of diffraction quality before being sent to the synchrotron for data collection. In excess of 500 crystals are prescreened by JCSG on a monthly basis.

2.3 Data Collection

Crystal samples are transported to the synchrotron in specially designed compact, cylindrical, aluminum crystal cassettes, which holds 96 crystals. Upon reaching the synchrotron samples are automatically mounted, entered into the high-energy X-ray beam and aligned automatically, a process taking approximately 30 s. Using a video system it is intended that data collection will eventually be done remotely without the need for the researcher to travel to the beamline itself. The online report of each crystalline sample is automatically augmented with information from the data collection process.

2.4 Structure Solution

Data collection provides X-ray diffraction patterns from the ordered crystal lattice which appear as a set of diffraction spots. The positions of the spots is defined by the size and type of crystal lattice; however, the intensity of the spots is a function of their amplitude based on the types of atoms (known) and their phases based on the positions of the atoms (unknown at the outset). This is referred to as the phase problem in crystallography. The majority of structures determined by the structure genomics centers worldwide solve the phase problem by establishing a starting set of phases using multi-wavelength anomalous dispersion [17] which requires collecting data at slightly different wavelengths, a process that is possible using synchrotron beamlines which can be tuned for this purpose. The discreet scattering of the X-ray beam by the electron cloud from specific atom types (anomalous scatterers), usually selenium introduced into the structure in the form of selenomethionine, when collected at different wavelengths, provides a starting set of phases, based on the atomic positions of the anomalous scatterers which can now be resolved. A disadvantage of this approach is that data must be collected at each wavelength, lengthening the data collection time. An alternative approach to establishing a starting set of phases is to have a model which approximates the final atomic positions. From this model a starting set of phases can be derived, hence solving the phase problem assuming, first, that the model is accurate enough and, second, that it can be positioned correctly within the crystal lattice. This technique, known as molecular replacement (MR), works well for similar structures, e.g. taking an existing solved native protein structure and using it to phase a mutant structure containing post-translational modifications. An exciting prospect is to routinely use a theoretically derived model structure to determine a staring set of phases. Likelihood for the routine success of this approach relies on having a wide variety of experimentally determined structures from which to model. While this represents somewhat of a chicken-and-egg situation, the number of available structures is increasing rapidly.

In general, MR solutions are seldom attempted (and are even less often successful) against templates with less than 35% sequence identity. Using a fold recognition approach [13] as opposed to an approach based solely on homology, to date, the JCSG MR pipeline was successfully applied to over 20 cases with less than 35% sequence identity, 10 cases with less than 30% and several cases where sequence identity was close to 15%. The analysis shows that fold recognition models, derived from work done in the discipline of protein structure prediction [44], have a significantly higher success rate than homology modeling, especially when the unknown structure and the search model share less than 35% sequence identity. Using the software programs

MOLREP [40] and EPMR [21], three out of 26 MR targets under 35% sequence identity could only be solved with models derived from fold recognition methods, and six showed significantly better statistics and behavior in subsequent refinement [34] than those defined by homology.

2.5 Structure Refinement

Structure refinement implies maximizing the agreement between the intensities observed on the diffraction pattern spots and those calculated from the atomic model. This can be roughly divided into two tasks: (i) getting the main chain and side chains into an optimal position and (ii) performing a final minimization. Ideally both steps must be completely automated to maximize throughput. Improvements to algorithms and usability of software are key factors in this process. A final check must be made to be sure the stereochemical quality of the model is reasonable and this is done primary by checking the relatively low-resolution structure of the complete macromolecule against what is known about macromolecular structure *en masse* (e.g. allowable dihedral angles) and what is known from high-resolution structures of small molecules, such as single amino acids and nucleotides. Despite significant progress in recent years, large parts of the refinement process are still done by hand and high-quality refinement is one of the most time-consuming tasks in high-throughput structure determination. Despite these difficulties, the quality of structures determined by structural genomics centers matches and often exceeds the quality of structures coming from standard structural biology laboratories [38].

2.6 PDB Deposition

Deposition within the PDB (http://www.pdb.org) [4] is a requirement for all structural genomics centers, thereby facilitating the maintenance of a single worldwide archive of macromolecular structures. An ideal goal is to fully automate the deposition process whereby a full structure submission contains not just the final atomic coordinates and experimental data (NMR restraints or X-ray structure factors), but all experimental information including experimental protocols for all the above steps. This would then be validated by the PDB prior to submission. This process is not yet in place, but significant progress has been made. A key element of the process is an ontology which defines in a formal way the items to be collected and their interrelationships. While details of the structure itself have been defined in this way using an ontology referred to as the macromolecular crystallographic information file (mmCIF) [14], additional ontological terms for the various detailed experimental protocols have yet to be fully defined. The progress that has been made thus far is reflected in the Protein Expression Purification and Crystallization Database (PEPCdb; http://pepcdb.pdb.org) which collects experimental protocols according to the beginnings of a full ontological description.

2.7 Functional Annotation

One of the underling goals of structural genomics is to study the relationship between gene sequence, protein structure and protein function, thereby expanding the knowledge of the underlying biology. However, at present most structural genomics centers, by design, stop after structure determination. As a result, a large number of proteins solved by structural genomics groups are listed in the PDB as "hypothetical proteins". This growing list provides raw data from which bioinformatics groups worldwide can apply a variety of methods to assigning putative function(s) to these uncharacterized structures (see Chapters 30–35, especially Chapter 33) [46]. Here, we outline a few of the approaches that have been adopted. In the results section some success stories are introduced. Popular approaches are as follows.

2.7.1 Biological Multimeric State

The structure solved in many cases does not comprise the biologically active molecule. Rather, it represents a unique component. That component may be one domain in a multi-domain protein, a situation found in the PDB in general. For example, multiple SH2 and SH3 domains have been solved and are known to be part of a larger macromolecular complex. Alternatively, the application of crystallographic symmetry can be used to construct the biologically active molecule. Identifying what components comprise the biologically active molecule often requires expert input, although efforts have been made to automate this determination. The Protein Quaternary Server (PQS) uses the notion of proximity of components to define the multimeric state [18].

2.7.2 Active-site Determination

This is an active area of research (see [37] for a review and Chapter 33). Active sites include a small number of residues involved in catalysis, substrate and cofactor binding sites, sites of protein–protein interaction, phosphorylation sites, glycosylation sites, fatty acylation sites, prosthetic group binding sites, hinge regions, domain–domain contacts, sites of membrane association and more. The complexity and importance of the problem is well illustrated by subtilisin and chrymotrypsin. Both are endopeptidases, yet share no sequence identity and their folds are unrelated. However, they share an identical 3-D motif comprising a Ser–His–Asp catalytic triad. The challenge becomes one of identifying an identical motif in two different structures undoubtedly resulting from convergent evolution. Methods are varied, but all comprise basic steps of protein structure representation, application of a search algorithm and assessment of the reliability of the result. Early work used a graph theoretic approach [2], progressing to the use of fuzzy functional forms [11], template modeling [43] and, most recently, an elegantly simple approach based on the proximity of the active site of an enzyme to the centroid of the molecule [3] has emerged. Each method builds upon empirical observations made as more structures are determined and functions classified by biochemical analysis. Thus, we have a rich repertoire from which functional prediction can only improve.

The need for improved methods for function prediction from structure leads to increased research into automated function prediction. The first two meetings of the Automated Functional Prediction (AFP) special interest group were held in 2005 and 2006 (http://biofunctionprediction.org) and the proceedings will be published in 2006. The first metaserver, collecting and analyzing prediction for several servers is now in beta testing (http://jafa.burnham.org).

2.8 Publishing

The original macromolecular structures represented a scientist's life's work. We are now faced with a situation where the rate-determining steps may well be writing the publication. Hence, a number of structures, while deposited in the PDB, remain unpublished. At the time of writing only a small percentage of structures determined by structural genomics are described by peer-reviewed publications, placing additional emphasis on the individual centers websites and the PDB to disseminate as much information about these structures as possible.

JCSG structures are shared with the scientific community not only through deposition in the PDB, but also through publication of a "structure note". Structure notes are short papers describing the annotation, biology, structure and functional implications of each protein. The process of collecting all relevant data from all stages of the JCSG pipeline has been streamlined through the central JCSG database, which includes information on the sequence, annotation, cloning, purification, crystallization, data collection, structure solution, tracing, refinement and structural evaluation. The structure note automatically captures any functional information in the JCSG annotation system (functional annotation is described above). The paper introduction, for example, includes annotation information, with a brief biological background taken and curated from the Pfam [12], Interpro [28], SwissProt [6], BRENDA [33] and SEED databases (http://theseed.uchicago.edu/FIG/index.cgi). Methodological and experimental data, as well as all crystallographic statistics, are automatically harvested from the JCSG database, and assembled into purification, crystallization, structure solution and refinement paragraphs. The structure description and the preparation of figures are done manually using PyMOL (http://pymol.sourceforge.net/). Structures are analyzed, compared and evaluated for biological significance using a plethora of structure analysis tools including structural homology searches (DALI [19], CE [36], FATCAT [25]) and extensive literature searches. In this way the preparation of a structure note is a semiautomated process.

3 Results – Number and Characteristics of Structures Determined

As of 17 November 2005 there were 90 613 targets under consideration by structural genomics projects. Of these 57 019 had been cloned and could be considered under investigation. Figure 4 from http://targetdb.pdb.org/ [10] shows the success rate for the steps described in Section 2. A total of 2540 structures have appeared in the PDB, which is 4.5% of the targets under investigation; 1% has come from NMR structure determination and 3.5% from X-ray crystallography. At that time 7.5% of all structures in the PDB could be considered from structural genomics, with an overall contribution of between 15 and 20% per year. An earlier study from Todd and coworkers [38], when only 316 structures had been deposited, indicated that the quality and size of structures determined by structural genomics versus functionally driven structure determination were comparable. Further, 29% of the domains solved revealed evolutionary relationships not apparent from sequence alone. Similarly, 19 and 11% contributed new superfamilies and folds, respectively. While this number of folds is significantly higher that the contribution from all structures (2% based on the SCOP definition of fold as indicated earlier), it reflects on the difficulty of finding new folds and surely indicates that protein fold space is indeed quite limited.

To get a sense of what structural genomics is contributing, it is first necessary to get some measure of what structure is contributing overall to our understanding of living systems. Clearly, this contribution is somewhat intangible and can be defined in different ways. One recent approach was to review what both structures and targets contribute to the functional and disease coverage of the human genome [45]. In some sense this measure cuts across the various criteria for choosing structural genomics targets that was outlined above. This contribution was measured by looking at the functional coverage of the human genome using either EC numbers (http://www.chem.qmul.ac.uk/iubmb/enzyme/) or Gene Ontology (GO) classifiers [16] and disease via the OMIM [15] classifiers and comparing what the solved structures and targets contributed. Human genome annotation was taken from Ensembl [5] and structure data from the PDB and targets from targetdb [10], the repository maintained by the RCSB PDB of protein sequences from all the structural genomics centers that are being considered for structure determination (http://targetdb.pdb.org). Comparisons were made for both single domains and whole structures. In addition, the ability to homology model was ascertained based on results from SUPERFAMILY [26]. SUPERFAMILY identifies proteins within complete proteomes based on their structural characterization. As such it represents the percentage of a given proteome that can be modeled by existing structures. The results can be summarized as follows:

- Single domains cover 37% of the GO molecular function classes identified in the human genome
- Whole structures cover 25% of the human genome.
- The 37% domain coverage extends to 56% using homology modeling.
- The 25% whole structure coverage extends to 31% using homology models.
- If all current structural genomics targets were solved (~3 times the current PDB):

  37% goes to 69%
  25% goes to 44%

4 Discussion

4.1 Follow-up Studies

One of the ultimate measures of the impact of a new structure is the number of follow-up studies and publications. This impact may not be apparent for several years and is difficult to assess in this comparatively short time frame. However, taking as an example JCSG, their structures have evoked numerous individual collaboration agreements (over 50), associations with larger consortiums detailed in Section 3.7, and numerous requests for clones and proteins for biochemical studies. As an example, TM0449 [23, 24] (PDB code: 1kg4) represents a novel fold which has inspired studies from three different laboratories [27, 29] and has led to the elucidation of a novel biochemical pathway of thymidylate synthesis present, among others, in several important human pathogens. TM0449 and its homologs present an attractive antibacterial drug target, since humans and most eukaryotes depend upon the conventional thymidylate synthase.

4.2 Examples of Functional Discoveries

Again we use JCSG to illustrate the power of long range function and structure projections. In these cases, a bacterial structure from a relatively obscure organism such as *T. maritima* proves to have significant biomedical relevance. For example, the *T. maritima* protein TM1620 provided a template to model a human protein PA26, which belongs to GADD (genes active in DNA defense) family that is highly upregulated in several cancers. It also highlights an interesting conservation of DNA antioxidant defense from bacteria to humans. TM1620 is the second protein solved in this family (the first was AhpD from *Mycobacterium tuberculosis*), which is closely related to 1300 proteins from all kingdoms of life. The mechanism of action of proteins from this family is not clear.

As a second example, TM0813 was shown to be unexpectedly similar to a domain from a known protein involved in antibiotic resistance. Interestingly, a homologous domain is also present in sacsin – a protein whose mutations are responsible for a human neurogenerative disease resulting in autosomal recessive spastic ataxia, often found in Quebec, but also in Turkey and several other areas of the world. In these and other similar cases there is a chance that bacterial proteins, which are easier to characterize and study, would provide hints as to specific mechanism of action of their (very distant) human homologs.

5 The Future

Remaining PSI centers in the US (labeled PSI-2 in Table 1) have just received a second round of 5-year funding and are working together to define the most valuable target list of proteins to be structurally determined. While the objectives of structural genomics remain relatively nebulous relative to the completion of the human genome, solving a significant number of protein structures on that final target list will have a significant outcome. That outcome will be measured in an improved understanding of structure-function relationships, improved coverage of protein fold space and improved technologies for all concerned within the science of structural biology.

RNA Secondary Structures

Ivo L. Hofacker and Peter F. Stadler

1 Secondary Structure Graphs

1.1 Introduction

The tendency of complementary strands of DNA to form double helices is well known since the work of Watson and Crick. Single-stranded nucleic acid sequences will in general contain many complementary regions that have the potential to form double helices when the molecule folds back onto itself. The resulting pattern of double-helical stretches interspersed with loops is what is called the *secondary structure* of an RNA or DNA. Secondary structure elements may in turn be arranged in space to form three-dimensional (3-D) tertiary structure, leading to additional noncovalent interactions (an example is shown in Figure 1). Energetically, however, these tertiary interactions are weaker than secondary structure. As a consequence RNA folding can be regarded as a hierarchical process in which secondary structure forms before tertiary structure [129, 130]. Since formation of tertiary structure usually does not induce changes in secondary structure, the two processes can be described independently. Functional RNA molecules (tRNAs, rRNAs, etc., as opposed to pure coding sequences), usually have characteristic spatial structures – and therefore also characteristic secondary structures – that are prerequisites for their function. As a consequence, secondary structures are highly conserved in evolution for many classes of RNA molecules.

Both the experimental determination of full spatial RNA structures and computational predictions of RNA 3-D structures are very hard tasks – arguably even harder than the corresponding problems for proteins [62, 82]. Computational approaches to RNA tertiary structure thus have been successful only for selected cases (see Chapter 15). RNA secondary structures, on the other hand, not only have a definite physical meaning as folding intermediates and are useful tools in the interpretation RNA molecules, but they give rise to efficient computational techniques. Secondary structure

prediction and comparison, the focal topics of this chapter, have therefore become a routine tool in the analysis of RNA function.

RNA secondary structures consists of two distinct classes of residues: those that are incorporated in double-helical regions (so called stems) and those that are not part of helices. For RNA, the double-helical regions consist almost exclusively of Watson–Crick C–G and A–U pairs as well as the slightly weaker G–U wobble pairs. All other combinations of pairing nucleotides, called *noncanonical* pairs, are neglected in secondary structure prediction, although they do occur, especially in tertiary structure motifs.

1.2 Secondary Structure Graphs

A secondary structure is primarily a list of base pairs Ω. To ensure that the structure is feasible, a valid secondary structure should fulfill the following constraints:

(i) A base cannot participate in more than one base pair, i.e. Ω is a match on the set of sequence positions.

(ii) Bases that are paired with each other must be separated by at least three (unpaired) bases.

(iii) No two base pairs (i, j) and $(k, l) \in \Omega$ “cross” in the sense that $i < k < j < l$. Matchings that contain no crossing edges are known as loop matchings or circular matchings.

Condition (i) excludes tertiary structure motifs such as base triplets and G-quartets; condition (ii) takes into account that the RNA backbone cannot bend too sharply.

Base pairs that violate condition (iii) are said to form a pseudoknot. While pseudoknots do occur in RNA structures, our definition (somewhat arbitrarily) classifies them as tertiary structure motifs. This is done in part because most dynamic programming algorithms cannot deal with pseudoknots. However, including pseudoknots entails other complications, since most hypothetical structures that violate condition (iii) would also be sterically impossible. Furthermore, little is known about the energetics of pseudoknots, except for some data on H-type pseudoknots [43], the simplest and most common type of pseudoknot (Figure 2). Pseudoknots should therefore be regarded as a first step toward prediction of RNA tertiary structure.

Secondary structures can be represented by "secondary structure graphs" (first two panels in Figure 3). In this representation one creates a graph whose nodes represent nucleotides. There are two kinds of edges: one kind representing the adjacency of nucleotides along the RNA sequence and the other kind representing base pairings. Condition (iii) above assures that this graph is planar, more precisely an *outer-planar graph*, in which all nodes can be arranged along a single face of the planar embedding made up by the edges forming the RNA sequence. We can therefore draw the secondary structure by placing the backbone on a circle and drawing a chord for every base pair such that no two chords intersect.

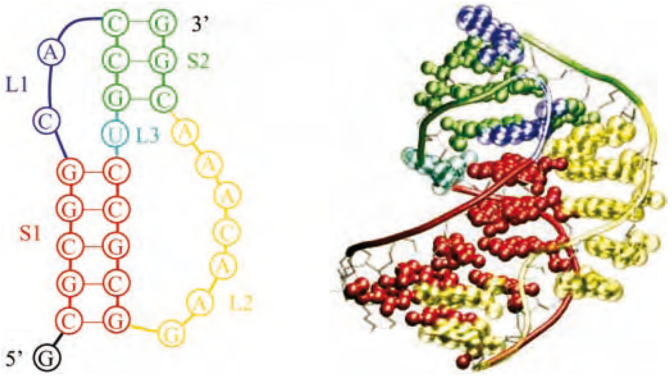

Figure 2 Example of an H-type pseudoknot from beet western yellow virus. The crystal structure (right) shows that the two helices S1 and S2 are coaxially stacked to form a single 3-D helix.

Figure 3 Representations of secondary structures. From left to right: Circle plot, conventional secondary structure graph, mountain plot and dot plot. Removing the backbone edges from the first two representations leaves the matching Ω. Below, the structure is shown in “bracket notation”, where each base pair corresponds to a pair of matching parentheses. The structure shown is the purine riboswitch (Rfam RF00167).

1.3 Mountain Plots and Dot Plots

A representation that works well for large structures and is well suited for comparing structures is the so-called mountain representation. In the mountain representation a single secondary structure is represented in a 2-D graph, in which the x-coordinate is the position k of a nucleotide in the sequence and the y-coordinate the number $m(k)$ of base pairs that enclose nucleotide k (third panel in Figure 3).

Another possible representation is the dot plot, where each base pair (i, j) is represented by a dot or box in row i and column j of a rectangular grid, representing the contact matrix of the structure. Dot plots are well suited to represent structure *ensembles* by superimposing structural possibilities. In particular, they are used to represent thermodynamic ensembles by plotting for each pair a box with area proportional to the equilibrium probability of the pair p_{ij}. Similarly, mfold uses colors to indicate the best possible energy for structures containing a particular pair (right-most panel in Figure 3).

1.4 Trees and Forests

Secondary structures can also be stored compactly in strings consisting of dots and matching brackets: For any pair between positions i and j ($i < j$) we place an open bracket "(" at position i and a closed bracket ")" at j, while unpaired positions in the molecule are represented by a dot (".") (bottom of Figure 3). Since base pairs may not cross, the representation is unambiguous.

An ordered forest F is a sequence of rooted ordered trees $T_1, T_2, \dots, T_m$ such that within each tree T_i the left-to-right order of siblings (children of the same parent) is given. In order to represent RNA secondary structures as ordered forests, we will need to associate a label from a suitable alphabet $\mathcal{A}$ with each node.

This representation of secondary structures in terms of matched parentheses suggests to interpret the structure as a tree [117, 119]. In the *full-tree* representation [32] each base pair corresponds to an interior node and each unpaired base is represented by a leaf (Figure 4). A virtual root vertex is added mostly for graphical reasons.

Leaves may be labeled with the corresponding unpaired base, while interior nodes are labeled with the corresponding base pair. In an extended representation, two leaves, one labeled with the $5'$ and one labeled with the $3'$ nucleotide of the base pair, are attached as the left-most and right-most children to each interior vertex. In this representation the sequence of the molecule can be read of the leaves of the Bielefeld tree in pre-order.

Various coarse-grained representations have been considered. Homeomorphically irreducible trees represent entire helices as interior nodes, while

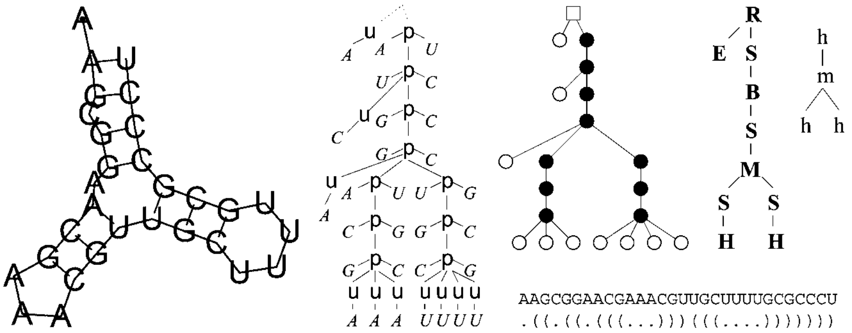

Figure 4 A variety of tree and forest representations of RNA secondary structures have been described in the literature. From left to right: conventional drawing, sequence annotated trees (as e.g. used in RNAforester [51]), "full tree" [32], Shapiro-style tree [117] and branching structure. For comparison, we also show the "bracket notation"

leaves correspond to runs of unpaired bases. Optionally, the length of such a structural element can be used as a weight. Shapiro–Zhang trees [117, 119] explicitly represent the different loop types (hairpin loop, interior loops, bulges, multiloops) as well as stacked regions with special labels. Figure 4 summarizes a few examples.

1.5 Notes

Since RNA secondary structures are planar graphs, they can always be drawn on paper without intersections. Nevertheless, finding a visually pleasing layout is difficult especially for large structures. Layout algorithms for RNA typically make use of the tree-like topology of secondary structure (e.g. Refs. [18, 47, 98, 118]). The problem becomes more complicated when pseudoknots are allowed [46].

2 Loop-based Energy Model

2.1 Loop Decomposition

Secondary structures can be uniquely decomposed into loops, i.e. the faces of the planar drawing of the structure. More formally, we call a position k *immediately interior* of the pair (i, j) if $i < k < j$ and there exists no other base pair (p, q) such that $i < p < k < q < j$. A loop then consists of the closing pair (i, j) and all positions immediately interior of (i, j). As a special case the exterior loop contains all positions not interior of any pair. The loops form a

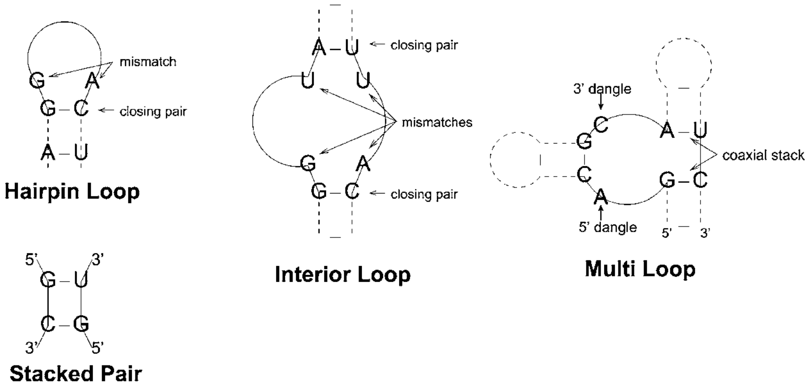

Figure 5 The major types of loops in RNA secondary structures.

minimal cycle basis of the secondary structure graph and this basis is unique for pseudoknot-free structures [80].

A loop is characterized by its length, i.e. the number of unpaired nucleotides in the loop, and its degree, given by the number of base pairs delimiting the loop (including the closing pair). Loops of degree 1 are called hairpin loops, interior loops have degree 2 and loops with degree above 2 are called multiloops (Figure 5). Bulge loops are a special cases of interior loops in which there are unpaired bases only on one side, while stacked pairs correspond to an interior loop of size zero.

The loop decomposition forms the basis of the standard energy model for RNA secondary structures, where the total free energy of a structure is assumed to be a sum over the energies of its constituent loops. As the energy contribution of a base pair in a helix now depends on the preceding and following pair, the model is often called the *nearest-neighbor* model.

2.2 Energy Parameters

Note that a secondary structure corresponds to an ensemble of conformations of the molecule at atomic resolution, i.e. the set of all conformations compatible with a certain base-pairing (hydrogen-bonding) pattern. For example, no information is assumed about the spatial conformation of unpaired regions. The entropic contributions of these restricted conformations have to be taken into account; hence, we are dealing with free energies which will be dependent on external parameters such as temperature and ionic conditions.

Qualitatively, the major energy contributions are base stacking, hydrogen bonds and loop entropies. While hydrogen bond and stacking energies *in vacuo* can be computed using quantum chemistry, the secondary structure model considers free energy differences between folded and unfolded states in an aqueous solution with rather high salt concentrations. As a consequence one has to rely on empirical energy parameters.

Energy parameters are typically derived by following the unfolding of RNA oligomers using a collection of energy parameters is maintained by the group of David Turner [90, 91, 145]. These standard parameters are measured in a buffer of 1 M NaCl at 37°C. As examples we list the free energies for stacked pairs in Table 1. Stacked pairs confer most of the stabilizing energy to a secondary structure, a single additional base pair can stabilize a structure by up to -3.4 kcal mol^{-1}. For comparison, the thermal energy at room temperature is about $RT = 0.6$ kcal mol^{-1}, i.e. the stabilizing energy contribution of a single base pair is typically of the same order of magnitude as the thermal energy. (RNA energy parameters are still published in kcal mol^{-1} to facilitate comparison with previous parameter sets; 1 kcal mol^{-1} $\approx$ 4.2 kJ mol^{-1} in SI units.)

In general, loop energies depend on the loop type and its size. Except for small loops (which are tabulated exhaustively [90]), sequence dependence is conferred only through the base pairs closing the loop and the unpaired bases directly adjacent to the pair. Thus, the loop energy takes the form:

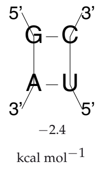
$$E_{\text{loop}} = E_{\text{mismatch}} + E_{\text{size}} + E_{\text{special}}, \tag{1}$$

where E_{mismatch} is the contribution from unpaired bases inside the closing pair and the base pairs immediately interior to the closing pair. The last term is used, for example, to assign bonus energies to unusually stable tetra loops, such as hairpin loops with the sequence motif GNRA. Polymer theory predicts that for large loops E_{size} should grow logarithmically. For multiloops, however, energies that are linear in loop size and loop degree have to be used in order to allow efficient dynamic programming algorithms for structure prediction. While the model allows only Watson–Crick (AU, UA, CG and GC) and wobble pairs (GU, UG), nonstandard base pairs in helices are treated as special types of interior loops in the most recent parameter sets.

The energy model above contains inaccuracies, on the one hand because it assumes that loop energies are strictly additive, on the other hand, because

Table 1 Free energies for stacked pairs (in kcal mol^{-1}).

	CG	GC	GU	UG	AU	UA
CG	−2.4	−3.3	−2.1	−1.4	−2.1	−2.1
GC	−3.3	−3.4	−2.5	−1.5	−2.2	−2.4
GU	−2.1	−2.5	1.3	−0.5	−1.4	−1.3
UG	−1.4	−1.5	−0.5	0.3	−0.6	−1.0
AU	−2.1	−2.2	−1.4	−0.6	−1.1	−0.9
UA	−2.1	−2.4	−1.3	−1.0	−0.9	−1.3



Note that both base pairs have to be read in 5′–3′ direction.

energy parameters carry experimental errors (typically about 0.1 kcal mol^{-1}). Most seriously, the sequence dependence of loop energies has to be kept relatively simple in order to deduce the parameters from a limited number of experiments.

2.3 Notes

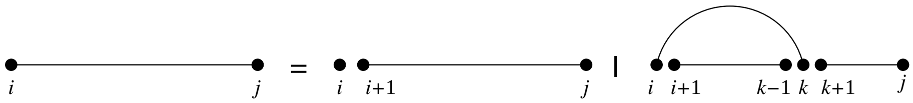
Adjacent helices in multiloops may stack coaxially to form a single extended helix. tRNA structures are prominent examples of this. In the four-armed multiloop the acceptor stem coaxially stacks on the T-stem and the anticodon stem stacks on the D-arm. This results in two extended helices which then form the L-shaped tertiary structure characteristic for tRNAs (Figure 1). Strictly speaking, coaxial stacking goes beyond the secondary structure model, since one has to know *which* helices in the loop will stack in order to include the energetic effect; the list of base pairs is no longer sufficient information to compute the energy. Coaxial stacking is also cumbersome to include in structure prediction algorithms. It has, however, been shown to improve prediction quality [135]. Useful energy parameters for structures with pseudoknots have so far only been collected for simple H-type pseudoknots [43].

3 The Problem of RNA Folding

3.1 Counting Structures and Maximizing Base Pairs

In order to understand the basic ideas behind the dynamic programming algorithms for RNA folding, it is instructive to first consider the underlying combinatorial problem: given an RNA sequence x of length n, enumerate all secondary structures on x. Let x_i denote the i-th position of x. We will simply write "(i, j) pairs" to mean that the nucleotides x_i and x_j *can* form a Watson–Crick or a wobble pair, i.e. $x_i x_j$ is one of GC, CG, AU, UA, GU or UG. A subsequence (substring) will be denoted by $x[i, \ldots, j]$. For notational convenience we interpret $x[j+1, \ldots, j]$ as the empty sequence and associate a single empty structure with it.

The basic idea is that a structure on n nucleotides can be formed in only two distinct ways from shorter structures: either the first nucleotide is unpaired, in which case it is followed by an arbitrary structure on the shorter sequence $x[i+1, \ldots, j]$, or the first nucleotide is paired with some partner base, say k. In the latter case the rule that base pairs must not cross implies that we have independent secondary structures on the subintervals $x[i+1, \ldots, k-1]$ and $x[k+1, \ldots, j]$. Graphically, we can write this decomposition of the set of structures like this:



It is now easy to compute the number N_{ij} of secondary structures on the subsequence $x[i,\ldots,j]$ from positions i to j [139,140]:

$$N_{ij} = N_{i+1,j} + \sum_{k,\,(i,k)\text{ pairs}} N_{i+1,k-1} N_{k+1,j}, \tag{2}$$

with $N_{ii} = 1$. The independence of the structures on $x[i+1,\ldots,k-1]$ and $x[k+1,\ldots,j]$ implies that we can simply multiply their numbers. This simple combinatorial structure of secondary structures was realized by Waterman in the late 1970s [139,140].

Historically, the first attempts at secondary structure prediction tried to maximize the number of base pairs in the structure. The solution to this problem by the Nussinov algorithm [101] is very similar to the combinatorial recursion above. Denote by E_{ij} the maximal number of base pairs in a secondary structure on $x[i,\ldots,j]$. Using the decomposition of the structure set, we see that E_{ij} is the optimal choice among each of the alternatives. In this context, independence of two substructures in the paired cases implies that we have to optimize these substructures independently. If we like, we can associate each base pair with a weight (negative energy) β_{ij} which depends on x_i and x_j; we arrive immediately at the recursion:

$$E_{ij} = \max\left\{ E_{i+1,j}, \max_{k,\,(i,k)\text{ pairs}} \left\{ E_{i+1,k-1} + E_{k+1,j} + \beta_{ik} \right\} \right\}. \tag{3}$$

Replacing the weights by binding energies (which are negative for stabilizing interactions) we simply have to replace max by min in the above recursions. In practice, this simplified energy model does not lead to reasonable predictions in most cases. We use it here for didactic purposes and relegate a more detailed description of the complete RNA folding problem to Section 3.3.

The energy contributions of individual base pairs are of the same order of magnitude as the thermal energy at room temperature. Thus, RNA molecules exist in a distribution of structures rather than in a single ground-state structure. Thermodynamics dictates that, in equilibrium, the probability of a particular structure Ψ is proportional to its Boltzmann factor $\exp[-E(\Psi)/RT]$. Here $E(\Psi)$ is the energy of the sequence in conformation (secondary structure) Ψ, R is the molar gas constant (Boltzmann's constant in molar units) and T is the absolute ambient temperature in Kelvin. This ensemble of structures is determined by its *partition function*:

$$Z = \sum_{\Psi} \exp(-E(\Psi)/RT)\,, \tag{4}$$

or, equivalently, by the free energy $\Delta G = -RT \ln Z$. The partition function Z can be computed in analogy to Eq. (3). Using Z_{ij} as the partition function over all structures on subsequence $x[i,\ldots,j]$ we obtain [93]:

$$Z_{ij} = Z_{i+1,j} + \sum_{k,\,(i,k)\text{ pairs}} Z_{i+1,k-1} Z_{k+1,j} \exp(-\beta_{ik}/RT)\,. \tag{5}$$

Note that we can transform the recursion for E_{ij} in Eq. (3) into the equation for Z_{ij} simply by exchanging maximum operations with sums, sums with multiplications and energies by their corresponding Boltzmann factors.

The partition function allows us to compute the equilibrium probability of a structure Ψ as $p(\Psi) = \exp[-E(\Psi)/RT]/Z$. The formalism is also used to efficiently compute the equilibrium probability of a base pair $p_{ij} = \sum_{(i,j)\in\Psi} p(\Psi)$. To this end one needs to compute the partition function $\widehat{Z}_{ij}$ of structures *outside* the subsequence $x[i,\ldots,j]$ using a recursion similar to the one above for Z. We can now compute the partition function over all structures containing the pair (i,j) and thus its probability:

$$p_{ij} = \widehat{Z}_{ij} Z_{i+1,j-1} \exp(-\beta_{ij}/RT)/Z\,. \tag{6}$$

Further variants of this scheme can be employed to compute, for example, the number of states with a given energy, to explicitly list all possible structures or to determine structures that optimize other properties. In Section 5.5 we will briefly mention how such variants can be constructed in a systematic way within the framework of *algebraic dynamic programming* (ADP) [36].

3.2 Backtracing

Recursion (3) computes only the optimal energy, not an optimal structure which realizes this energy. This is typical for most dynamic programming algorithms: one first computes the value of the optimum, then uses *backtracing* (sometimes called *backtracking*) to generate one (or more) structures in a stepwise fashion based on the information collected in the forward recursions. This section closely follows an exposition of the topic in Ref. [29]. The basic object is a partial structure π consisting of a collection Ω_π of base pairs and a collection Υ_π of sequence intervals in which the structure is not (yet) known. Positions that are known to be unpaired can easily be inferred from this information. The completely unknown structure on the sequence interval $[1,n]$ is therefore $\varnothing = (\varnothing, \{[1,n]\})$ while a structure is complete if it is of the form $\pi = (\Omega, \varnothing)$.

Suppose $I = [i, j] \in \Upsilon$ are positions for which the partial structure $\pi = (\Omega, \Upsilon)$ is still unknown. If we know that i is unpaired, then $\pi' = (\Omega', \Upsilon')$ with $\Omega' = \Omega\ \Upsilon' = \Upsilon \setminus \{I\} \cup \{[i+1, j]\}$. If $(i, k), i < k \leq j$, is a base pair, then $\Omega' = \Omega \cup \{(i, k)\}$ and $\Upsilon' = \Upsilon \setminus \{I\} \cup \{[i+1, k-1], [k+1, j]\}$. Here we use the convention that empty intervals are ignored. Furthermore, base pairs can only be inserted within a single interval of the list Υ. We write $\pi' = \pi \blacktriangleleft (i)$ and $\pi' = \pi \blacktriangleleft (i, k)$ for these two cases.

The energy of a partial structure π is defined as:

$$E(\pi) = \sum_{(k,l) \in \Omega} \beta_{kl} + \sum_{I \in \Upsilon} E_{\text{opt}}(I)\,, \tag{7}$$

where $E_{\text{opt}}(I) = E_{ij}$ is the optimal energy for the substructure on the interval $I = [i, j]$.

The standard backtracing for the minimal energy folding starts with the unknown structure. Instead of a recursive version we describe here a variant where incomplete structures are kept on a stack $\mathfrak{S}$. We write $\pi \leftarrow \mathfrak{S}$ to mean that π is popped from the stack and $\pi \rightarrow \mathfrak{S}$ to mean that π is pushed onto the stack.

If we want all optimal energy structures instead of a single representative we simply test all alternatives, i.e. we omit the **next** in Algorithm B1, Table 2. It is now almost trivial to modify the backtracing to produce all structures within an energy band $E_{\text{opt}} \leq E \leq E_{\text{max}}$ above the ground state.

Stochastic backtracing procedures for dynamic programming algorithm such as pairwise sequence alignment are well known [97]. Replacing Z_{ij} by N_{ij} in Algorithm B3 we recover recursions for producing a uniform ensemble of structures similar to the procedure for producing random structures without sequence constraint used in Ref. [127].

Note that the probabilities of $\pi \blacktriangleleft (i+1)$ and $\pi \blacktriangleleft (i, k)$ for all k add to 1 so that in each iteration we take exactly one step. Hence, we simply fill one structure which we output as soon as it is complete. See Table 2.

3.3 Energy Minimization in the Loop-based Energy Model

Using the loop-based energy model is essential in order to achieve reasonable prediction accuracies. As we shall see, the more complicated energy model results in somewhat more complicated recursions and requires additional tables. However, memory and CPU requirements are still $\mathcal{O}(n^3)$ and $\mathcal{O}(n^2)$. The main difference from the simple model discussed in the previous sections is that we now have to distinguish between different types of loops. Thus, we have to further decompose the set of substructures enclosed by the base pair (i, k) according to the loop types: hairpin loop, interior loop

Table 2 Comparison of backtracing recursions for different algorithms

and multi(branched) loops (Figure 6). The hairpin and interior loop cases are simple since they reduce again to the same decomposition step.

The multiloop case is more complicated, however, since the multiloop energy depends explicitly on the number of substructures ("components") that emanate from the loop. We therefore need to decompose the structures within the multiloop in such a way that we can at least implicitly keep track of the number of components. To this end we represent a substructure within a multiloop as a concatenation of two components: an arbitrary 5′ part that contains *at least* one component, and a 3′ part that starts with a base pair and contains only a single component. These two types of multiloop substructures are now decomposed further into parts that we already know: unpaired inter-

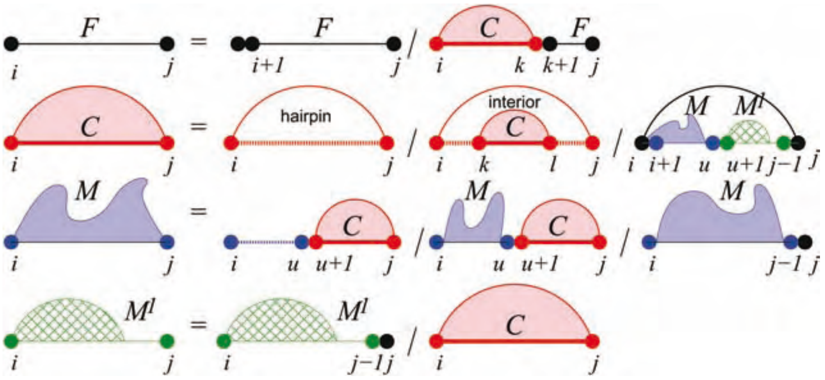

Figure 6 Decomposition of RNA secondary structure. Dotted lines indicate unpaired substructures, while full lines denote arbitrary structures; base pairs are indicated as arcs. Multiloop contributions with an arbitrary number of components are shown as irregular "mountains". See text for further details.

vals, structures enclosed by a base pair and (shorter) multiloop substructures (Figure 6). It is not too hard to check that this decomposition really accounts for all possible structures and that each secondary structure has a unique decomposition.

Given the recursive decomposition of the structures, we can now rather easily derive the associated energy minimization algorithm. We will use the abbreviations $\mathcal{H}(i,j)$ for the energy of a hairpin loop closed by the pair (i,j), similarly $\mathcal{I}(i,j;k,l)$ shall denote the energy of an interior loop determined by the two base pairs (i,j) and (k,l). We will also tabulate the following quantities:

F_{ij} free energy of the optimal substructure on the subsequence $x[i,\dots,j]$.

C_{ij} free energy of the optimal substructure on the subsequence $x[i,\dots,j]$ subject to the constraint that i and j form a base pair.

M_{ij} free energy of the optimal substructure on the subsequence $x[i,\dots,j]$ subject to the constraint that that $x[i,\dots,j]$ is part of a multiloop and has at least one component.

M^1_{ij} free energy of the optimal substructure on the subsequence $x[i,\dots,j]$ subject to the constraint that that $x[i,\dots,j]$ is part of a multiloop and has exactly one component, which has the closing pair i,h for some h satisfying $i < h \leq j$.

The recursions for computing the minimum free energy of an RNA molecule in the loop based energy model were first formulated by Zuker and Stiegler [150]. They can be summarized as follows:

$$\begin{aligned}
F_{ij} &= \min\left\{F_{i+1,j}, \min_{i<k\leq j}\left(C_{ik}+F_{k+1,j}\right)\right\} \\
C_{ij} &= \min\left\{\begin{matrix}\mathcal{H}(i,j), \min_{i<k<l<j}\left(C_{kl}+\mathcal{I}(i,j;k,l)\right), \\ \min_{i<u<j}\left(M_{i+1,u}+M^1_{u+1,j-1}+a\right)\end{matrix}\right\} \\
M_{ij} &= \min\left\{\begin{matrix}\min_{i<u<j}\left((u-i+1)c+C_{u+1,j}+b\right), \\ \min_{i<u<j}\left(M_{i,u}+C_{u+1,j}+b\right),\ M_{i,j-1}+c\end{matrix}\right\} \\
M^1_{ij} &= \min\left\{M^1_{i,j-1}+c,\ C_{ij}+b\right\},
\end{aligned} \tag{8}$$

where we assume linear multiloop energies of the form $E_{\mathrm{ML}} = a + b \cdot \text{degree} + c \cdot \text{size}$. In contrast to most implementations the version shown here decomposes structures in such a way that each substructure occurs exactly once.

While this is not strictly necessary for energy minimization, it allows us to use essentially the same recursions for all variants of the problem, including the computation of the partition function, or the backtracing of all or a sample of suboptimal structures.

3.4 RNA Hybridization

Intermolecular base pairing between two RNA molecules can be treated in the same way as intramolecular interactions. The most straightforward approach is to concatenate the two molecules. One can then apply the folding algorithms for single molecules. There is only a single necessary modification to the folding algorithms: the energy contribution of the loop that contains the cut point is different. Implementations of this approach are RNAcofold [56] and pairfold [5].

From a physics point of view, however, additional effects need to be taken into account: the interaction of two distinct molecules is concentration dependent. Furthermore, there is an additional (entropic) contribution for the initiation of an intermolecular interaction. The extension of the folding algorithms of course compute both inter- and intra-molecular contributions. It is therefore necessary to correct for the initialization energy E^i:

$$\begin{aligned} Z_{AA} &= (Z^\circ_{AA} - Z^2_A)\exp(-E^i/RT) \\ Z_{BB} &= (Z^\circ_{BB} - Z^2_B)\exp(-E^i/RT) \quad \text{and} \\ Z_{AB} &= (Z^\circ_{AB} - Z_A Z_B)\exp(-E^i/RT)\,. \end{aligned} \tag{9}$$

where Z° is the partition function as calculated from the folding algorithm for the concatenated sequences, and Z_A and Z_B are the partition functions of the isolated molecules A and B. Standard statistical thermodynamics can then be used to compute the concentration dependencies of the complex formation (e.g. Ref. [20] for a discussion in the context of RNA hybridization).

Various simplified approaches have been discussed in recent years. In particular, the most common approximation is to neglect the secondary structures of the two interacting molecules. This amounts to a model in which the concatenated structure can only have base pairs and interior loops, and the cut point is located in the single hairpin loop. It does, however, result in a much faster algorithm with time complexity $\mathcal{O}(n \cdot m)$ instead of $\mathcal{O}((n+m)^3)$ for two sequences of length n and m. Algorithms for this case have been described in Refs. [20, 105]; the Vienna RNA Package also provides an implementation. The RNAhybrid program was in particular used to detect microRNA/target interactions.

3.5 Pseudoknotted Structures

Many functionally important RNA structures contain pseudoknots, including rRNAs [12], RNase P RNAs [10,49] and tmRNA [151]. Recently, algorithms have been described that are able to deal with certain classes of pseudoknotted structures. However, as we shall see below, these are plagued by considerable computational costs. In addition, a common problem of all these approaches is the still very limited information about the energetics of pseudoknots [43,66].

In the general case of unrestricted pseudoknots the problem is NP-complete when a loop-based energy model is used [3,86]. Arbitrarily complex pseudoknots, however, are also biologically unrealistic. While every secondary structure has a plausible 3-D realization (this follows directly from the tree structure of secondary structures), this is not true for more general structures: it may well be impossible to embed a given arbitrary set of base pairs in 3-D space such that chemically reasonable distances are maintained. By construction, such constraints cannot be incorporated into our graph-based model of RNA structure. One remedy is to restrict oneself to certain (simple) classes of pseudoknots.

Figure 7 shows the algorithmic problem with pseudoknots. In principle, one could include (a certain type of) pseudoknots as additional structural elements into the dynamic programming recursion. The further decomposition of the structure, however, requires at least two coupled cut points, here k and l, even if we assume that the structures of crossing arc sets are only single stems. This increases the CPU requirements to at least $\mathcal{O}(n^4)$. More realistic models, such as the H-type model, require additional memory as well.

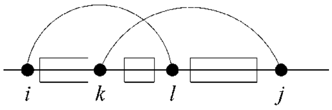

Figure 7 Additional requirements for computing pseudoknotted structures. In order to evaluate the contribution for the pseudoknot on $[i, j]$ we need to iterate over all combinations of cutpoints $k < l$.

Algorithms for a number of different classes of pseudoknots have been published in recent years, (e.g. Refs. [3,22,86,104,109]). Figure 8 summarizes the relationships between the algorithmic complexities of predicting secondary structures from some of these structure classes [16].

3.6 Notes

The basic counting recursion can be readily modified to enumerate other quantities of interest such as the structures with particular properties and distributions of structural elements (e.g. Ref. [58]). The combinatorics of RNA

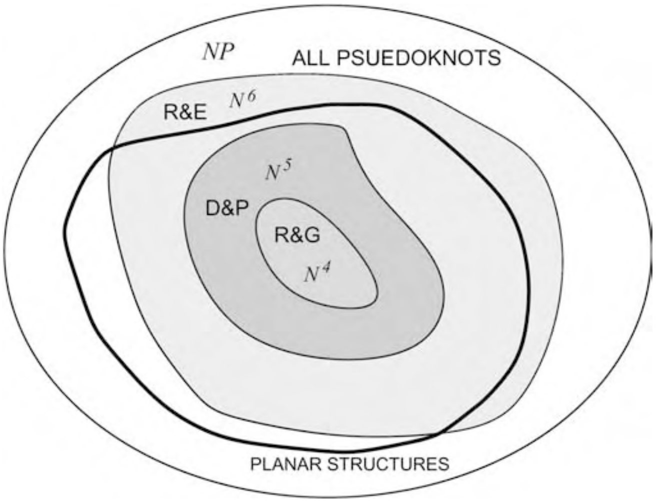

Figure 8 The most prominent classes of pseudoknotted structure are those investigated by Reeder and Giegerich R&G [104], Dirks and Pierce D&P [22], and Rivas and Eddy R&E [109].

secondary structures and related mathematical objects such as ordered trees, Motzkin paths and noncrossing partitions is still an active area of research (e.g. Refs. [13, 19, 81] and the references therein).

The recursions for the loop-based energy model as displayed above, in fact, give rise to $\mathcal{O}(n^4)$ CPU requirements due to the interior loop contribution. However, very long interior loops are extremely unlikely (and unstable), so that the length of interior can be bounded by a constant, e.g. $M = 30$. The interior loop contribution thus remains quadratic. Under certain plausible assumptions on the interior loop energies, a cubic time algorithm can be designed [87] that takes interior loops of all sizes into account.

A restriction of the folding algorithm to local structure is described in Ref. [57]. Here, the maximum span $|j - i + 1|$ of a base pair (i, j) is bounded by a constant L. The resulting "scanning" algorithms are linear in time and space, and hence can be used to screen entire genomes for locally stable structures.

Circular RNA molecules are rare, but their secondary structures are of considerable interest because structural features are important, e.g. in viroids [108,123]. A straightforward way of dealing with circular RNA molecules is to compute C_{ij} and M_{ij} also for the subsequences of the form $x[j, \dots, n]x[1, \dots, i]$ [149]. The disadvantage of this approach is, however, that it doubles the memory requirements. An alternative is described in Ref. [60].

A secondary structure Ω is *saturated* if none of its stems can be elongated, i.e. if any single base pair that is inserted into Ω does not stabilize the structure by stacking to any other base pairs. The recursions (Figure 6) can be modified to produce only saturated structures [26]. Similarly, we may call Ω *locally base pair optimal* if Ω cannot be expanded by any additional base pair. In Ref. [15] a dynamic programming algorithm is described that computes such locally optimal structures in quartic time with cubic memory requirements.

Prediction of pseudoknotted structures based on maximum matching can be done using algorithms for Maximum Weighted Matching [125]. While this approach requires only $O(n^3)$ time, it cannot take the loop-based energy model into account. "Iterated loop matching", i.e. the repeated (greedy) application of the Nussinov algorithm, is another approximate way of computing pseudoknotted structures [113]. Finally, heuristics such as genetic algorithms can be used to compute pseudoknotted structures [78].

4 Conserved Structures, Consensus Structures and RNA Gene Finding

4.1 The Phylogenetic Method

Most functional RNA molecules have characteristic secondary structures that are highly conserved in evolution. Well-known examples include rRNAs, tRNAs, RNase P and MRP RNAs, the RNA component of signal recognition particles, tmRNA, group I and group II introns, and small nucleolar RNAs. It is therefore of considerable practical interest to efficiently compute the consensus structure of a collection of such RNA molecules.

Given a sufficiently large database of aligned RNA sequences, one can directly infer a consensus secondary structure from the data. The basic idea is that substitutions in the sequence will respect the common structural constraints. Therefore, substitutions in helical regions have to be correlated, since in general only six (GC, CG, AU, UA, UG and GU) out of the 16 combinations of two bases can be incorporated in the helix. Two columns in the alignment thus will covary if they form a base pair.

For concreteness, assume that we are given a multiple sequence alignment $\mathbb{A}$ of N sequences. By $\mathbb{A}_i$ we denote the i-th column of the alignment, while a_i^α is the entry in the α-th row of the i-th column. The length of $\mathbb{A}$, i.e. the number of columns, is n. Furthermore, let $f_i(\mathrm{X})$ be the frequency of base X at aligned position i and let $f_{ij}(\mathrm{XY})$ be the frequency of finding simultaneously X at position i and Y at j.

The most common way of quantifying sequence covariation for the purpose of RNA secondary determination is the *mutual information* score [14,44,45]:

$$MI_{ij} = \sum_{\mathrm{X,Y}} f_{ij}(\mathrm{XY}) \log \frac{f_{ij}(\mathrm{XY})}{f_i(\mathrm{X}) f_j(\mathrm{Y})}. \tag{10}$$

Usually, the mutual information score makes no use of RNA base-pairing rules. For large datasets this is desirable, since it allows us to identify noncanonical base pairs and tertiary interaction. For the small datasets considered in the following subsections, however, neglecting base pairing rules does more harm (by increasing noise) than good. In particular, mutual information does not account at all for consistent noncompensatory mutations, i.e. if we have, say, only GC and GU pairs at positions i and j then $M_{ij} = 0$. Thus, sites with two different types of base pairs are treated just like a pair of conserved positions.

A straightforward measure of covariation takes the form:

$$C_{ij} = \sum_{\mathrm{XY},\mathrm{X'Y'}} f_{ij}(\mathrm{XY}) \mathbf{D}_{\mathrm{XY},\mathrm{X'Y'}} f_{ij}(\mathrm{X'Y'}). \tag{11}$$

where a suitable choice for the 16×16 matrix $\mathbf{D}$ has entries $\mathbf{D}_{\mathrm{XY},\mathrm{X'Y'}} = d_H(\mathrm{XY},\mathrm{X'Y'})$ if both $\mathrm{XY} \in \mathcal{B}$ and $\mathrm{X'Y'} \in \mathcal{B}$ and $\mathbf{D}_{\mathrm{XY},\mathrm{X'Y'}} = 0$ otherwise. Here $\mathcal{B} = \mathrm{GC}, \mathrm{CG}, \mathrm{AU}, \mathrm{UA}, \mathrm{GU}$ or UG, and $d_H(\mathrm{XY},\mathrm{X'Y'})$ is the Hamming distance of XY and X′Y′. The idea here is that consistent mutations such as GC → GU should count less (here half) of a compensatory mutation such as GC → AU. Note that Eq. (11) is a scalar product, $C_{ij} = \langle f_{ij} \mathbf{D} f_{ij} \rangle$ and hence can be evaluated efficiently. If desired, $\mathbf{D}$ could be replaced by a different kernel that, for example, could incorporate measured substitution rates [35].

The purely phylogenetic approach suffers from two limitations. (i) It requires a very large set of sequences in order to obtain a reliable estimate of covariance or mutual information for each pair of sequences. With the exception of rRNAs and tRNAs, such large datasets are usually not (yet) available. (ii) It is sensitive to alignment errors and hence not applicable to very diverse sets of sequences. A possibly remedy is provided by approaches towards solving the folding and alignment problems simultaneously or iteratively. These are discussed in the following section.

4.2 Conserved Structures

The amount of data that is required for inferring structures can be reduced dramatically by taking thermodynamics of folding into account. Indeed, Ref. [48] suggested to resolve ambiguities in the phylogenetic analysis based on thermodynamic considerations.

However, the converse approach, i.e. to use the information which base pairs are thermodynamically plausible, appears to be more efficient. Most of the alignment-based methods therefore start from thermodynamics-based folding and use the analysis of sequence covariations or mutual information for postprocessing (see, e.g. Refs. [54, 59, 71, 77, 84, 85]). We describe here the alidot algorithm (Figure 9) [54, 59].

For each of the aligned sequences secondary structures are computed separately. The resulting lists of base pairs from either minimum free energy calculations or from a partition function calculation are then superimposed by using the multiple sequence alignment to determine which pairs in different sequences are equivalent. For each pair we now have both thermodynamic and sequence covariation information, which is used to hierarchically rank order base pairs depending on their support across the entire data set. A greedy procedure then extracts contiguous stems from the rank ordered list and combines them to a partial secondary structure which contains only those sequence/structure elements that are significantly conserved throughout the aligned input sequences.

An alternative to the ranking/greedy approach of alidot is to compute a score or weight w_{ij} for each possible base pair. The program ConStruct [84] uses a simple scoring function that exclusively combines the base-pairing probabilities of the individual sequences. Covariance or mutual information score as well as contributions that consider the potential to extend the pair to a longer helix [141] could easily be included. A secondary structure can then be computed using the Nussinov algorithm with weights w_{ij} for the base pairs. The downside of this approach is that it returns a global secondary structure rather than a collection of well-supported local features.

Comparative approaches are based on the fact that RNA secondary structure is quite fragile against randomly placed point mutations. Our earlier computational studies suggest that even with 85% sequence identity we should expect no significant structural similarity [33, 116]. While this result

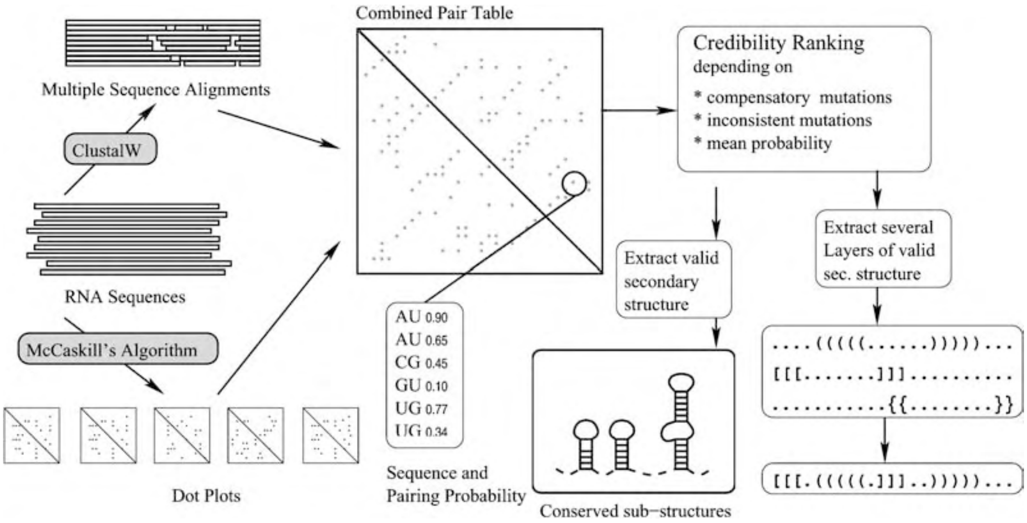

Figure 9 Flow chart of the alidot algorithm.

may seem surprising, there has been convincing experimental evidence (see e.g. Ref. [115]). Methods such as alidot thus can discriminate very well between conserved and nonconserved RNAs. Both alidot and ConStruct require interactive work and are therefore best suited for small genomes as found in RNA viruses [61,131,142].

4.3 Consensus Structures

Sometimes it is known *a priori* that the aligned sequences should fold into a common secondary structure. This is the case, for example, for rRNAs, tRNAs and many other small noncoding RNA (ncRNA) molecules. In this case it makes sense to ask, what is the most stable structure that can be formed simultaneously by all (or almost all) input sequences? This problem is solved in a rather straightforward way by RNAalifold [55]. It treats the entire alignment like a single sequence and solves the secondary structure problem for this "generalized sequence". To this end, of course, an extension of the standard energy model to alignments is required. RNAalifold simply averages the energy contribution over all sequences. In the simple case of base-pair-dependent energies this means:

$$\beta_{ij}^{\mathbb{A}} = \frac{1}{N} \sum_{\alpha} \beta_{x_i^\alpha, x_j^\alpha}. \tag{12}$$

For the realistic energy model, energies for the different loop types are averaged individually.

Both the mutual information score and the covariance score assign a bonus to compensatory mutation. Neither score deals with inconsistent sequences, i.e. with sequences that cannot form a base pair between positions i, j. The simplest ansatz for this purpose is to simply count the number of sequences q_{ij} that cannot form a canonical base pair between columns i and j. Here, combinations of a nucleotide and a gap are counted as inconsistent while gap–gap combinations (i.e. deletions of an entire base pair) are ignored.

In a multiple alignment of a larger number of sequences we have to expect occasional sequencing errors and of course there will be alignment errors. Thus, we cannot simply mark a pair of positions as nonpairing if a single sequence is inconsistent. Furthermore, there is the possibility of a nonstandard base pair [44]. Thus, we define a threshold value for the combined score $B_{ij} = C_{ij} - \phi_1 q_{ij}$ and declare a pair of positions i, j as nonpairing if B_{ij} is too small.

Figure 10 shows the consensus structure of the mir-105 microRNA family as an example. Such consensus structures are needed for the derivation of pattern descriptions that can be used to search for structurally similar RNAs in genomic DNA, as briefly described in the following section.

4.4 RNA Gene Finding

It is, of course, possible to identify genomic sequences that are homologous to known RNA genes, using either BLASTN or, as in the case of tRNAs, more specialized methods. For most functional ncRNA molecules the secondary

Figure 10 Consensus secondary structure of the 11 sequences from mammalian microRNA mir-105. Sequences are taken from the microRNA Registry (version 6.0) and from BLAST searches in vertebrate genomes. (a) *Mountain plot:* a base pair (i, j) is represented by a slab ranging from i to j. The $5'$ and $3'$ sides of stems thus appear as up-hill and down-hill slopes, respectively, while plateaus indicate unpaired regions. Colors indicate sequence variation by encoding the number of different types of base pairs (GC, CG, AU, UA,GU, UG) that occur in the two paired columns of the alignment. Pairs with conserved sequence are shown in red; ocher, green, cyan, blue and violet indicate two to six types of base pairs. Pairs with one or two inconsistent mutations are shown in (two degrees of) pale colors. (b) In the *conventional secondary structure graph* paired positions are color coded as in the mountain plot. Consistent mutations are indicated by circles around the varying position, compensatory mutations thus are marked by circles around both pairing partners.

structure is much more conserved than their sequence. This can be used to identify putative ncRNA sequences using programs such as RNAmot [34], tRNAscan [83] or HyPa [40]. Nevertheless, all these approaches are restricted to searching for new members of the few well-established families such as tRNAs, small nucleolar RNAs, microRNAs and certain spliceosomal RNAs.

A different approach is taken in the program QRNA [110]. This method for comparative analysis of two aligned homologous sequences can detect novel structural RNA genes by deciding whether the substitution pattern fits better with (i) synonymous substitutions, which are expected in protein-coding regions, (ii) the compensatory mutations consistent with some base-paired secondary structure or (iii) uncorrelated mutations.

The alidot approach has never been used for large-scale gene finding since it has turned out to be nontrivial to assign statistical significance values to its results. Most recently, however, a conceptually related technique has been developed that is efficient and sensitive enough to allow genome-wide screens for RNAs.

The program RNAz [138] combines a comparative approach (scoring conservation of secondary structure) with the observation [8,76,136] that ncRNAs are thermodynamically more stable than expected by chance. This excess stability is conveniently measured in terms of the z-score:

$$z = \frac{E - \overline{E}}{\sigma}, \tag{13}$$

where $\overline{E}$ and σ are mean and standard deviation of the distribution of shuffled sequences. Instead of dealing with individual sequences, RNAz uses multiple sequence alignments of potential RNAs from different species as input. The computation of z by direct sampling is extremely time-consuming. In RNAz it is therefore replaced by a support vector machine that has been trained to solve the regression problems of estimating $\overline{E}$ and σ from properties of the input sequences.

Structural conservation is also quantified in thermodynamical terms. The structure conservation index S is defined as the ratio of the average energy of the consensus structure (as computed by RNAalifold) and the average of the unconstrained folding energies of the individual sequences. An alignment of identical sequences thus has $S = 1$. On the other hand, completely unrelated sequences will not be able to form a consensus structure since there are always some sequences that contradict any particular pairing, thus $S = 0$. Sequences that form a well-conserved consensus sequence in the presence of sequence covariations, finally, will have the same energy contributions in the consensus and in the individual folds. In addition, however, the consensus energy contains the bonus contributions for sequence covariations, so that we obtain $S > 1$. See Figure 11.

RNAz uses a support vector machine (SVM) [17] to determine from the z-score and the structure conservation index whether a given multiple sequence alignment is a structurally conserved RNA. Surveys of animal genomes [96,

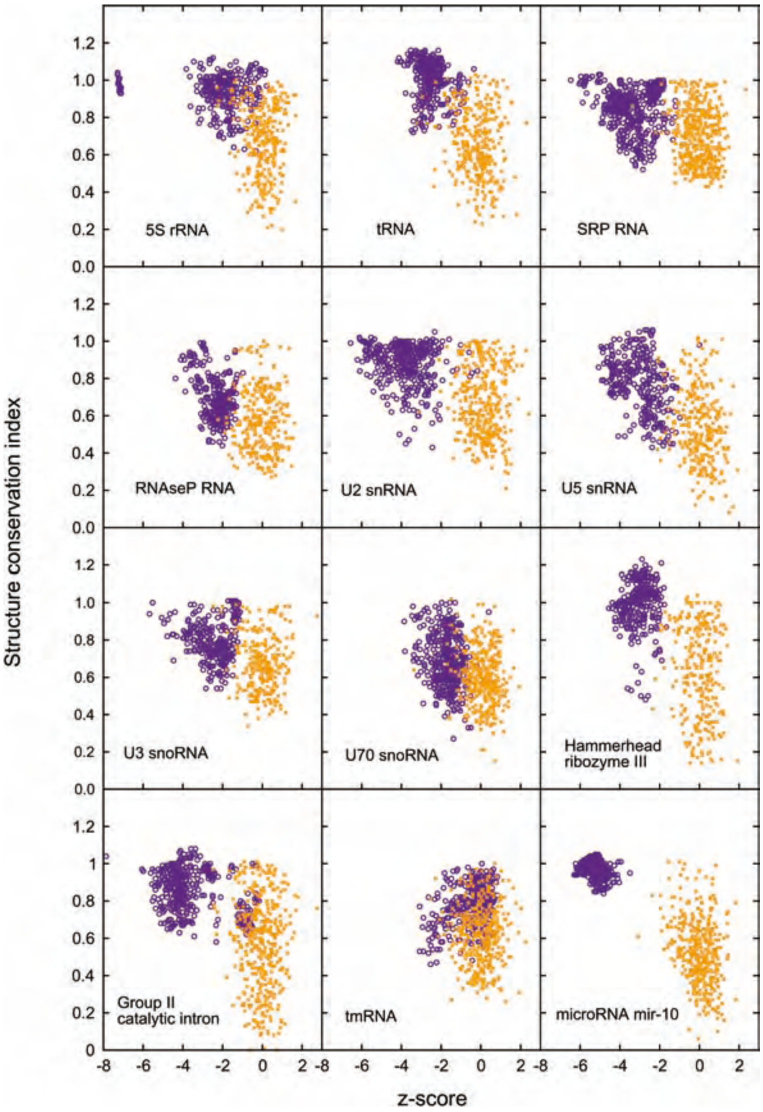

Figure 11 Scatter plot of structure conservation index S (x-axis) and energy z-score (y-axis) for different families of structured ncRNAs. In each panel, the properties of the true sequences (dark) are compared with controls obtained by shuffling the sequence. Data are taken from Ref. [138].

137] reveal a very large number of previously unknown candidates for both independent ncRNAs and structured *cis*-acting elements in mRNAs.

4.5 Notes

Including covariation information is also a good way to improve the accuracy of structure predictions including pseudoknots. One approach is to forgo a loop-based energy model and use base pair scores instead, in which case the resulting Maximum Weighted Matching problem can be solved efficiently [125]. Good accuracies can be achieved by using a combination of covariance and thermodynamic criteria for scoring potential base pairs [141]. The ILM program of Ruan and coworkers [113], uses the Nussinov algorithm iteratively in order to build pseudoknotted structures.

5 Grammars for RNA Structures

5.1 Context-free Grammars (CFGs) and RNA Secondary Structures

The recursions for RNA folding in Figure 6 suggest a close connection with certain grammars. More precisely, we may interpret Figure 6 as the production rules of an "RNA language". The tree representations in Figure 4, on the other hand, are suggestive of a connection between RNA structures and parse trees of a grammar that generates RNA sequence. As we shall see in this section, these connections can be made precise and open the door to the application of learning techniques in RNA bioinformatics.

Recall that a formal language $\mathcal{L}$ is a set of strings over a given alphabet $\mathcal{A}$. A *grammar* G for the language $\mathcal{L}$ consists of:

- A set T of *terminals* which are the letters of the alphabet $\mathcal{A}$ possibly augmented by the null-character ε.
- A set N of *nonterminals* which represent the syntactic categories of $\mathcal{L}$
- A set P of *production* or *derivation rules* which are used to derive the strings in $\mathcal{L}$. Each production consists of a nonterminal "head" that is produced and a string of zero or more nonterminal and terminals (the "body" of the production)
- A single nonterminal $S \in N$ that is designated as the start symbol.

The "dot-parenthesis" grammar for RNA, in the simplest case, can be written as $\mathrm{G}_0 = (T, N, P, s)$ with $T = \{(,), ., \varnothing\}$, $N = \{S\}$, $s = S$ and:

$$P = \left\{S \to S., S \to (S)S, S \to \varnothing\right\}, \tag{14}$$

where $\varnothing$ denotes the empty string. The grammar above is *context-free* since all productions are of the form $V \longrightarrow w$, where V is a nonterminal and w is a string consisting of terminals and/or nonterminals. The grammar generates strings of dots and balanced parenthesis; the parse trees of this grammar correspond to the secondary structures. More elaborate grammars can be designed that explicitly encode different types of loops or other substructures. In particular, the decompositions of the structure sets in Section 3.3 can be recast in terms of a grammar:

$$\begin{aligned} F &\longrightarrow uF|CF|\varnothing \\ C &\longrightarrow pL'\bar{p} \mid pLCL\bar{p} \mid pMN\bar{p} \\ M &\longrightarrow LC \mid MC \mid Mu \\ N &\longrightarrow Nu \mid C \\ L' &\longrightarrow uuuL \\ L &\longrightarrow uL \mid \varnothing. \end{aligned} \tag{15}$$

This grammar generates RNA sequences, while again the parse trees correspond to secondary structures (Figure 12). The terminal u denotes an unpaired base, while p and $\bar{p}$ is a shorthand for one of the six pairing combinations of bases. The start symbol F represents any structure, L stands for an unpaired sequence within a loop, M and N represent the left and right half of a multiloop. The production for L' enforces the minimum length of a hairpin loop.

Chomsky normal forms have only productions of the form $V \longrightarrow XY$ and $V \longrightarrow a$ with $V, X, Y \in N$ and $a \in T$. One can show that every context-free grammar can be converted to normal form, i.e. there is a CFG in normal form that produces the same language $\mathcal{L}$.

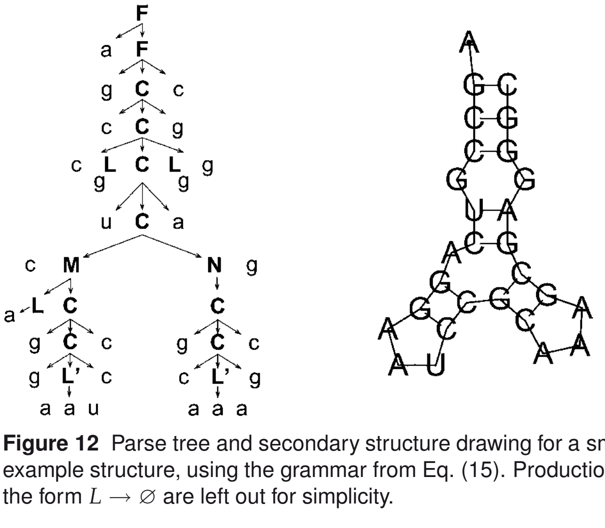

Figure 12 Parse tree and secondary structure drawing for a small example structure, using the grammar from Eq. (15). Productions of the form $L \longrightarrow \varnothing$ are left out for simplicity.

Given a CFG $G = (T, N, P, s)$ we obtain a *stochastic CFG* (*SCFG*) by assigning probabilities $\mathbb{P}(\alpha)$ to all productions $\alpha \in P$ such that $\sum_{\alpha \in P} \mathbb{P}(\alpha) = 1$ is satisfied.

The probabilities associated with the individual productions take on the role of the energy parameters in the previous sections. While the energy parameters must be measured directly, the values of $\mathbb{P}(\alpha)$ can be inferred from training sets of known sequence/structure pairs in a generic machine learning setting. Thus, they can, at least in principle, readily combine different sources of information that can be expressed probabilistically, such as an evolutionary model (derived from a comparative analysis of RNA sequences) and a biophysically motivated model of structure plausibility. In the following three subsection we briefly outline the basic techniques: finding the most likely parse-tree, computing the probability of a given word and the estimation of production probabilities from a given dataset. None of these algorithms is RNA specific; rather, they apply to any SCFG in Chomsky normal form.

5.2 Cocke–Younger–Kasami (CYK) Algorithm

The analog of the minimum free energy folding problem in the SCFG setting can be phrased in the following way: given a string $x \in \mathcal{L}$, find the most likely parse tree for x in a grammar G.

Under the assumption that G is in Chomsky normal form, there is an efficient (polynomial-time) solution to this question, the CYK algorithm [146].

Let $w(i, j, V)$ denote the likelihood of the most likely parse tree on the substring $x[i, \ldots, j]$ rooted at the nonterminal V. Clearly, we have $w(i, i, V) = \log \mathbb{P}(V \to x_i)$ for all i and V. For all larger substrings, $j > i$, we try all productions of the form $V \to XY$ and select the one that maximizes the likelihood. This immediately leads to the recursion

$$w(i, j, V) = \max_X \max_Y \max_{i \le k < j} \left[\log \mathbb{P}(V \to XY) + w(i, k, X) + w(k+1, j, Y) \right] \quad (16)$$

with the initialization $w(i, i, V) = \log \mathbb{P}(V \to x_i)$. The same type of backtracing approach as in the Nussinov algorithm can be used to explicitly recover the parse tree, which corresponds to the secondary structure of the RNA molecule.

5.3 Inside and Outside Algorithms

Instead of retrieving the most likely parse tree one may instead be interested in the probabilities of generating substrings in a particular way. In particular, let $p(i, j, V)$ be the probability that the "inside" substring $x[i, \ldots, j]$ is generated by the nonterminal V. Furthermore, let $q(i, j, V)$ be the probability that the "outside" substrings $x[1, \ldots, i-1] \cup x[j+1, \ldots, n]$ are generated from the start symbol S under the condition that (the parse subtree of) the subsequence $x[i,\ldots,j]$ is rooted at V. Conceptually, these quantities correspond to the partition functions inside and outside of a subsequence $x[i,\ldots,j]$. It is straightforward to derive the corresponding *inside recursion*:

$$p(i,j,V) = \sum_X \sum_Y \sum_{k=i}^{j} \mathbb{P}(V \to XY) p(i,k,X) p(k+1,j,Y), \tag{17}$$

which is initialized with $p(i,i,V) = \mathbb{P}(V \to x_i)$. The *outside recursion* consists of two parts, depending on whether the root V of the interior parse tree is the right or the left nonterminal in the previous production. This yields:

$$\begin{aligned} q(i,j,V) =& \sum_X \sum_Y \sum_{k<i} \mathbb{P}(Y \to XV) p(k,i-1,X) q(k,j,Y) \\ &+ \sum_X \sum_Y \sum_{k>j} \mathbb{P}(Y \to VX) q(i,k,Y) p(j+1,k,X), \end{aligned} \tag{18}$$

with the initial conditions $q(1,n,S) = 1$ and $q(1,n,X) = 0$ for all $X \in N \setminus \{S\}$. The probability to produce the sequence x is:

$$\mathbb{P}(x) = p(1,n,S) = \sum_X q(i,i,X) \mathbb{P}(X \to x_i). \tag{19}$$

5.4 Parameter Estimation

One problem with SCFG approaches is that the production probabilities have to be estimated from data. To this end, we compute the expected number $c(V)$ that V is used to parse x and the expected numbers $c(\alpha)$ that production α is used in the derivation of x. It is straightforward to derive:

$$\begin{aligned} c(V) &= \frac{1}{\mathbb{P}(x)} \sum_{i,j=1}^{n} p(i,j,V) q(i,j,V) \\ c(V \to a) &= \frac{1}{\mathbb{P}(x)} \sum_{i:x_i=a} q(i,i,V) \mathbb{P}(V \to a) \\ c(V \to XY) &= \frac{1}{\mathbb{P}(x)} \sum_{i,j=1}^{n} \sum_{k=i}^{j} q(i,j,V) p(i,k,X) p(k+1,j,Y) \mathbb{P}(V \to XY). \end{aligned} \tag{20}$$

Updated estimates for the production probabilities can thus be obtained as $\mathbb{P}'(\alpha) = c(\alpha)/c(V)$ for all $\alpha \in P$. The procedure is then repeated until $\sum_\alpha |\mathbb{P}'(\alpha) - \mathbb{P}(\alpha)| < \varepsilon$, where ε is a user-defined accuracy.

5.5 Algebraic Dynamic Programming

Algebraic Dynamic Programming (ADP) [36] was introduced to facilitate and systematize the development of dynamic programming algorithms. Conceptually, a dynamic programming algorithm consists of three components: a search space of candidate solutions (in our case RNA secondary structures), a scoring scheme (free energies, partition functions, etc.) and an objective function [minimize (energy), sum up (Boltzmann factors)]. The idea behind ADP is to separate these three aspects. For a comprehensive discussion of ADP in the context of bioinformatics we refer to Ref. [36]. We can give here only a very brief, qualitative sketch of the topic.

The search space is defined by a *yield grammar*, i.e. a tree grammar that generates a string language by mapping its terminal symbols at the leaves of the tree into sequences of symbols. A tree grammar is similar to a CFG, with terminal and nonterminal symbols, and productions where the right-hand sides are trees (formulas) from some underlying term algebra. Intuitively, first the search space is "constructed" by enumerating all candidate solutions. This is a parsing problem for which standard solutions, so-called tabulating yield parsers, exist. Scoring and choice are described in terms of an *evaluation algebra*, which is independent of the details of the search space.

The main advantage is that complex variants of folding problems can be implemented very easily. It suffices to modify the grammar to restrict the dynamic programming recursions to all canonical secondary structures, i.e. those that have no isolated base pairs. Conversely, the evaluation algebra can be changed easily. Once the energy model is implemented, one can change the choice function from minimizing energies to adding up Boltzmann factors or listing all structures within an energy range.

The restrictions of the search space can be quite dramatic. One can, for example, restrict oneself to saturated secondary structures, which consist solely of maximally extended stacking regions, i.e. no adjacent single-stranded nucleotides exist that could form a base pair and stack on top of a helix [26]. A particularly interesting application of the ADP framework is RNAshapes [37] which can be used to systematically generate (sub)optimal RNA structures belonging to distinct course-grained structural classes. For example, one can search for the most stable clover-leaf shaped secondary structure that can be formed by the input sequence.

5.6 Notes

Due to space restrictions we only gave a brief sketch of the SCFG approach to RNA secondary structures. A variety of implementations of SCFG-based algorithms are available for different purposes: pfold [74, 75] as an SCFG-approach to "folding an alignment" similar in spirit to the thermodynamics-based RNAalifold.

A general approach to computing suboptimal parse trees, similar in spirit to the backtracing of RNA secondary structures with suboptimal energies, is described in Ref. [70]. A systematic comparison of several alternative grammar models for RNA secondary structures showed that the actual performance of SCFGs can depend considerably on the details of the grammar being used [23].

A practical problem for the application of SCFGs is that one needs a grammar that is both unambiguous and in Chomsky normal form. The decomposition of Figure 6, for example, does not satisfy this requirement, because the last case in the second line, for example, requires nonterminals for the closing base pair as well as for the two enclosed multiloop components. Without discussing the details here, this creates problems in particular with the multiloop decomposition.

Sean Eddy's Infernal [25] creates a covariance model from local alignments and can be used to search a sequence database for sequences that are likely to be produced from this SCFG. Rsearch [73] aligns an RNA query to target sequences, using SCFG algorithms to score both secondary structure and primary sequence alignment simultaneously.

So-called pair SCFGs can be used to solve the combined folding and alignment problem in analogy to Sankoff's algorithm described in the next section, (e.g. Ref. [63]). The QRNA program [111] uses a pair SCFG to compute the probability that the substitution pattern in a pairwise alignment is derived from RNA secondary structure conservation. It has been used successfully to predict ncRNA candidates in *Escherichia coli* and *Saccharomyces cerevisiae* [94, 112]. Most recently, Pedersen and coworkers [102, 103] devised an SCFG-based algorithm for detecting conserved secondary structure motifs specifically within coding sequences. An SCFG-like approach to pseudoknotted structures can be found in Ref. [11].

6 Comparison of Secondary Structures

Many classes of functional RNA molecules, including tRNAs, rRNAs and many other "classical" ncRNAs, are characterized by highly conserved secondary structures, but little detectable sequence similarity. Reliable multiple alignments can therefore be constructed only when the shared structural features are taken into account. Since multiple alignments are used as input for many subsequent methods of data analysis, structure-based alignments are an indispensable necessity in RNA bioinformatics. This problem is far from being solved in a satisfactory way, both because the available approaches are computationally expensive and because little is known about the evolution of RNA at the structural level, and hence on the appropriate edit cost parameters.

6.1 String-based Alignments

The problem of comparing two structures Ψ_1 and Ψ_2 of the *same* RNA molecule is trivial. Since a secondary structures is simply a set of base pairs one may use, for example, the size of the symmetric difference between the two sets $|\Psi_1 \triangle \Psi_2|$ as a distance measure that is obviously a metric. In other words, we simply count the number of base pairs that occur in one of the structures, but not in both,

The question immediately becomes nontrivial, however, if we do not assume that the two structures have the same underlying sequence length, i.e. if we do not know *a priori* which sequence positions in the two molecules correspond to each other.

As we have seen, RNA secondary structures can be faithfully represented as strings over the alphabet $\{(,),.\}$. Clearly, we can use this string representation to compute a metric on secondary structures by means of standard sequence alignment methods, e.g. using the Needleman–Wunsch algorithm [99].

This approach can be generalized to a comparison of base pair probability matrices [7]. From the pairing probabilities of base i we construct a vector containing the probabilities of being paired upstream $p^{<}(i) = \sum_{j>i} P_{ij}$, downstream $p^{>}(i) = \sum_{j<i} P_{ji}$ or unpaired $p^{\circ}(i) = 1 - p^{<}(i) - p^{>}(i)$. The resulting profiles can be aligned by means of a standard string/profile alignment algorithm in $\mathcal{O}(n^2)$ time using:

$$\rho = \sqrt{p_A^{>} p_B^{>}} + \sqrt{p_A^{<} p_B^{<}} + \sqrt{p_A^{\circ} p_B^{\circ}}, \tag{21}$$

as the match score (or $1 - \rho$ as an edit cost). While this approach of "string-like alignments" is fast, it often produces misaligned pairs (Figure 13).

```
  Sequence alignment          Structure alignment
CAGUCUCAGGUGGUUGGGCU-       CAGUCUCAGGUGGUUG-GGCU
.((((.(((....)))))))-       .((((.(((....)))-))))
UAG-CUGAGGUG-UCGUGCUA       -UAGC-UGAGGUGUCGUGCUA
(((-((((....-))).))))       -((((-(((....))).))))
```

Figure 13 Sequence versus structure alignment. Compared to the structural alignment (right), the sequence alignment (from ClustalW) misaligns five of the seven base pairs.

6.2 Tree Editing

The string-based alignments above essentially use only the information whether a nucleotide is paired or unpaired, but neglect the connectivity information who pairs with whom. This limitation can be overcome by methods based on the tree representation of secondary structures. Of particular interest are tree editing and the related tree alignment, since they are still fast enough to be applicable to genome wide surveys. We present these approaches in detail here since there does not appear be a good textbook exposition of this topic.

The three most natural operations ("moves") that can be used to convert ordered trees (and, more generally, ordered forests) into each other are depicted in Figure 14:

(i) *Substitution* $(x \to y)$ consists of replacing a single vertex label x by another vertex label y.

(ii) *Insertion* $(\varnothing \to z)$ consists of adding a vertex z as a child of x, thereby making z the parent of a consecutive subsequence of children of x. A node z can also be inserted at the "top level", thereby becoming the root of a tree.

(iii) *Deletion* $(z \to \varnothing)$ consists of removing a vertex z, its children thereby become children of the parent x of z. Removing the root of a tree produces a forest in which the children of z become roots of trees.

Naturally, we associate a *cost* with each edit operation, which we will denote by $\gamma(x \to y)$, $\gamma(\varnothing \to z)$ and $\gamma(z \to \varnothing)$ for substitutions, insertions and deletions, respectively. We assume that γ is a metric on the extended alphabet $\mathcal{A} \cup \{\varnothing\}$. By using an appropriate alphabet of vertex labels, one can easily include sequence information in the cost function.

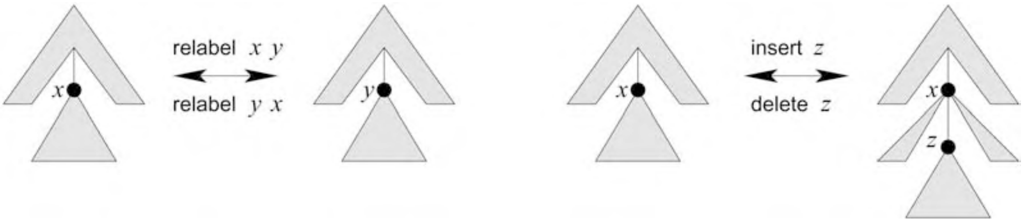

Figure 14 Elementary operations in tree editing

A sequence of moves that transforms a forest F_1 into a forest F_2 is known as an *edit script*. Its cost is the sum of the costs of edit operations in the script.

A *mapping* from F_1 to F_2 is a binary relation $M \in V(F_1) \times V(F_2)$ between the vertex sets of the two forests such that for pairs $(x,y), (x',y') \in M$ holds

(i) $x = x'$ if and only if $y = y'$ (one-to-one condition).

(ii) x is an ancestor of x' if and only if y is an ancestor of y' (ancestor condition).

(iii) x is to the left of x' if and only if y is to the left of y' (sibling condition).

By definition, for each $x \in F_1$ there is a unique "partner" in $y \in F_2$ such that $(x, y) \in M$ or there is no partner at all. In the latter case we write $x \in M_1'$. Analogously, we write $y \in M_2'$ if $y \in F_2$ does not have a partner in F_1. With each mapping we can associate the cost:

$$\gamma(M) = \sum_{(x,y)\in M} \gamma(x \to y) + \sum_{y \in M_2'} \gamma(\varnothing \to y) + \sum_{x \in M_1'} \gamma(x \to \varnothing). \tag{22}$$

Clearly, each edit operation gives rise to a corresponding mapping between the initial and the final tree. In the case of a substitution, all vertices have partners; in the case of insertion and deletion, there is exactly one vertex without partner.

Mappings are relations and hence they can be composed in a natural way. Consider three forests F_1, F_2 and F_3 and mappings M_1 from F_1 to F_2 and M_2 from F_2 to F_3. Then:

$$M_1 \circ M_2 = \left\{(x, z) \,\middle|\, \exists y \in V(F_2) \text{ such that } (x, y) \in M_1 \text{ and } (y, z) \in M_2\right\}, \tag{23}$$

is a mapping from F_1 to F_3. It is easy convince oneself that the cost function defined in Eq. (22) is subadditive under composition, $\gamma(M_1 \circ M_2) \leq \gamma(M_1) + \gamma(M_2)$. Using this result and the fact that every mapping can be obtained as a composition of edit operations one can show that the minimum cost mapping is equivalent to the minimum cost edit script [128].

For a given forest F we note by $F - x$ the forest obtained by deleting x and $F \setminus T(x)$ is the forest obtained from F by deleting with x all descendants of x. Note that $T(x) - x$ is the forest consisting of all trees whose roots are the children of x.

Now consider two forests F_1 and F_2, and let v_i be the root of the right-most tree in F_i, $i = 1, 2$ and an optimal mapping M. Apart from the trivial cases, in which one of the two forests is empty, we have to distinguish three cases. (i) v_2 has no partner in the optimal mapping. In this case, v_2 is inserted and the optimal mapping consists of an optimal mapping from F_1 to $F_2 - v_2$ composed with the insertion of v_2. (ii) v_1 has no partner. This corresponds to the deletion of v_1. (iii) both v_1 and v_2 have partners. In this case $(v_1, v_2) \in M$.

To see this, one can argue as follows. Suppose $(v_1, h) \in M$, $h \neq v_2$ and $(k, v_2) \in M$. By the one-to-one condition, $k \neq v_1$. By the sibling condition, if v_1 is to the right of k, then h must be to the right of v_2. If v_1 is a proper ancestor of k, then h must be a proper ancestor of v_2 by the ancestor condition. Both cases are impossible, however, since both v_1 and v_2 are by construction right-most roots.

For each of the three cases it is now straightforward to recursively compute the optimal cost of M. We arrive directly at the dynamic programming recursion:

$$D(F_1, F_2) = \min \begin{cases} D(F_1 - v_1, F_2) + \gamma(v_1 \to \varnothing), \\ D(F_1, F_2 - v_2) + \gamma(\varnothing \to v_2), \\ D(T(v_1) - v_1, T(v_2) - v_2) + \\ \qquad\qquad D(F_1 \setminus T(v_1), F_2 \setminus T(v_2)) + \gamma(v_1 \to v_2). \end{cases} \tag{24}$$

which allows us to compute the tree edit distance $D(F_1, F_2)$ from smaller subproblems. The initialization is the distance between $D(\emptyset, \emptyset) = 0$ of two empty forests. In the cases where one of the two forests is empty, Eq. (24) reduces to $D(\emptyset, F_2) = D(\emptyset, F_2 - v_2) + \gamma(\varnothing \to v_2)$ and $D(F_1, \emptyset) = D(F_1 - v_1, \emptyset) + \gamma(v_1 \to \varnothing)$.

One can show that the time complexity of this algorithm is bounded by $\mathcal{O}(|F_1|^2|F_2|^2)$. Various more efficient implementations exist (see in particular Refs. [72, 148]). A detailed performance analysis of the algorithm by Zhang and Shasha [148] is given in Ref. [24].

A common feature of all tree representations discussed above is that each subtree $T(x)$ rooted at a vertex x corresponds to an interval I_x of the underlying RNA sequence. We can thus regard every pair (v_1, v_2) as a prescription to match up the intervals I_{v_1} with J_{v_2} between the two input sequences. In particular, if v_1 and v_2 are leaves in the forests F_1 and F_2, then they correspond to individual bases. Interior nodes serve as delimiters of intervals in Giegerich's encoding, while they correspond to base pairs in the encoding used in the Vienna RNA Package. In either case, one can derive all (mis)matches directly from M. The sibling and ancestor properties of M guarantee that (mis)matches preserve the order in which they appear on the RNA sequence. All other nucleotides, i.e. those that correspond to vertices $v_1 \in M_1'$ and $v_2 \in M_2'$, are deleted or inserted, respectively, in the appropriate positions. Every mapping M therefore implies a (canonical) pairwise alignment $\mathbb{A}(M)$ of the underlying sequences.

6.3 Tree Alignments

An alternative way of defining the difference of two forests is using *tree alignments* [69]. Consider a forest G with vertex labels taken from $(\mathcal{A} \cup \{-\}) \times (\mathcal{A} \cup \{-\})$. Then we obtain restrictions $\pi_1(G)$ and $\pi_2(G)$ by considering only the first or the second coordinate of the labels, respectively, and by then deleting all nodes that are labeled with the gap character "–" (Figure 15). We say that G is an alignment of the two forests F_1 and F_2 if $F_1 = \pi_1(G)$ and $F_2 = \pi_2(G)$. Naturally, we score the alignment G by adding up the costs of the

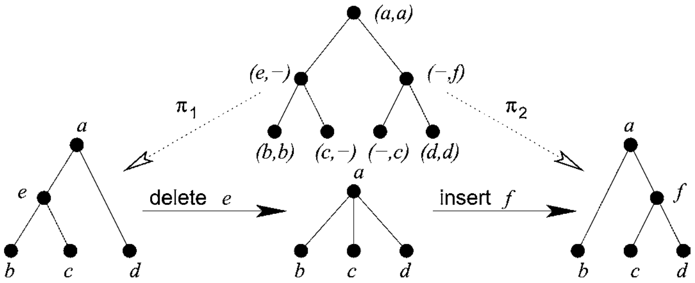

Figure 15 Alignment of two forests F_1 and F_2 and a mapping from F_1 to F_2 that cannot be derived from an alignment.

label pairs:

$$\gamma(G) = \sum_{(v_1,v_2)\in G} \gamma(v_1 \to v_2), \tag{25}$$

where a pair $(v_1, -)$ corresponds to the edit operation $(v_1 \to \varnothing)$. On the other hand, an alignment G defines a mapping M_G from F_1 to F_2 by setting $(v_1, v_2) \in M_G$ iff $(v_1, v_2) \in G$ and neither v_1 nor v_2 is a gap character. One easily verifies that the three defining properties of mapping are satisfied. Furthermore, it follows that $\gamma(M_G) = \gamma(G)$ as pair of the form $(v_1, -)$ and $(-, v_2)$ corresponds to deletion and insertion operations, respectively. Note that, in the special case of two a totally disconnected forests, the problem reduces to ordinary sequence alignment with additive gap costs.

However, as the example in Figure 15 shows, not all mappings derive from alignments. It follows, therefore, that the minimum cost alignment is more costly than the minimum cost edit script, in general.

In order to compute the optimal alignment, let us first investigate the decomposition of an alignment at a particular (mis)match (v_1, v_2) or in/del $(-, v_2)$ or $(v_1, -)$. We will need a bit of notation (Figure 16). Let F be an ordered forest. By $i : F$ we denote the subforest consisting of the first i trees, while $F : j$ denotes the subforest starting with the $j + 1$-th tree. By $F^{\downarrow}$ we denote forest consisting of the children trees of the root $v = r_F$ of the first tree in F. $F^{\rightarrow} = F : 1$ is the forest of the right siblings trees of F.

Now consider an alignment A of two forests F_1 and F_2. Let $a = r_A$ be the root of its first tree. We have either:

(i) $a = (v_1, v_2)$. Then $v_1 = r_{F_1}$ and $v_r = r_{F_2}$; $A^{\downarrow}$ is an alignment of $F_1^{\downarrow}$ and $F_2^{\downarrow}$; $A^{\rightarrow}$ is an alignment of $F_1^{\rightarrow}$ and $F_2^{\rightarrow}$.

(ii) $a = (-, v_2)$. Then $v_2 = r_{F_2}$; for some k, $A^{\downarrow}$ is an alignment of $k : F_1$ and $F_2^{\downarrow}$ and $A^{\rightarrow}$ is an alignment of $F_1 : k$ with $F_2^{\rightarrow}$.

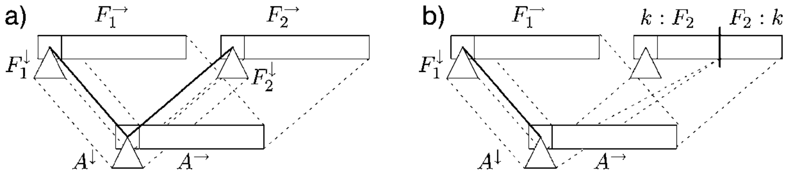

Figure 16 Decomposition of tree alignments. (a) In the match case the subtrees $F_1^{\downarrow}$ and $F_2^{\downarrow}$ are aligned to form $A^{\downarrow}$ and, correspondingly, the sibling subforests $F_1^{\rightarrow}$ and $F_2^{\rightarrow}$ must be aligned to yield $A^{\rightarrow}$. (b) In the deletion case the subforest $F_1^{\downarrow} - v_1$ must be aligned with a part $k : F_2$ of the second forest. $F_1^{\rightarrow}$ then must be aligned with remainder of $F_2 : k$ of the top-level trees of F_2. The insertion case is analogous to the deletion case, with the roles of F_1 and F_2 exchanged.

(iii) $a = (v_1, -)$. Then $v_1 = r_{F_1}$; for some k, $A^{\downarrow}$ is an alignment of $F_1^{\downarrow}$ and $k : F_2$ and $A^{\rightarrow}$ is an alignment of $F_1^{\rightarrow}$ with $F_2 : k$.

See Figure 16 for a graphical representation.

Let $S(F_1, F_2)$ be the optimal score of an alignment of the forests F_1 and F_2. For easier comparison with the tree-editing algorithm in the previous section we formulate the problem here as a minimization problem. One can, however, just as well maximize appropriate similarity scores. The three cases discussed above and in Figure 16 imply the following dynamic programming recursion:

$$S(F_1, F_2) = \min \begin{cases} S(F_1^{\downarrow}, F_2^{\downarrow}) + S(F_1^{\rightarrow}, F_2^{\rightarrow}) + \gamma(v_1 \to v_2) \\ \min_k S(k : F_1, F_2^{\downarrow}) + S(F_1 : k, F_2^{\rightarrow}) + \gamma(\varnothing \to r_{F_2}) \\ \min_k S(F_1^{\downarrow}, k : F_2) + S(F_1^{\rightarrow}, F_2 : k) + \gamma(r_{F_1} \to \varnothing). \end{cases} \tag{26}$$

In the special cases where one of the forests is empty this reduces to $S(\emptyset, F_2) = S(\emptyset, F_2^{\downarrow}) + S(\emptyset, F_2^{\rightarrow}) + \gamma(\varnothing \to r_{F_2})$ for the insertion case, and $S(F_1, \emptyset) = S(F_1^{\downarrow}, \emptyset) + S(F_1^{\rightarrow}, \emptyset) + \gamma(r_{F_1} \to \varnothing)$ for the deletion case. The initial condition is again $S(\emptyset, \emptyset) = 0$.

In order to estimate the resource requirements for this algorithm, we observe that we have to consider only those subforests of F_1 and F_2 that consist of trees rooted at an uninterrupted interval of sibling nodes. These forests have been termed *closed subforests* in Ref. [51]. If d_i is the maximum of the number of trees and the numbers of children of the nodes in F_i, we see that there are at most $\mathcal{O}(d_i^2)$ closed subforests at each node and hence at most $\mathcal{O}(|F_1|\,|F_2| d_1^2 d_2^2)$ entries $S(F_1, F_2)$ need to be computed, each of which requires $\mathcal{O}(d_1 + d_2)$ operations, i.e. tree alignments can be computed in polynomial time. A compact, memory-efficient encoding of the subforests is described in detail in Ref. [51], where a careful analysis shows that pairwise tree alignments can be computed in $\mathcal{O}(|F_1| d_1\, |F_2| d_2)$ space and $\mathcal{O}(|F_1|\,|F_2|\, d_1\, d_2 (d_1 + d_2))$ time.

6.4 The Sankoff Algorithm and Variants

David Sankoff described an algorithm that simultaneously allows the solution of the structure prediction and the sequence alignment problem [114]. The basic idea is to search for a maximal secondary structure that is common to two RNA sequences. Given a score $\sigma_{ij,kl}$ for the alignment of the base pairs (i, j) and (k, l) from the two sequences (as well as gap penalties γ and scores α_{ik} for matches of unpaired positions) we compute the optimal alignment recursively from alignments of the subsequences $x[i, \ldots, j]$ and $y[k, \ldots, l]$. Let $S_{ij,kl}$ be the score of the optimal alignment of these fragments. We have:

$$\begin{aligned} S_{ij;kl} = \max \Big\{ & S_{i+1,j;kl} + \gamma, S_{ij;k+1,l} + \gamma, S_{i+1,j;k+1,l} + \alpha_{ik}, \\ & \max_{(p,q) \text{ paired}} \Big\{ S_{i+1,p-1;k+1,q-1} + \sigma_{ij,pq} + S_{p+1,j;q+1,l} \Big\} \Big\} . \end{aligned} \tag{27}$$

Backtracing is just as easy as in the RNA folding case. Only now π is a partial alignment of two structures and we insert aligned positions instead of positions in individual structures. More precisely we have to insert individual columns or pairs of columns of the form:

$$\pi \blacktriangleleft \begin{pmatrix} i. \\ - \end{pmatrix} \quad \pi \blacktriangleleft \begin{pmatrix} - \\ j. \end{pmatrix} \quad \pi \blacktriangleleft \begin{pmatrix} i. \\ j. \end{pmatrix} \qquad \pi \blacktriangleleft \begin{pmatrix} i(& & j) \\ p(& , & q) \end{pmatrix} , \tag{28}$$

into a growing partial alignment π, just as we insert unpaired bases or base pairs in the backtracing of the folding algorithm in Section 3.2.

This algorithm is computationally very expensive, however. It requires $\mathcal{O}(n^4)$ memory and $\mathcal{O}(n^6)$ CPU time. Currently available software packages such as foldalign [39,65] and dynalign [92] therefore implement only restricted versions. The simple, maximum matching style version is used in pmcomp [52] as an approach to comparing base pairing probability matrices.

6.5 Multiple Alignments

Pairwise alignment methods, be they for sequences or structures, can be readily generalized to alignments of many objects. Usually, it is too costly to compute optimal multiple alignments exactly and one therefore resorts to heuristics such as progressive multiple alignments. pmmulti [52], for example, produces multiple structural alignments in the context of the Sankoff algorithm by calling pmcomp for pairwise alignments. For tree alignments, the RNAforester programs can be used to compute both pairwise and progressive multiple alignments.

As we have seen above, the mappings produced by tree editing do not correspond to tree alignments in general. These methods can therefore not be used for comparing multiple structures. The edit scripts can, however, be interpreted in terms of a sequence alignment. One may therefore still use these methods as the starting point for multiple sequence alignments. This is the central idea of the MARNA program [121] which uses pairwise structural alignments as input to the multiple alignment program T-Coffee [100].

6.6 Notes

Various variants, specializations and generalizations of the tree-editing approach have been described in recent years. Examples include efficient algorithms for similar trees [67] and with simplified edit cost models [120]. Tree-editing with restricted mappings M satisfying stronger requirements on structural conservation are described in Ref. [147]. Let $\mathrm{lca}(a,b)$ denote the "last common ancestor" of a and b. For all $(x',x''),(y',y''),(z',z'') \in M$ holds: $\mathrm{lca}(x',y')$ is a proper ancestor of z' if and only if $\mathrm{lca}(x'',y'')$ is a proper ancestor of z''. Other variants of tree edit distances have also been discussed (e.g. Ref. [132]). A tree-edit model for RNA that allows additional "node-fusion" and "edge-fusion" events is described in Ref. [4].

More general edit models with application to RNA structures are described in Refs. [68, 88], an alignment distance for pseudoknotted structures can be found in Ref. [9].

A very different approach to the pairwise comparison of RNA structures, with or without pseudoknots, converts the RNA alignment problem into an integer programming problem [79]. Recently, efficient algorithms based on Lagrangian relaxation have been developed [6], that have helped to make the performance of this approach comparable to other methods.

A partition function version of the Sankoff algorithm, which can be used to compute the probabilities of all possible (mis)matches in a structural alignment of two RNA base pairing probability matrices is described in Ref. [53]. RNA structure comparison can also be recast in the SCFG framework [64]. The corresponding pair-SCFG algorithms correspond to the Sankoff algorithm.

7 Kinetic Folding

7.1 Folding Energy Landscapes

The folding dynamics of a particular RNA molecule can also be studied successfully within the framework of secondary structures. The folding process is determined by the energy landscape [or potential energy surface (PES) in the terminology of theoretical chemistry]. Instead of considering all possible spatial conformations, it is meaningful to partition the conformation space into sets of conformations that belong to a given secondary structure. Instead of a smooth surface defined on a space of real-valued coordinate vectors we are therefore dealing with a landscape on a complex graph [107]. The vertices of this graph are the secondary structures that can be formed by the given RNA sequence, the edges are determined by a rule specifying which structures can be interconverted and the height of the landscape at a structure x is its free energy $E(x)$. Typically, one considers a "move set" that allows the insertion and deletion of single base pairs. In addition, a shift-move that changes (i,j) to (i,k) or (h,j) is sometimes included [30]. Further coarse-grainings of this landscape can be achieved, e.g. by considering secondary structures as composed of stacks instead of individual base pairs.

7.2 Kinetic Folding Algorithms

Several groups have designed kinetic folding algorithms for RNA secondary structures, mostly in an attempt to obtain more accurate predictions or in order to include pseudoknots (see e.g. Refs. [2, 41, 89, 95, 126]). Only a few papers have attempted to reconstruct folding pathways [42, 50, 124]. These algorithms generally operate on a list of all possible helices and consequently use move sets that destroy or form entire helices in a single move. Such a move set can introduce large structural changes in a single move and, furthermore, *ad hoc* assumptions have to be made about the rates of helix formation and disruption. A more local move set is, therefore, preferable if one hopes to observe realistic folding trajectories.

The process of kinetic folding itself can be modeled as homogeneous Markov chain. The probability p_x that a given RNA molecule will have the secondary structure x at time t is given by the master equation:

$$\frac{\mathrm{d}p_x}{\mathrm{d}t} = \sum_{y \in X} r_{xy} p_y(t)\,, \tag{29}$$

where r_{xy} is the rate constant for the transition from secondary structure y to secondary structure x in the deterministic description [38]. The transition state model dictates an expression of the form:

$$r_{yx} = r_0 \mathrm{e}^{-\frac{E^{\neq}_{yx} - E(x)}{RT}} \quad \text{for } x \neq y \quad \text{and} \quad r_{xx} = -\sum_{y \neq x} r_{yx}, \tag{30}$$

where the transition state energies $E^{\neq}_{yx}$ must be symmetric, $E^{\neq}_{yx} = E^{\neq}_{xy}$, and r_0 is a scaling constant. In the simplest case one can use:

$$E^{\neq}_{yx} = \max\{E(x), E(y)\}. \tag{31}$$

For short sequences or very restricted subsets of conformations Eq. (29) can be solved exactly or integrated numerically [126]. Solving the master equation for larger conformation spaces is out of the question. In such cases the dynamics can be obtained by simulating the Markov chain directly by a rejection-less Monte Carlo algorithm [27] and sampling a large number of trajectories.

7.3 Approximate Folding Trajectories and Barrier Trees

An alternative approach to the direct simulation of the master equation (29) starts with a more detailed analysis of folding energy landscape. Let us start with a few definitions.

A conformation x is a global minimum if $E(x) \leq E(y)$ for all $y \in X$ and a local minimum if $E(x) \leq E(y)$ for all neighbors y of x. The energy $\hat{E}$ of the lowest saddle point separating two local minima x and y is:

$$\hat{E}[x,y] = \min_{\mathbf{p} \in \mathbb{P}_{xy}} \max_{z \in \mathbf{p}} E(z), \tag{32}$$

where $\mathbb{P}_{xy}$ is the set of all paths $\mathbf{p}$ connecting x and y by a series of consecutive transformations taken from the move set. If the energy function is nondegenerate then there is a unique saddle point $s = s(x,y)$ connecting x and y characterized by $E(s) = \hat{E}[x,y]$. To each saddle point s there is a unique collection of conformations $B(s)$ that can be reached from s by a path along which the energy never exceeds $E(s)$. In other words, the conformations in $B(s)$ are mutually connected by paths that never go higher than $E(s)$. This property warrants to call $B(s)$ the *basin of attraction* below the saddle s.

Two situations can arise for any two saddle points s and s' with energies $E(s) < E(s')$. Either the basin of s is a "subbasin" of $B(s')$ or the two basins are disjoint. This property arranges the local minima and the saddle points in a unique hierarchical structure which is conveniently represented as a tree, termed a *barrier tree* (Figure 17).

An efficient flooding algorithm [31] can be used to identify local minima and saddle points starting, for example, from the complete list of suboptimal secondary structures produced by the RNAsubopt program [144]. Consider a stack Σ which initially contains all secondary structures in the order of ascending energy. We pop the element z from the top of Σ and check which of its neighbors we have already seen before, i.e. which of its neighbors have a lower energy. There are three cases:

(i) z has no neighbor with lower energy, then it is a local minimum, i.e. a new leaf of the barrier tree.

(ii) z has only lower energy neighbors that all belong the same basin, say $B(x)$. Then z itself also belongs to $B(x)$.

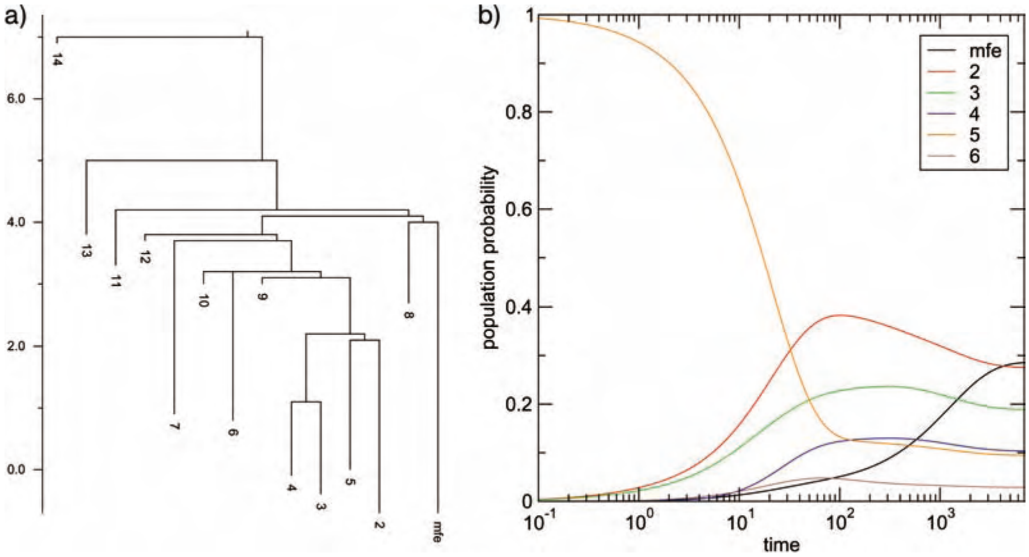

Figure 17 (a) Barrier tree of short artificial sequence UAUGCUGCGGCCUAGGC. The leaves of the tree are the local minima of the energy landscape. (b) Folding kinetics from the open structure. Population density p_α for the basin containing the local minimum α is shown for the six largest basins as a function of time.

(iii) z has lower-energy neighbors in two or more different basins. In this case z is the saddle point separating these basins, i.e. an interior vertex of the barrier tree. For the subsequent computation we now unify all basins connected by z into a new basin $B(z)$ and remove its subbasins from the list of "active" basins.

At the end, we are left with the barrier tree of the landscape. As a byproduct we also obtain the assignment of each secondary structure to its basin $B(x)$. Instead of searching through the list of all previously encountered structures it is more efficient to generate all neighbors of z and to check whether they have already been seen before by means of a hash-table lookup. The procedure thus runs in $\mathcal{O}(LD)$ time, where L is the length of the list of structures and D is the maximal number of moves that can be applied to a secondary structure. The barriers program implements this algorithm [31].

A description of the energy landscape or the dynamics of an RNA molecule based on all secondary structures is feasible only for very small sequences. We therefore need to coarse-grain the representation of the energy landscape. Let $\mathbf{\Pi} = \{\alpha, \beta, \dots\}$ be a partition of the state space. The classes of such a partition are *macrostates*. As a concrete example consider the partition of X defined by the gradient basins $\mathcal{B}(z)$ of the local energy minima. To each macrostate α we can assign the partition function:

$$Z_\alpha = \sum_{x\in\alpha} \mathrm{e}^{-E(x)/RT}, \tag{33}$$

and the corresponding free energy:

$$G(\alpha) = -RT \ln Z_\alpha. \tag{34}$$

The transition rates between macrostates can be obtained at least approximately from the elementary rate constants using the assumption that the random process is equilibrated within each macrostate [143]. Then:

$$r_{\beta\alpha} = \sum_{y\in\beta}\sum_{x\in\alpha} r_{yx} \frac{\mathrm{e}^{-E(x)/RT}}{Z_\alpha} \quad \text{for } \alpha \neq \beta. \tag{35}$$

We can use the transition state model to define the free energies of the transition state $G^{\neq}$ by setting:

$$r_{\beta\alpha} = r_0 \mathrm{e}^{-\frac{G^{\neq}_{\beta\alpha} - G(\alpha)}{RT}}. \tag{36}$$

A short computation then yields:

$$G^{\neq}_{\beta\alpha} = -RT \ln \sum_{y\in\beta}\sum_{x\in\alpha} \mathrm{e}^{-\frac{E^{\neq}_{yx}}{RT}}, \tag{37}$$

as one would expect.

In practice one can compute $r_{\beta\alpha}$ "on the fly" while executing the barriers program if two conditions are satisfied: (i) for each x we can efficiently determine to which macrostate it belongs and (ii) the double sum in Eq. (35) needs to be evaluated only for pairs of neighboring conformations (x, y). Condition (i) is easily satisfied for each of the gradient basins: in each step of the barriers algorithm all neighbors y of the newly added structures x that have a smaller energy have already been processed. Condition (ii) is satisfied by construction of the microscopic transition rates r_{xy}, which vanish unless x is a neighbor of y. In the case of short sequence, both the microscopic model and the macro-state model can be solved exactly. In many cases (e.g. Figure 17) the macro-state model provides a very good approximation of the dynamics.

7.4 RNA Switches

Some RNA molecules exhibit two meta-stable conformations, whose equilibrium can be shifted easily by external events, such as binding of another molecule. This can be used to regulate gene expression, when the two mutually exclusive alternatives correspond to an active and in-active conformation of the transcript. The best known example of such behavior are the riboswitches [133] found in the $5'$ untranslated regions of bacterial mRNAs, where the conformational change is triggered by binding of a small organic molecule.

Molecules that may be RNA switches can be recognized by inspection of the barrier tree, but this is feasible only for rather short sequences. The paRNAss program [134] instead uses a sample of suboptimal structures, and computes for every pair of structures "morphological" distance (e.g. tree edit distance) and a simple estimate of the energy barrier. The structures are then clustered according to these two measures, RNA switches are expected to exhibit two well separated clusters.

Interestingly, for any two secondary structures there exist sequences that are compatible with both structures, i.e. that can form both structures in principle [106]. If both structures are reasonably stable, it is not hard to design switching sequences with these two structures as stable conformations [28].

7.5 Notes

The analysis of landscapes becomes technically more complicated when structures, in particular adjacent structures, may have the same energy. In this case there is no unique definition of gradient basins and a variety of concepts, all related to saddle points, have to be distinguished (see Ref. [31] for further details).

The notion of barrier trees can be generalized to multivalued landscapes, which arise, for example, in the context of multiobjective optimization problems with conflicting constraints [122].

A computationally simpler alternative to the macrostate approach for transition rate is to assume an Arrhenius law $r_{\beta\alpha} \sim \exp(E^{\neq}/RT)$ and to approximate the transition state energy $E^{\neq}$ by the energy of the saddle point between the local minima α and β [143]

A generalization of the "intersection theorem" characterizes sets of more than two secondary structures that can be realized simultaneously by a common RNA sequence [28]. This observation can be used as a starting point for computational designs of switches with multiple states [1].

8 Concluding Remarks

Secondary structure drives the RNA-folding process, arguably even more so than it is the case for proteins. This renders the prediction of RNA secondary structure highly relevant for the prediction of RNA structure and analysis, in general. As this chapter shows, the field of RNA structure prediction is comparatively well developed. As a matter of fact, it is one of the fields in bioinformatics that benefits most comprehensively from algorithmic methods derived from computer science. The comparatively technical makeup of this chapter is a mirror of this phenomenon. Notably, very different questions, which in the protein world require different mathematical models, can be described and analyzed in the RNA case at the level of secondary structures: the thermodynamics of folding as well as the thermodynamics of RNA–RNA interactions are accessible via the same parameters and the same algorithms that can also be used to compute consensus structures in an evolutionary context or to investigate the dynamics of the folding process itself.

With the increased importance of RNA in biology, in general (consider, for instance, the recent surge in work on RNA interference (see also Chapter 45) and in the analysis of structural aspects of mRNA in the context of gene regulation), RNA secondary structure prediction is rapdily becoming an obligatory tool in the arsenal of bioinformatics analysis methods.

15
RNA Tertiary Structure Prediction

François Major and Philippe Thibault

1 Introduction

During the last decade, the number of high-quality X-ray crystallographic RNA three-dimensional (3-D) structures has increased significantly, and the resolution of the large ribosomal subunit crystal structure was considered a major step towards a better understanding of RNA tertiary structure and folding. The recent discovery of the RNA interference (RNAi) pathway (see Chapter 45) has also contributed greatly to the popularity of RNAs, by suggesting their direct implication in genetic expression and regulation. More than ever, determining rapidly and precisely the tertiary structure and function of noncoding RNAs is a crucial step towards our understanding of several cellular metabolic pathways.

This chapter is dedicated to the RNA tertiary structure prediction problem – the determination of the complete set of chemical interactions (and therefore 3-D fold) of an RNA from sequence data. To achieve RNA structure prediction, one needs to discover and apply its structural and architectural principles, which can be learnt from thermodynamics, as well as from structural data gathered from X-ray crystallography and other high-resolution, but also low-resolution, experimental methods. Here, we present a series of nomenclatures and formalisms to describe RNA tertiary structure, as well as computer data structures and algorithms that implement three important research activities with the aim of solving RNA tertiary structure prediction: annotation, motif discovery and modeling.

We present in Section 2 a series of RNA structure components and the terms employed by the RNA specialists to discuss them – their universe of discourse (nowadays referred to as their ontology). First, we present an ontology of nucleotide conformations and binary interactions. Then, visual or automated inspection of RNA 3-D structures is necessary to depict higher-order architectural principles (the next abstraction levels). In Section 3, we introduce a definition of *n*-ary nucleotide interactions to describe RNA higher-order motifs, which are found repeated in RNA structures, and are often

Bioinformatics - From Genomes to Therapies Vol. 1. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

linked to specific structural and biochemical functions, and an approach to search them. Finally, in Section 4, we present how accurate computer models of RNA tertiary structures can be generated and how, by challenging them experimentally, they bring insights about function.

The flowchart in Figure 1 shows the relationships between structural data and hypotheses, and how the research activities that aim at solving the RNA tertiary structure prediction problem are intimately linked. The high-resolution (better than 3 Å) X-ray crystal structures of the Protein Data Bank (PDB) (www.rcsb.org) [1] constitute an excellent structural (learning) data set that aids the research, and from which RNA tertiary structure prediction algorithms can be inspired and tested. The characterization and formalization of RNA structural data (annotation), the discovery of high-order components (motif discovery) and the building of RNA tertiary structure models (modeling) contribute directly to the learning and discovery processes, leading to new knowledge that is fed back to research.

An ultimate solution to the tertiary structure prediction problem will provide us with invaluable structural information, and will allow us to determine the function and the evolutionary relationships of RNAs. Knowledge of RNA tertiary structure impacts on molecular medicine techniques to control genetic expression, and to inhibit and activate specific cellular functions. The cell controls its own genetic expression by processing micro RNAs through the RNAi pathway. As we discover and characterize the elements of RNAi, we learn how to design RNAs that interfere and block the expression of several genes. Knowledge of the structure and of the interplay between the RNAs and the other RNAi elements is fundamental. Alternatively, we could target the natural micro RNAs of the cell using drugs. Again, knowledge of the targeted RNA structure is necessary to design accurate drugs. Targeting the noncoding RNAs of the cell allows us to manipulate its fundamental mechanisms prior to protein translation; like playing with the "source code" of the cell. Antibiotics such as aminoglycosides and macrolides target the site-A of prokaryotic ribosomes, blocking protein translation. The search and discovery of other sites in the ribosome or in other RNAs involved in such fundamental mechanisms require the determination of their tertiary structure if we want to design drugs capable of inhibiting them. Ribozymes are catalytic RNAs that can cleave a substrate efficiently and precisely. For instance, ribozymes can be used to cleave a messenger prior to its translation by the ribosome. Here, again, knowledge of the tertiary structure of ribozymes and of their complex with the substrate is essential for rational design.

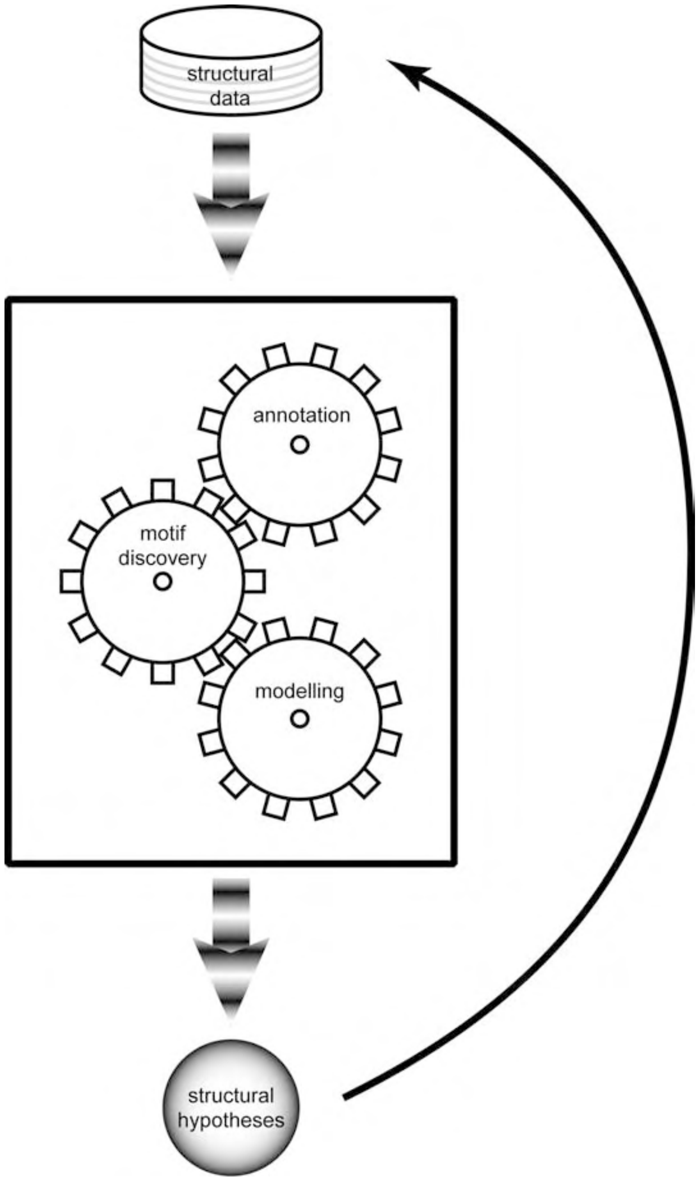

Figure 1 Data flow and research activities of tertiary structure prediction. Structural data are used to develop the (computational) tools employed by the researchers to annotate, inspect and model RNA tertiary structures. Structural hypotheses are generated and, when challenged experimentally, bring new structural data to research.

2 Annotation

The annotation of an RNA tertiary structure is the assignment (manual or automated) of appropriate symbols, taken from the RNA ontology, that apply to a given RNA. One can see annotation as a data refinement process that complements the 3-D atomic coordinates – a different and perhaps higher level of abstraction which can be thought of as an efficient and sound data format to study further tertiary structures.

A human RNA expert recognizes the attributes of tertiary structures by visualization using interactive computer graphics and can therefore annotate a given RNA 3-D structure. An automated procedure loads the RNA 3-D atomic coordinates in memory and then computes the annotations. Gendron and coworkers have developed a computer program, MC-Annotate, which annotates a fraction of the current RNA ontology, in particular the terms related to the nucleotide conformations, as well as base stacking and base pairing types [2] (see Section 2.2). MC-Annotate can be run over the web (www-lbit.iro.umontreal.ca; under Research and MC-Annotate). Westhof and coworkers, in collaboration with the PDB, developed RNAView, a computer program that draws the secondary structure of an RNA while using the *LW* nomenclature (see Sections 2.2.2) to display the base pair types [3]. RNAView is accessible on the web (ndbserver.rutgers.edu/services).

In this section, we present a series of RNA tertiary structure attributes and how they can be computed from 3-D atomic coordinates from X-ray crystallographic structures of the PDB. We present the nucleotide conformations (Section 2.1) and interactions (Section 2.2) that are needed to define higher-order RNA components (Section 3), and to build and describe RNA tertiary structure (Section 4).

2.1 Nucleotide Conformations

RNAs are polymeric molecules. The monomer unit is a ribonucleotide, or simply nucleotide, which divides in three units: the nucleobase (or simply base), the ribose and the phosphate group (see Figure 2). There are four bases: adenine (A), guanine (G), cytosine (C) and uracil (U). The four bases partition in two families: the pyrimidines (Y) C and U, which are composed of a single pyrimidine ring, and the purines (R) A and G, which are composed of the fusion of the pyrimidine ring ($C_4H_4N_2$) and an imidazole ring ($C_3H_4N_2$). The

Figure 2 RNA chemical structure. The polynucleotide chain (on the left) is made of the bases (hexagons), riboses (pentagons) and phosphate groups (diamonds). The four common types of bases (on the right): the two purines adenine and guanine, and the two pyrimidines cytosine and uracil. The phosphodiester linkage (middle) connects two nucleotides. The ribose (center) links two phosphate groups: one to its 5′ oxygen (above) and the other to its 3′ oxygen (below). The conventional atomic numbering system is used. Small black circles represent the carbon atoms and their complementary hydrogen atoms are not shown.

International Union of Pure and Applied Chemistry (IUPAC) defined a one-letter code for all possible subsets of {A, C, G, U} (shown in Table 1).

Table 1 IUPAC nucleotide nomenclature

Code	Nucleotide subset
M	{A, C}
R	{A, G}
W	{A, U}
S	{C, G}
Y	{C, U}
K	{G, U}
V	{A, C, G}
H	{A, C, U}
D	{A, G, U}
B	{C, G, U}
N	{A, C, G, U}

The ribose links the phosphate groups to which the bases are attached by the glycosidic bond: C1′–N9 in purines and C1′–N1 in pyrimidines. The riboses and the phosphate groups constitute the backbone, and are linked through diester bonds: C5′–O5′ and C3′–O3′. The chain C3′–O3′–P–O5′–C5′ from one ribose to another is referred to as the phosphodiester linkage that ties the nucleotides together (see Figure 2).

When 3-D points represent the center of the atoms in the structure, the covalent bond lengths, and the bond and torsion angles can be computed directly. The covalent bond length between atoms A and B is simply defined by the Cartesian distance between points A and B. The covalent bond angle between atoms A, B and C is defined by the angle between vectors $\overrightarrow{BA}$ and $\overrightarrow{BC}$. Finally, the covalent bond torsion angle between atoms A, B, C and D is defined by the angle between the projection of $\overrightarrow{BA}$ and $\overrightarrow{CD}$ in a plane perpendicular to $\overrightarrow{CD}$. In general, bond lengths and angles are considered constant in most computer prediction systems. Consequently, the 3-D conformation of a nucleotide can be described by its torsion angles. The phosphodiester linkage has six torsions (α, β, γ, δ, ε and ζ), the ribose has five torsions (θ_0–θ_4) and there is one torsion around the glycosidic bond (χ) (see Figure 3a).

Note the δ and θ_1 torsions are measured on the same covalent bond, C3′–C4′, but from different end-points, respectively, C2′ and O4′ in the ribose for θ_1, and C5′ and O3′ in the phosphodiester chain for δ. The glycosidic torsion, χ, is measured respectively in purines and pyrimidines from atoms O4′–C1′–N9–C4 and O4′–C1′–N1–C2. The furanose ring stereochemistry imposes interdependent relations on θ_{0-4}, which is expressed by the cosine function:

$$\theta_j = \theta_{\max} \cos(\rho + j\varphi), \tag{1}$$

where $j = 0, \ldots, 4$ and $\varphi = 144°$ (720°/5).

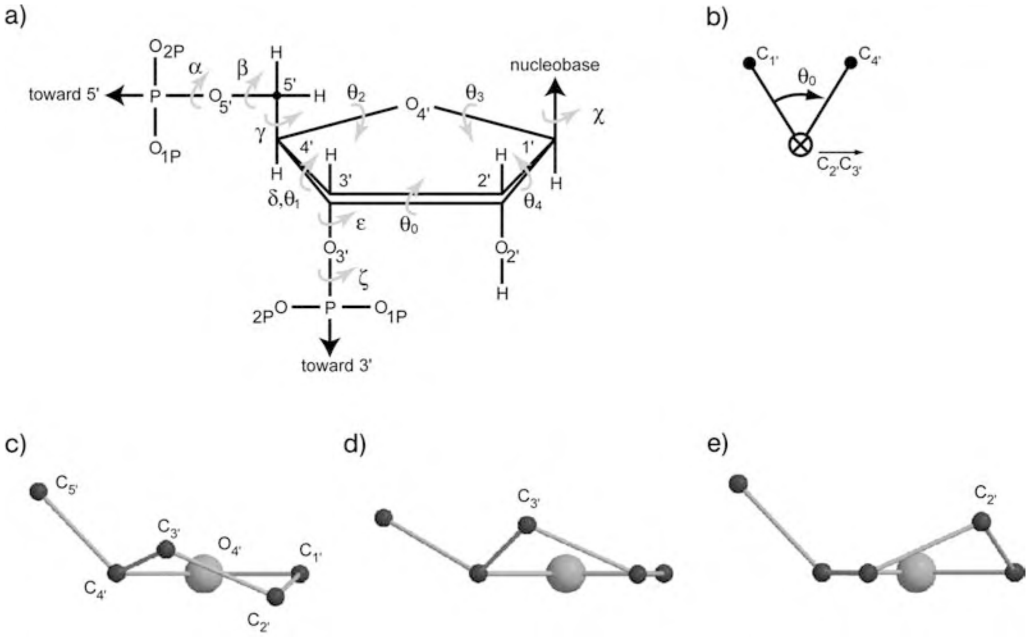

Figure 3 The nucleotide torsion angles. (a) Individual torsions are shown using grey arrows: χ on the glycosidic bond between the base and the ribose, θ_{0-4} around the ribose, and α, β, γ, δ, ε and ζ along the phosphodiester chain (θ_1 and δ are defined on the same covalent bond). (b) θ_0 measurement. The torsion is computed as the angle between the projection of vectors $\overrightarrow{C_{2'}C_{1'}}$ and $\overrightarrow{C_{3'}C_{4'}}$ in the plane perpendicular to vector $\overrightarrow{C_{2'}C_{3'}}$ (crossed circle). (c) The $^2T_3$ twist shape C2′-*exo*–C3′-*endo* ribose pucker mode. (d) The ^3E envelope shape C3′-*endo* ribose pucker mode. (e) The ^2E envelope shape C2′-*endo* ribose pucker mode.

When $j = 0$, we have:

$$\theta_0 = \theta_{max} \cos(\rho). \tag{2}$$

In Eqs. (1) and (2), ρ is the pseudorotation of the ribose ring [4]. By varying ρ from 0 to 360° by steps of 90°, θ_0 goes from θ_{max} to 0, to θ–θ_{max}, back to 0 and, finally, back to θ_{max}. The θ_{max} value is reached twice – at the initial conformation [$\rho = 0$, as $\cos(0) = 1$] and at $\rho = 360°$. At each step of $\rho + 180°$, the sign of all torsions is inversed, corresponding to the mirror image of the conformation at ρ. A useful equation is derived from Eq. (1), which determines ρ:

$$\tan\rho = \frac{(\theta_2 + \theta_4) - (\theta_1 + \theta_3)}{2\theta_0(\sin 36° + \sin 72°)}\ . \tag{3}$$

Equation (2) determines θ_{max}.

Two geometric shapes characterize the stereochemistry of the ribose: envelope and twist (or half-chair). The ribose forms an envelope when only one of the five atoms of the furanose (C1′, C2′, C3′, C4′ or O4′) is out of the plane formed by the four others. The ribose forms a twist when two atoms are out of the plane formed by the remaining three. In a 360° period of the pseudorotation angle, the ribose stereochemistry alternates from the envelope to the twist shapes, successively, on each atom. At $\rho = 0°$, the ribose is in the twist shape with the C3′ atom above and the C2′ atom below the plane, which is conveniently denoted by $^3T_2$ (numbered atom above the plane in superscript and below the plane in subscript), as illustrated in Figure 3(c). All molecule 3-D rendered images were generated using MolScript [5] and Raster3D [6], as well as PyMOL (www.pymol.org). When the ball-and-stick representation is used, sphere radii are proportional to atomic masses ($C < N < O < P$). Then, the geometry of the ribose shifts at each 18°; for $\rho \in [18°, 36°]$, the ribose forms an envelope with the C3′ atom above the plane, ^3E (see Figure 3d); for $\rho \in [36°, 54°]$, the geometry changes to $^3T_4$; $_4E$ for $\rho \in [54°, 72°]$ and so forth for the 20 different geometries [7]. The ribose geometries are referred to as the sugar pucker modes. Another widely used ribose pucker mode nomenclature among RNA structure specialists is one where the atom(s) bulging out of the plane are suffixed with either *endo* or *exo*, respectively, for above and below the plane. Thus, in the example of Figure 3(c), the $^3T_2$ shape is equally named C2′-*exo*-C3′-*endo*; C3′-*endo* for the example in Figure 3(d) and C2′-*endo* for the example in Figure 3(e).

Single-stranded RNAs fold back on themselves to form double-stranded helices in the A-RNA conformation which is similar to the A-DNA double helix. Among all 20 ribose pucker modes, the C3′-*endo* is the most common, as it is the conformation of the riboses in the Watson–Crick base pairs of the A-RNA double helix (Figure 4). The asymmetry of the Watson–Crick base pair geometry (Section 2.2.2) induces the formation of two grooves in the helix. The major groove of the A-RNA double helix is narrow and deep, whereas the minor groove is broad and shallow (Figure 4b). Theoretically, the C2′-*endo* mode, adopted by the nucleotides in the B-RNA double-helical form, is unstable because of the proximity of the 2′-OH groups to the bases. Nevertheless, a good fraction of RNAs contain nucleotides in the C2′-*endo* conformations, as in loop regions and at the extremities of a double helix.

→

In addition to the pucker mode, the glycosidic torsion χ is also divided in a range of values. The *anti* conformation characterizes a base oriented away from the ribose. From χ = 180°, where the plane of the base is aligned with the O4′–C1′ bond in a direction away from O4′, the *anti* conformation covers a rotation of ±90°: $\chi \in [-180°, -90°]$ and $\chi \in [90°, 180°]$ (see Figure 5a). At χ = 0°, where the plane of the base is aligned with the O4′–C1′ bond in a direction towards the O4′ atom, the *syn* conformation covers the remaining rotations of ±90°: $\chi \in [-90°, 90°]$ (see Figure 5b). The nucleotide conformations in both the A-RNA and B-RNA double-helical forms adopt the *anti* conformation.

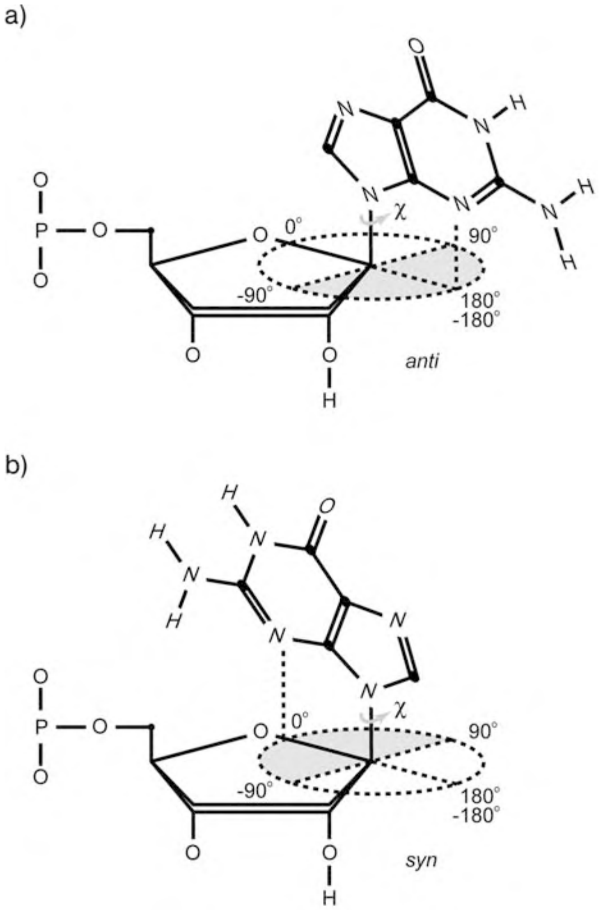

Figure 5 The glycosidic bond torsion. The ranges of χ values are shown in grey. (a) The *anti* conformation aligns the base away from the ribose. (b) The *syn* conformation aligns the base towards the ribose.

The nucleotide conformations can be annotated directly from their torsion angles: θ_{0-4} to determine the ribose puckering modes (C3′-*endo*, C2′-*endo*, etc.) and χ to determine the base to ribose relative orientation (*anti* or *syn*).

As mentioned above, the nucleotide conformation is mainly, if not completely, characterized by its free torsion angles. Consequently, many attempts aim at classifying nucleotide conformations according to torsion angles. In the late 1970s, Olson reduced the six phosphodiester chain torsions to two pseudotorsions of virtual bonds spanning the chain in two C–C–O–P segments (C4′–C5′–O5′–P and C4′–C3′–O3′–P). She reported a statistical correlation between the individual torsions and those spanned by the two pseudotorsions [8]. Gautheret and coworkers proposed a different approach that analyzed the clustering of dinucleotide conformations. They used a RMSD distance to compare pairs of dinucleotides aligned by their P–O3′ bond. The clustering discriminated families of dinucleotides with similar P–P orientations, and was used as the basis of a conformational search space in early versions of the MC-Sym computer program (see Section 4.2) [9, 10]. They observed with this approach the "crankshaft effect" [11], as different torsion patterns lead to similar 3-D conformations. In more recent studies, Duarte and coworkers extended Olson's work by defining two pseudotorsions and identified recurrent torsion patterns as well [12].

Hershkovitz and coworkers analyzed individual Gaussian distribution data fitting of the four backbone torsions α, γ, δ and ζ in the crystal structure of *Haloarcula marismortui* 23S rRNA. They identified 37 different conformers from which they defined nucleotide signatures [13]. Others, such as Murray and her colleagues, have classified three-torsion patterns (α, β, γ) and (δ, ε, ζ) into 42 conformers by applying quality filtering to high-resolution X-ray crystal structures [14]. According to them, each nucleotide conformer represents a high-quality reference nucleotide conformation. Schneider and coworkers have analyzed the torsion angles of dinucleotides by Fourier averaging of six selected 3-D distributions. They found 18 conformers, apart from the overrepresented A-RNA helical conformation [15]. Similarly to Gautheret and coworkers, they concluded the structural conformational space of RNA 3-D structures could be sampled by a small number of dinucleotide conformers.

2.2 Nucleotide Interactions

Inter-nucleotide interactions contribute to the overall stability of RNA tertiary structure. The obvious example is the stacked Watson–Crick base pairs that forms the A-RNA double helix. Interactions outside double helices that are distant in sequence are often referred to as tertiary interactions and play a major role in RNA folding. Here, we define and present a nomenclature to describe base stacking and base pairing information.

2.2.1 Base Stacking

Base stacking involves London dispersion inter-molecular interactions between two bases that induce a 3-D arrangement where one base is stacked on top of the other (see Figure 4). Bases can stack towards each side and therefore there are four different base stacking types. To identify on which side a base is stacked, a vector normal to the plane of the base is defined so that any base in a classical A-form helix have their normal vectors oriented in the same direction; towards the 3′-strand end-point. In pyrimidines, this normal vector is the rotational vector $\overrightarrow{n}_{\mathrm{Y}}$ obtained by a right-handed rotation from N1 to N6 around the pyrimidine ring. The pyrimidine ring in purines is reversed with respect to that of pyrimidines, as stacked in the A-form helix, and therefore the pyrimidine ring normal vector for purines must be reversed. We define $\overrightarrow{\sigma}$ as the normal vector for any base: $\overrightarrow{\sigma} = \overrightarrow{n}_{\mathrm{Y}}$ in cytosine and uracil, whereas $\overrightarrow{\sigma} = -\overrightarrow{n}_{\mathrm{Y}}$ in adenine and guanine (see Figure 6a). When bases A and B stack, $\overrightarrow{\sigma}_{\mathrm{A}}$ is in the same or opposite direction to $\overrightarrow{\sigma}_{\mathrm{B}}$, and B is either above or below A. Therefore, a base stack is "straight" or "reverse" and the second base is either "above" or "below".

The four cases are shown in Figure 6(b). The "upward" stacking corresponds to "straight" and "above"; "downward" to "straight" and "below"; "inward" to "reverse" and "above"; and "outward" to "reverse" and "below". Consequently, the base stack in A-form helices is "upward". The four cases can be written using the less than (<) and greater than (>) characters. For instance, if A and B stack inward, then we can simply write "A >< B" (see Figure 6b).

Note that base stacking is independent of the backbone direction. Two adjacent bases in a sequence can be stacked in any of the four cases. As an example, consider the A-riboswitch aptamer module adenine-sensing messenger RNA (mRNA) crystal structure from *Vibrio vulnificus* (PDB ID 1Y26), where U22 and A23 are stacked downward (U22 << A23) (see Figure 7). This particular stacking interaction occurs at a junction that connects two fragments inside the adenine-sensing pocket. Both U22 and A23 participate in base triples (a base simultaneously pairs to two other bases) [16].

MC-Annotate implements base stacking as in Gabb and coauthors [17], by using the distance between the ring centers, and the dihedral angle and horizontal shift between the rings. As purines are made of two rings, the pyrimidine and imidazole, both are verified. The base stacking interactions are labeled according to the nomenclature above. Note that biased cutoffs on each parameter are needed to decide whether two bases stack.

The bases shown in color are involved in two base triples: U22 (blue) with A52 (red) and A73 (orange), and G46 (green) with U23 (blue) and C53 (red). U22 and A23 are stacked downward. The *LW* nomenclature is used: w for water-mediated; circle for W; square for H; triangle for S. (b) Tertiary structure of the two base triples. The arrows indicate each normal vector, $\overrightarrow{\sigma}$

2.2.2 **Base Pairing**

Base pairing involves the formation of hydrogen bonds between exocyclic hydrogen donor groups (mainly NH and NH_2) and acceptor groups (mainly CO and N). The well-known canonical Watson–Crick G=C and A–U base pairs have three and two hydrogen bonds, respectively. Successive Watson–Crick base pairs that stack upward result in the A-form helix, also called stem (see Figure 4). The determination of the helices of an RNA from sequence data is the goal of secondary structure prediction (see Chapter 14). As stems have a tight and local 3-D structure, they are often manipulated as rigid objects in computer modeling. Other than Watson–Crick base pairs abound in RNAs; near 20% in the yeast phenylalanine transfer RNA (tRNA-Phe) and near 50% in the large ribosomal subunit), and are often qualified as "non-canonical", or non-Watson–Crick.

In his famous 1984 book, Saenger compiled 28 base pairing patterns involving at least two hydrogen bonds [7]. Each base pair was assigned a roman number: for instance XIX for the G=C Watson–Crick base pair, XX for the A–U Watson–Crick base pair, XXIII for the "Hoogsteen" A–U base pair, XXIV for the "reverse Hoogsteen" A–U base pair and XI for the "sheared" G–A base pair; see Ref. [7], p. 120 for the complete list).

More recently, Leontis and Westhof proposed a new nomenclature, *LW* [18]. In *LW*, three hydrogen bond contact edges (*W* = Watson–Crick, *H* = Hoogsteen and *S* = Sugar) were defined in each base (see Figure 8). To describe a base pair, one has simply to name its interacting edges. For the Watson–Crick base pair, since the hydrogen bonds are formed by chemical groups on the *W* edges of each base, we refer to it as W/W. In addition, the relative orientation of the riboses with respect to the plane of the base pair is annotated as *cis* or *trans*, respectively, if the glycosidic bonds extend towards the ribose are in the same (as in the A-form helix) or opposite orientation (see Figure 9a).

To introduce more precision and distinguished among possible ambiguities of the *LW*, and in particular in one-hydrogen-bond base pairs, Lemieux and Major divided each contact edge in three regions they named faces [19]. In this extension of *LW*, *LW+*, each possible hydrogen bond face is named by its corresponding *LW* edge, to which one of three possible orientations was added: w, h and s. For instance, the *W* edge has the *Ww* face at the center of the edge, the *Wh* face towards the *H* edge and the *Ws* face towards the *S* edge (see Figure 8). The wobble GU base pair is annotated W/W in *LW*, and more precisely *Ww/Ws* in *LW+*. Bifurcated hydrogen bonds that oscillate between two *LW* edges have their own faces in *LW+*: *Bh* between *W* and *H* edges, and *Bs* between *W* and *S* edges.

Finally, the normal vector $\overrightarrow{\sigma}$ used to annotate base stacking can also be used in base pairing to address the relative orientation (parallel or antiparallel) of

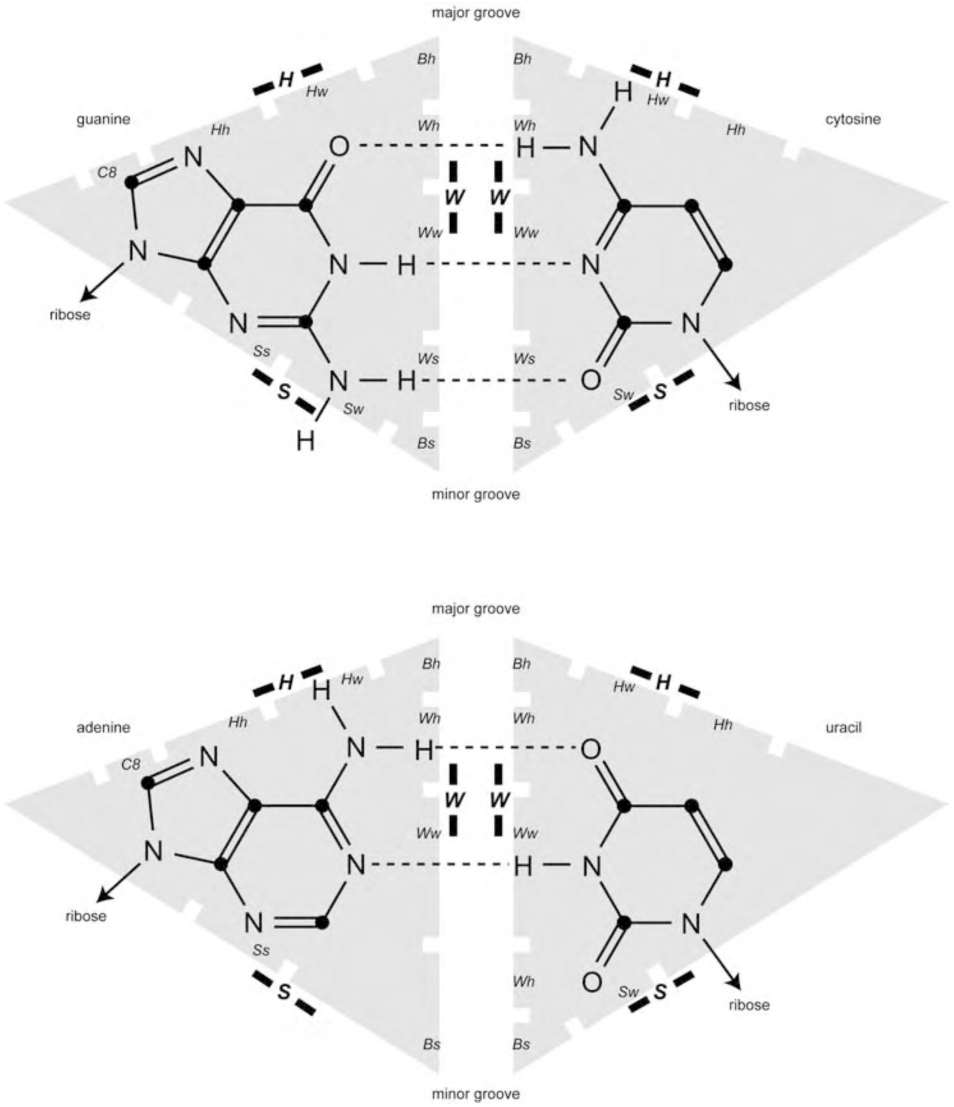

Figure 8 Base pairing patterns. The two canonical Watson–Crick base pairs and their hydrogen bonds (dashed lines) are shown (top: G=C; bottom: A–U). The *LW* nomenclature is shown by engulfing shaded triangles, where the arcs represent the W, H and S edges on the four standard bases. Here, the W edges are in contact in both base pairs. Notches along each edge delimit the *LW+* faces for each base. The major groove of the A-RNA double helix is on the H side, whereas the minor groove is on the S side.

the two bases in a base pair. The *cis* W/W base pairs in the A-form helix are characterized by the antiparallel orientation (see Figure 9b).

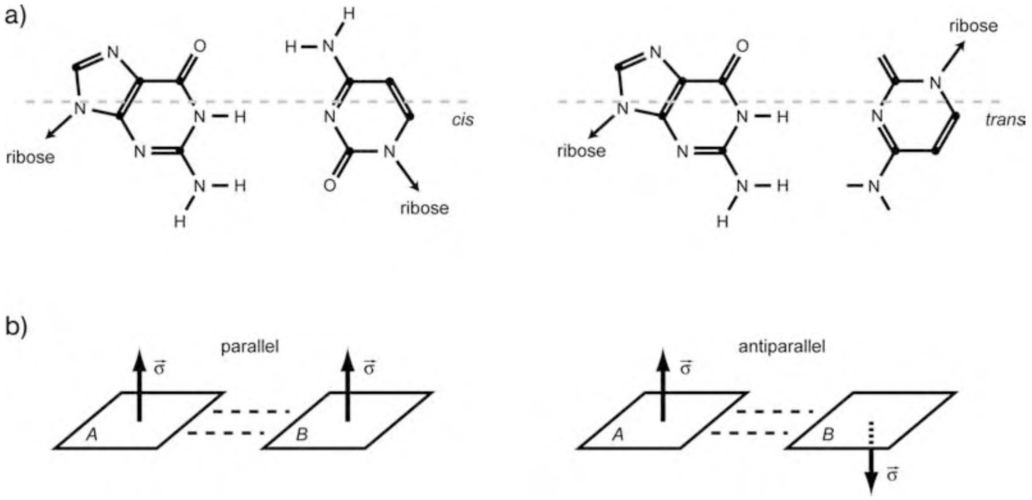

Figure 9 Base pairing orientations. (a) From the plane of the base pair, if both glycosidic bonds are oriented on the same side of the line that splits the plane evenly in two (dashed gray line), the base pair is *cis* (left). Else, if the glycosidic bonds are on each side, the base pair is *trans* (right). (b) Base normal vector $\vec{\sigma}$ relative orientation. Two bases, A and B, represented here by planes in perspective view, are either "parallel" if their $\vec{\sigma}$ are oriented in the same direction (left) or "antiparallel" if their $\vec{\sigma}$ are oriented in opposite directions (right).

In order to limit the bias of using cutoffs, Gendron and coworkers, in MC-Annotate, implemented the detection of the base pair types by using unsupervised learning [19]. Single hydrogen bonds are selected by Gaussian distribution fitting of three geometric parameters calculated between all pairs of bases: the hydrogen, the donor, the acceptor and the lone electron pair (positioned 1 Å away from the acceptor in the direction of the orbital). The subset of hydrogen bonds between two bases is selected by solving the equilibrium state of the maximal flow of the directed bipartite graph formed by all possible hydrogen bonds between the two bases. The base pair is labeled according to the *LW*+ nomenclature. The relative orientations of the glycosidic bonds (*cis* or *trans*) and of the normal vectors (parallel or antiparallel) are also computed. The RNAView annotation procedure of base pairs differs considerably from the one implemented in MC-Annotate, as it is based on geometrical cutoffs.

Lee and Gutell proposed an alternative topological nomenclature, *LG*. Starting with the Watson–Crick C=G or A–U, or even with the wobble G–U base pair, they defined 14 families by successively manipulating the base plane and glycosidic bond relative orientations: shearing, flipping, reversing, paralleling or slipping. The resulting 14 families are the Watson–Crick (*WC*), wobble (*Wb*), slipped Watson–Crick (*sWC*), slipped wobble (*sWb*), reversed Watson–Crick (*rWC*), reversed wobble (*rWb*), Hoogsteen (*H*), reversed Hoogsteen (*rH*), sheared (S), reversed sheared (*rS*), flipped sheared (*fS*), parallel flipped sheared (*pfS*), parallel sheared (*pS*) and reversed parallel sheared (*rpS*) [20].

2.2.3 Isosteric Base Pairs

Base pairs are isosteric if they preserve a local tertiary structure and, thus, function, as observed in evolutionary related RNAs whose sequences may diverge. Leontis and coworkers have superimposed the geometry of all possible base pairs according to their C1′–C1′ distances and *cis*/*trans* base orientations [21]. Then, they mapped all 16 combinations to the 12 families of the *LW* nomenclature, which resulted in isostericity matrices from which it can be shown that all canonical Watson–Crick combinations are isosteric and that the wobble G–U base pair is isosteric to the protonated A–C base pair. Walberer and coworkers defined isostericity from a theoretical analysis [22]. They generated a base pair database for all possible hydrogen bond arrangements and deduced an isostericity measure based on glycosidic bond overlap. They observed high isostericity values in helical base pairs, validating their approach, and more surprisingly in several purine–purine and pyrimidine–pyrimidine combinations.

Accurate RNA sequence comparison requires precise (structural) alignments in order to ensure the positions compared truly correspond in the tertiary structure. Including isosteric information in sequence alignment gives better insights into the sequence requirement of structural motifs (see Section 3) across RNA phylogenies [23]. The presence of isosteric base pairs is another fact that supports a structural rather than sequential RNA evolution.

3 Motif Discovery

In the previous section, we presented a series of nomenclature and formalisms to describe some already acknowledged components of RNA tertiary structure: the nucleotide conformations and interactions. Here, we take one step further and describe higher-order RNA components.

The increase in high-resolution X-ray crystallographic structures, in particular the resolution of the large ribosomal subunit [24–26], has increased the literature describing repeated RNA fragments or motifs [27]. Many occurrences of each of these fragments can be found in one or among several different 3-D structures, they are conserved among evolutionary related RNAs, and they are often related to specific structural and biochemical functions.

One can think of RNA motifs as fundamental RNA building blocks. Therefore, finding and characterizing all of them should provide us with invaluable knowledge about RNA folding and aid substantially in tertiary structure prediction. Here, we present some classical RNA motifs, and introduce a formal definition allowing us to computationally represent, search for and discover them.

3.1 RNA Motifs

The most obvious RNA motif is the double helix, which is composed of a succession of stacked Watson–Crick base pairs. Similarly to the double helix, RNA motifs are thermodynamically stable and fold into similar tertiary structures that can be found in various structural contexts.

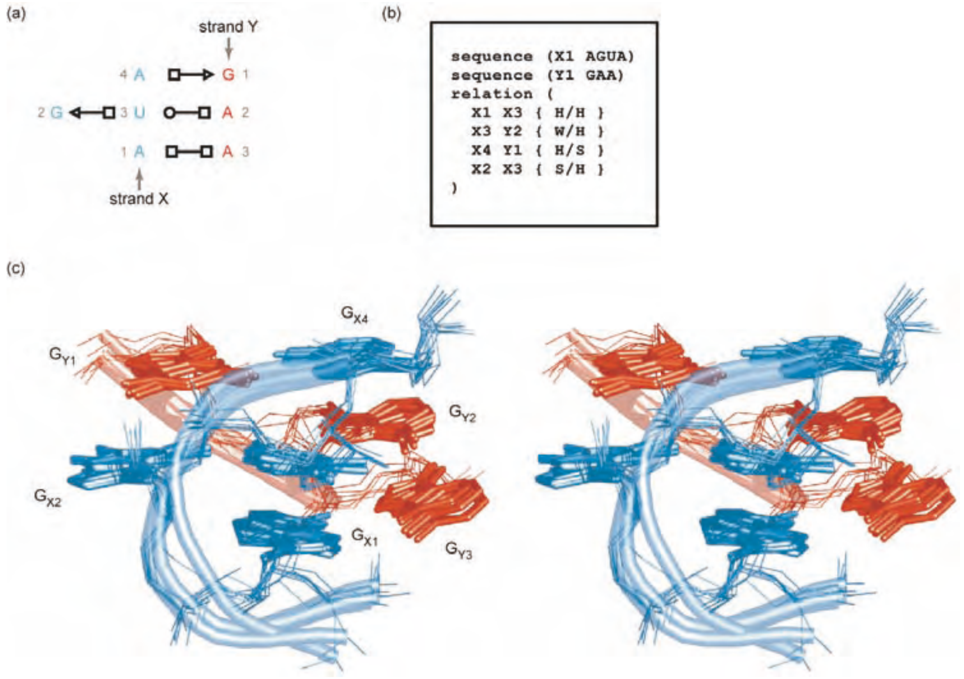
Let us define an RNA motif as a graph of nucleotide conformations and interactions, where the nucleotides are the vertices of the graph. An arc between two nucleotides is present if the two nucleotides are adjacent in the sequence or if their bases interact. Note that if we use the nomenclature introduced in the previous section, then this definition is equivalent to our formal representation of an annotated RNA tertiary structure and is, in fact, the output of the MC-Annotate computer program.

While RNA graphs are easily represented in computer programs by classical data structures, there is currently no consensus in the RNA ontology nor is there a data file format to represent them. RNA graphs in computer programs such as MC-Annotate are serialized into opaque binary files using the C++ MC-Core library developed in our laboratory (also freely available at sourceforge.net/projects/mccore). The RNAML format, derived from XML (extensible markup language), can handle RNA graphs and is portable among many different RNA applications [28,29].

Since RNA motifs can be represented by characteristic RNA graphs, they can be searched within hosting RNA tertiary structures via graph isomorphism; the occurrences of an RNA motif are simply the isomorphic subgraphs in the hosting graphs. Our laboratory implemented the classical graph isomorphism algorithm [30] in a computer program called MC-Search. The input to MC-Search is a description of the target RNA structure, or pattern, from which MC-Search returns all occurrences of the target motif found in a set of pre-selected PDB files.

3.1.1 Classical Examples

Consider the sarcin/ricin motif (Figure 10), which has been predicted to occur in many different locations of the large ribosomal subunit by comparative sequence analysis [31]. The MC-Search descriptor file for the sarcin/ricin motif is shown in Figure 10(b). MC-Search finds seven occurrences of this motif in the crystal structure of the *H. marismortui* 23S rRNA (PDB ID 1JJ2). All occurrences found share a maximum RMSD of 0.93 Å. Interestingly, the annotation of the found occurrences revealed four conserved base stacking interactions (see Figure 10c), including those among nonadjacent nucleotides:



```

Figure 10 Sarcin/ricin motif. The motif is made of two strands, here named X (shown in blue) and Y (red), and their nucleotides, respectively, numbered 1–4 and 1–3. (a) A schematic representation using *LW* (circle for W; square for H; triangle for S). (b) MC-Search input. (c) The seven occurrences in *H. marismortui* 23S rRNA crystal structure optimally aligned (stereoview). The threads follow the phosphorus atoms in each strand. The hydrogen atoms are not shown.

A_{X1} <> U_{X3} (outward), G_{X2} >< G_{Y1} (inward) and A_{X4} <> A_{Y2} (outward). Here, the two strands involved in the motif were arbitrarily named X and Y, and their nucleotides numbered, respectively, 1–4 and 1–3.

A motif corresponding to the T-loop conserved across tRNAs was matched in the ribosome. In tRNAs, the loop capping the T-stem is characterized by a *trans* W/H U–A base pair stacked on the last W/W G=C base pair of the stem with a two- or three-nucleotide bulge on the A side. Several instances of the motif where found by visual inspection in *H. marismortui* 23S and in *Thermus thermophilus* 16S subunits [32]. These tRNA T-loop motifs in the ribosome were found to interact with other elements of their rRNA through tertiary interactions, similarly to the interactions found between the T- and the D-loop in tRNAs. Two instances of the two-nucleotide bulge version are found by MC-Search in the *H. marismortui* 23S subunit (Figure 11).

The frequently observed A-minor motif [33] is made of an adenine that interacts with the minor groove of a double helix and is of particular interest since it is involved in the selection of tRNAs by the ribosome [34]. Nine

The threads follow the phosphorus atoms in each strand. The hydrogen atoms are not shown.

instances of the A-minor motif are found by MC-Search in the *H. marismortui* 23S subunit (Figure 12). Note that the *S* edge in the base pair annotation of the double-helix nucleotide indicates the minor groove interaction. The A-minor motif is a key element of the larger K-turn motif which induces a bend between two double helices [35]. The core of the K-turn motif is constituted of two *S*/*H* G–A base pairs. There is only one occurrence of the K-turn motif in the *H. marismortui* 23S subunit (Figure 13).

The tetraloop/receptor motif is most frequent in RNAs. It stabilizes the conformation of a hairpin loop interacting with the minor groove of a stem. It was discovered in the hammerhead ribozyme [36] and in the group I intron [37]. The tetraloop/receptor participates in protein translation fidelity, and in the association of the rRNA 16S and 30S subunits, as mutations in the motif induce loss of ribosomal activity [38]. In *T. thermophilus* rRNA, a conserved

(c) The nine occurrences in *H. marismortui* 23S rRNA crystal structure optimally aligned (stereoview). The threads follow the phosphorus atoms in each strand. The hydrogen atoms are not shown.

GCAA tetraloop (referred to as loop 900) caps helix 27 in the 16S subunit and binds to the minor groove of helix 24 in the 30S subunit. Two occurrences of the tetraloop/receptor motif-binding stems of at least three W/W base pairs are found by MC-Search in the *H. marismortui* 23S subunit (Figure 14). Interestingly, the two occurrences found have different base pair orientations.

As found in many pathogenic viruses, the formation of a pseudoknot motif in mRNAs may induce frameshifting in the protein translation [39,40]. The pseudoknot is made of a hairpin stem–loop whose nucleotides in the loop participate in the formation of a second stem. In fact, a pseudoknot occurs when the four strands, A5′, A3′, B5′ and B3′, involved in the formation of two stems, A and B, interleave in the sequence: A5′–B5′–A3′–B3′. Pseudoknots are reported by the MC-Annotate computer program, and 15 are found in the crystal structure of the *H. marismortui* 23S rRNA (PDB ID 1JJ2). In feline immunodeficiency virus (FIV), a pseudoknot was found by comparative sequence and mutagenesis analyses [41]. The secondary and tertiary structures of the FIV pseudoknot are shown in Figure 15. See Section 4.3.2 for details

how Fabris and his collaborators combined mass spectroscopy and computer modeling to determine the FIV pseudoknot tertiary structure [42].

3.2 Catalytic Motifs

The structure and function of catalytic RNAs (ribozymes) have extensively been studied [43–51]. In particular, the crystal structure of the hammerhead ribozyme shows a three-way junction catalytic core [45]. The three-way junc-

A star in the schema (left) is used as a wildcard matching any type of base pairs, which is denoted “pairing” in the input file (right). (b) The secondary structure of the occurrence found in *T. thermophilus* 16S rRNA. *LW* is used (circle for *W*; square for *H*; triangle for *S*). This motif matches in helix 44 of the 16S rRNA (left) and forms many ribose–ribose contacts and two A-minor motifs with helix 13 (right). (c) Stereoview of helix 44 (blue) and helix 13 (red). The match is at 1.40 Å of RMSD of the NMR structure of the VS ribozyme SL1′ loop. The shared sheared G–A base pairs are shown in bold. The nucleotides in helix 13 that participate to the A-minor motifs are shown in bold.

Another relationship between the structure and catalytic activity of RNAs was discovered in the *Neurospora* Varkud Satellite (VS) ribozyme. Six helical domains characterize the secondary structure of the self-cleaving VS ribozyme (see Figure 16a). The substrate domain at stem–loop I is recognized by the catalytic core by, so far, unknown loop–loop interactions between stem–loop I and V [55]. The cleavage mechanism of this ribozyme is induced by a modification of the base pair registry in stem I (see Figure 16b and c). C_{637}

is paired to G_{623} in the active state, reducing the size of the 3′ strand of the internal loop from three to two.

To get a deeper insight into the 3-D structure of the VS ribozyme active conformation, a nuclear magnetic resonance (NMR) spectroscopy structure of a stem–loop I mutant (SL1′) was built to mimic the active conformation [56]. In previous NMR structures of the inactive stem–loop I, the 3–3 internal loop was composed of three stacked base pairs, two S/H G–A base pairs and a wobble A–C base pair. In the SL1′ active structure, the A–C base pair is broken by the helix shift, resulting in a double S/H base pair shared between both As on the 5′ strand and the G on 3′ strand (see Figure 16c).

This distinctive internal loop motif was searched in other RNAs with the MC-Search computer program without any specific interaction types in the loop, by using the "pairing" keyword. The pattern matched a fragment in helix 44 of the *T. thermophilus* 16S rRNA, which is at 1.4 Å of RMSD to the NMR structure of the interior loop of SL1′ (see Figure 17). Helix 44 in the rRNA interacts with helix 13 to form a ribose zipper motif [57], which is defined by ribose–ribose interactions and the presence of the A-minor motif. Both adenines share one sheared (S/H) G–A base pair. The SL1′ structure became a model for the active substrate element of the VS ribozyme, which can bind to another helix and form a ribose zipper motif. Since the catalytic mechanism is characterized by tertiary interactions between stem–loop I and V (see Figure 16a), the authors suggest that the specific interaction needed for an accurate recognition of the substrate is this ribose zipper.

3.3 Transport and Localization

A joint effort between Chartrand's laboratory in Montreal and our group resulted in a deeper understanding of the molecular basis behind cytoplasmic mRNA transport and localization to the yeast bud [58]. A small RNA motif was found conserved across four localization elements within the mRNA of the *ASH1* protein. The motif was found to interact with She2p, one of the important components of the yeast mRNA localization machinery in *Saccharomyces cerevisiae*.

Three localization elements occur in the coding region (E1, E2A and E2B) [59] and the fourth is located in the 3′ untranslated region (E3) [60]. Conserved nucleotides in each element were identified by *in vivo* selection from a polymerase chain reaction (PCR) library. Similar She2p RNA motif-binding sites were characterized, and their secondary structures predicted. The generalized motif is composed of two loops, separated by a short stem, which contains a conserved C on the 3′ strand and a CGA sequence on the 5′ strand (see Figure 18), but for E3 for which the loops are inversed.

A structural rule of the generalized She2p-binding motif was deduced: *i*:*s*:*j*, where *i* is the number of nucleotides in the loop before the conserved CGA sequence (*cf.* one in the 5′ loop of E1: GCGAAGA), *j* is the number of nucleotides before the conserved C in the 3′ loop (*cf.* one in the 3′ loop of E1: ACCCAAC) and *s* the length of the stem separating the two loops (*cf.* four in E1). The localization element E1 is thus a 1:4:1 motif, E2A and E2B are 2:4:0, and E3 is a 0:5:1. The sum $i + s + j = 6$ is invariant.

To find a structural explanation of the invariant rule, MC-Search was used to scan the high-resolution RNA 3-D structures to seek occurrences of these three types of She2p-binding motifs (see Figure 19). In total, 123 matches were found for type 1:4:1 (E1), 85 for type 2:4:0 (E2A/E2B) and 717 for type 0:5:1 (E3). The distance between the 3′ phosphate groups of the two conserved cytosines in all occurrences was 28.3 ± 0.9 Å for type 1:4:1, 28.0 ± 1.0 Å for type 2:4:0 and 28.2 ± 0.7 Å for type 0:5:1. Increasing the length of the She2p-binding motif stem in each localization elements in the yeast three-hybrid assay resulted in a total loss of interaction with She2p.

The resolution of the X-ray crystal structure of She2p revealed a helical region essential for its interaction with *ASH1* mRNA localization elements. This helical region covers a distance of about 27 Å. It was thus logical to the authors to propose a model of the *ASH1* mRNA localization element motif binding to this region of the protein through interactions between the two conserved Cs. An interesting conclusion from this project is that tertiary structure conservation of the RNA motif is more relevant to the binding function than sequence conservation.

4 Modeling

In the previous sections, we introduced an ontology to model RNA tertiary structure components and motifs. Here, we employ the term "modeling" to describe 3-D model building. Two types of 3-D models exist: physical or handicraft models (wood, plastic, metal or any other artistic materials) and computer models (interactively built or directly generated). Often, scientists start with the former type, mainly to draft ideas and to get a global picture of the RNA tertiary structure, and then, when enough structural data are gathered, they switch to the latter.

The goal of RNA tertiary structure modeling is to summarize and project in 3-D structural data. In the last few decades, many low-resolution techniques, e.g. footprinting, and enzymatic and chemical probing, have improved and produced a large quantity of structural data. Consequently, RNA tertiary structure modeling has become very popular and useful in recent years to translate these structural data in to precise 3-D models. The low-resolution techniques compensate when higher-resolution ones cannot be applied, e.g. in the case of *in vivo* or reactive conformations.

In this section, we focus on computer-assisted model building. There are two major approaches to 3-D modeling. The first approach starts with all nucleotides in an extended or randomized state, which is then successively modified until a folded and satisfactory state is reached. The conformational space of such folding methods is defined by the number of accessible states, e.g. molecular mechanics is a folding method that defines satisfaction as the optimum of an objective function. Harvey's laboratory has developed an RNA objective function composed of penalty terms corresponding to experimentally determined nucleotide interactions and distances. The objective function is penalized if the observed interactions and distances are not present in a state. They simplified the RNA model by using one to five points per nucleotide to speedup the folding operations. Using YAMMP, their computer program, they were able to build models of large ribosomal subunits [61]. In the second approach, one assembles the components of the RNA by using

(b) Stereoview of three occurrences, one for each type, aligned by their stems. Type E2A/B is shown in red and was found in *H. marismortui* 23S rRNA (PDB ID 1M1K, strands 1463–1467 and 1477–1485 in chain 'A'). Type E3 is shown in blue and was found in *Deinococcus radiodurans* 23S rRNA (PDB ID 1JZY, strands 295–300 and 363–369 in chain "A"). Finally, type E1 is shown in green and was found in a NMR structure of a hairpin similar to the P5abc region within group I intron (PDB ID 1EOR, strands 4–11 and 16–21 in chain "A"). The conserved Cs are shown in bold in the three models.

construction operators to position and orient them in 3-D space. MANIP [54], an interactive system, and MC-Sym [62], an automated procedure, are among the most employed computer systems to model RNA tertiary structures.

In this section, we present how RNA tertiary structure modeling can be mapped to the discrete constraint satisfaction problem (CSP) and how the CSP solver was implemented in the MC-Sym computer program.

4.1 The CSP

The CSP can be described by three finite sets: the variables $V = \{v_1, v_2, \dots, v_n\}$, the domains $D = \{d_1, d_2, \dots, d_n\}$ and the constraints $C = \{c_1, c_2, \dots, c_m\}$ [63,64]. A variable v_i is assigned values from domain $d_i = \{d_{i,1}, d_{i,2}, \dots, d_{i,|d^{i}|}\}$. Each constraint restricts the assignment of a subset of V, called the constraint scope. For example, if the scope of $c_1 \in C$ is $\{v_2, v_4, v_5\} \subset V$, then $c_1 \subset d_2 \times d_4 \times d_5$.

The three sets are defined in the context of the problem application. In RNA tertiary structure prediction, the variables could be the nucleotides and the domains their possible 3-D coordinates. An example of constraint would be two nucleotides that form a base pair. The scope of the base pair constraint is the two nucleotide partners which link their relative positions and orientations in 3-D space.

A solution to the CSP is a complete variable assignment, $v_i \in d_i$ for $i \in \{1 \dots n\}$, so that all constraints in C, $c_j \in C$ for $j \in \{1 \dots m\}$ are satisfied. A constraint c_j is satisfied only if its scope in the solution is assigned according to the relation it defines. Solving the CSP consists in finding one, many or all solutions.

The search space of a CSP is the Cartesian product of all d_i:

$$\prod_{i=1}^{n} |d_i| \, . \tag{4}$$

The size of a CSP search space is exponential in the number of variables domain sizes. The solutions of a CSP are found by exploring the variable assignments of its search space and verifying if they satisfy the constraints. Backtracking is the classical search algorithm to solve a CSP deterministically and exhaustively. In backtracking, the variables are assigned values systematically, one at a time and to the next available value from its associated domain. When all the values of a domain have been tried, the domain is reset and backtracking moves to the previous variable, assigning its next value, before continuing. The search finishes when the domain of the first variable is reset, indicating that all possible assignments have been tried.

Backtracking develops a search tree (see Figure 20), where the nodes are visited in a depth-first manner. A path from the root of the search tree to a leaf represents a solution if all of its nodes are consistent (the black nodes in

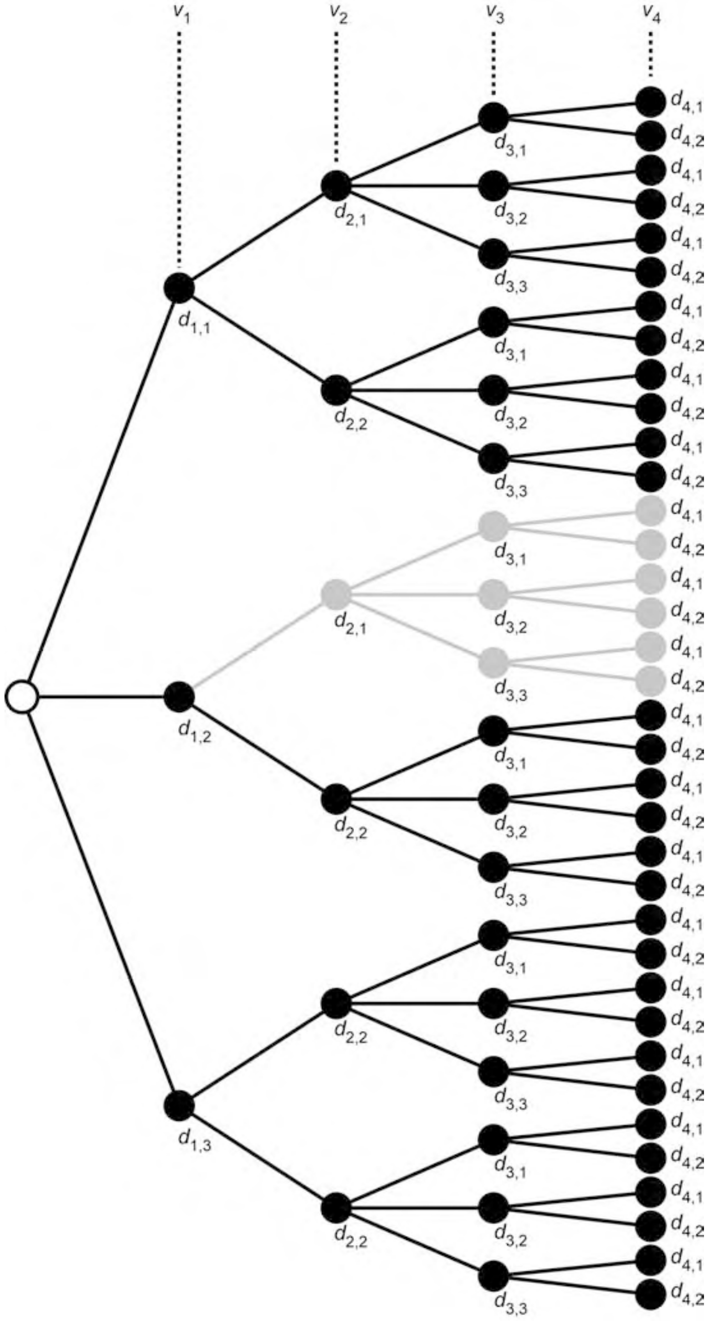

Figure 20 Backtracking search tree. The search space is defined by $V = \{v_1, v_2, v_3, v_4\}$ and $D = \{d_1, d_2, d_3, d_4\}$, where $d_1 = \{d_{1,1}, d_{1,2}, d_{1,3}\}$, $d_2 = \{d_{2,1}, d_{2,2}\}$, $d_3 = \{d_{3,1}, d_{3,2}, d_{3,3}\}$ and $d_4 = \{d_{4,1}, d_{4,2}\}$. Any path from the root (empty circle) to a leaf assigns each variable to a value from its respective domain. A verification of the constraint $\{(v_1, v_2) \in d_1 \times d_2 \quad | \; (v_1, v_2) \neq (d_{1,2}, d_{2,1})\}$ prunes the subtree in grey, as soon as the backtracking assigns v_2 to $d_{2,1}$, and then the search jumps to the next assignment for v_2.

Figure 20). The search tree size is given by Eq. (5):

$$1 + \sum_{i=1}^{n} \sum_{j=1}^{i} |d_i| \ . \tag{5}$$

However, the search can avoid visiting most inconsistent nodes by pruning from the search tree inconsistent branches (those with grey nodes in Figure 20), as soon as one inconsistent node is found. This trick does not change the search time complexity of backtracking, which is exponential in n and $|d_i|$, but can reduce the search time in practice. Using MC-Sym (see next section), the search space of a particular instance of the CSP for the yeast tRNA-Phe tertiary structure was 10^{26}, but the constraints used to explore it defined a consistent search tree of only about 5×10^5, which was explored in seconds and included only about 30 solutions [65]. The best model was at approximately 3.0 Å of RMSD to the yeast tRNA-Phe, as well as with the yeast tRNA-Asp crystal structures (crystal structure resolution). In RNA tertiary structure prediction, it is customary to assess the quality of a prediction method by evaluating its performances at refolding known structures, and RMSD is a very popular quantitative measure.

4.2 MC-Sym

MC-Sym (Macromolecular Conformations by SYMbolic programming) is a computer program for building RNA tertiary structure models from syntactic descriptions of the RNA, similar to the ones used for MC-Search. The computer program implements a CSP solver with backtracking and thus generates models that are consistent with the constraints [6,62,65,66].

In MC-Sym, the variables, V, correspond to the vertices, v, and arcs, a, of the RNA graph (see Section 3.1). The domains of the vertices, D_v, are rigid nucleotides (the relative 3-D atomic coordinates never change) and those of the arcs, D_a, are linear transformation matrices encoding base stacking and base pairing. Consequently, the domains, D, are taken from the Cartesian product, $D = D_v \times D_a$. The goal is to generate consistent 3-D atomic coordinates to each nucleotide in the global frame of the RNA. The rigid sets of nucleotide 3-D atomic coordinates, as well as the linear transformation matrices, are extracted from the PDB [1]. The nucleotide is defined by cutting the phosphodiester chain at the O3′–P bond.

The linear transformation matrices combine nucleotide rotations and translations in 4-D homogeneous coordinates, which represent the spatial relation between two stacked or paired bases. As we saw in Section 2.2, nucleotide interactions involve their bases and thus we represent their spatial relations by coordinate frame relative transformations. The frames are defined at the

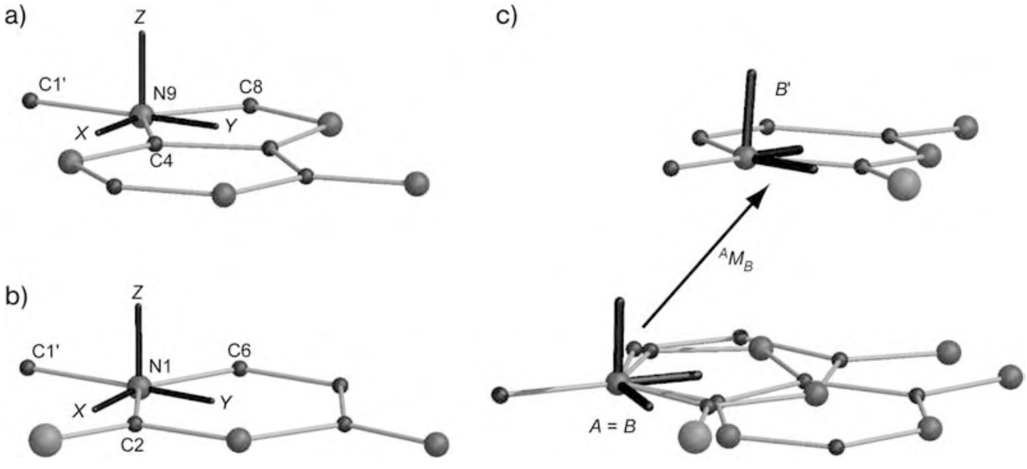

Figure 21 Nucleotide coordinate frame. Hydrogen and backbone atoms are not shown. (a) Frame for a purine (here an adenine). The origin is on the N9 atom, and the *XY* plane is aligned on the plane described by atoms N9, C4 and C8, shared by all purines. (b) Frame for a pyrimidine (here a cytosine). The origin is on the N1 atom, and the *XY* plane is aligned on the plane described by atoms N1, C2 and C6, shared by all pyrimidines. (c) Transformation of cytosine B in adenine A's frame that expresses a stacking interaction. B is moved from a position aligned on A's local frame to B' by applying $^{A}M_{B}$.

terminal nitrogen atom (N9 in purines and N1 in pyrimidines), with the XY plane aligned with the base plane (see Figure 21a and b).

For any coordinate frames A and B, the relative transformation $^{A}M_{B}$ expresses B's position (right subscript) in A's coordinates (left superscript). For example, let $^{A}M_{B}$ be a relative transformation that expresses a stacking interaction between an adenine (frame A) and a cytosine (frame B). As the relative transformation $^{A}M_{B}$ is defined in A's frame, B can be moved from a position aligned on A's frame to a position that expresses the stacking interaction between the two bases (Figure 21c). This relative transformation places B in the local frame of A, independently of A's position in the global frame. Then, to obtain B's position in the global frame, O, it must be transformed by the relative matrix $^{O}M_{A}$, which expresses A's position in the global frame.

Using such transformations, all nucleotides of an RNA graph can be positioned relative to another by starting with an initial origin nucleotide, whose frame defines the global frame, O. A construction order is defined by selecting a spanning tree of the RNA graph rooted at the origin nucleotide. The transformations of the arcs of the spanning tree applied to the rigid coordinates of the vertices build the RNA (see Figure 22). Ideally, the chosen spanning tree of the RNA graph would include all arcs. However, RNA graphs are rarely

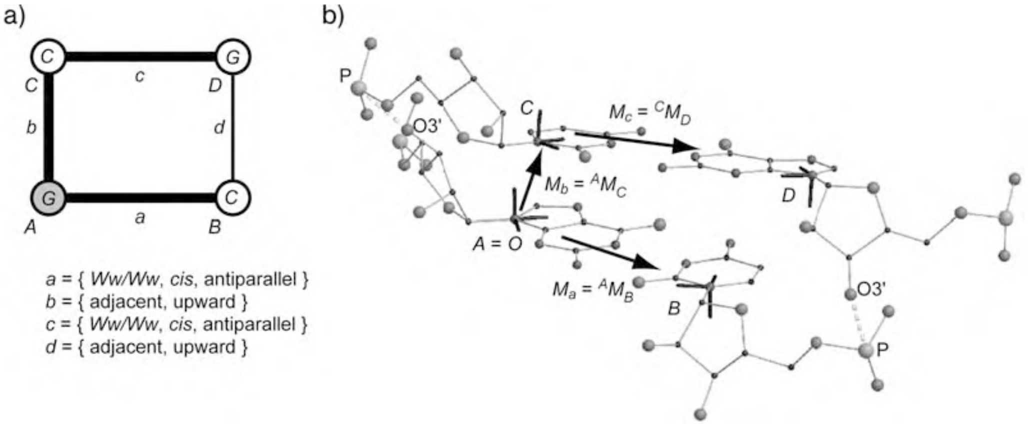

Figure 22 A two-stacked G=C base pairing CSP. (a) RNA graph. The vertices are in uppercase; arcs in lowercase. The arcs of a chosen spanning tree are shown in bold; rooted at vertex A (shaded). (b) One solution: the nucleotide structure for each vertex and a local transformation matrix for each arc (M_i for arc "i"). The root is aligned to the global coordinate frame O. B is positioned by applying $M_a = {}^AM_B$ in the local frame A, which is aligned with O, and thus B is directly placed in the global frame by M_a; vertex C directly placed by $M_b = {}^AM_C$. Finally, to position D, $M_c = {}^CM_D$ is applied in the local frame of C, which is then moved to the global frame by applying $M_b = {}^AM_C$. The O3′–P bond lengths shown in dashed lines are verified by a distance constraint. In this spanning tree, arc d is not considered in the construction.

trees, [1]as they include cycles of interactions. (The only situation where an RNA graph is a tree is when the only information available is the sequence.) Consequently, the missing arcs must be represented by constraints in the CSP, C. As we will see in Section 4.3.3, this problem can be overcome.

The search space for an RNA tertiary structure prediction problem defined with this instance of the CSP is given by the spanning tree n nucleotide variables and $n - 1$ interactions. Equation (6) gives the size of the search space, the Cartesian product $D_v \times D_a$, where $x_i \in D_v, y_i \in D_a$:

$$\prod_{i=1}^{n} |x_i| \times \prod_{i=1}^{n-1} |y_i| \,. \tag{6}$$

Two types of constraints need to be verified at each variable assignment: the atomic clashes and the O3′–P covalent bond distances. The scope of the atomic clash constraints is all nucleotide pairs and they are needed to insure that no pair of atoms from both nucleotides are overlapping. A threshold inter-atomic distance, typically 1 Å, implements the steric clash constraints.

The adjacency constraint, as we name it, has a scope of two adjacent nucleotides in the sequence and is used to verify the covalent O3′–P bond

[1] The only situation where a RNA graph is a tree is when the only information available is the sequence.

distance (dashed lines in Figure 22b), as the nucleotide backbone are positioned independently. The distance threshold is fixed by a user distance range, typically set to [1,2] Å, as the O–P theoretical distance is approximately 1.6 Å (see Section 4.3). Note that choosing a lower bound smaller that the atomic clash threshold would be useless. Increasing the upper bound is equivalent to "relaxing" the CSP. If an overstretched backbone results from choosing a high upper bound, it can easily be fixed by applying numerical refinement [9].

4.2.1 Backbone Optimization

In the above mapping of the RNA tertiary structure CSP, the adjacency constraint is violated more than 50% of the time, even if its range is relaxed to [1,5] Å. This problem comes from the rigid nucleotide conformations that do not reflect well the overall flexibility of the backbone.

To address this problem, we propose a slight modification of the above CSP mapping. We make the assumption that the RNA tertiary structure is driven by rigid base interactions. Consequently, the backbone conformation can be derived from the bases, and we can define a new CSP on the bases alone. The new CSP defines a search space over the transformation matrices, D_a, reducing considerably its size to $\prod_{i=1}^{n-1} |y_i|$ (see Eq. 6).

To reduce the complexity of building a complete backbone from six free torsion angles (11 in total minus the five of the furanose), we define rigid conformations made of the base and the phosphate group. The ribose interconnects a base with two phosphate groups. To position all of the ribose atoms, six free torsions are needed: θ_0, θ_1, θ_2, θ_3, θ_4 and χ (see Figure 3a). However, we know from Eqs. (1) and (3) that θ_0 to θ_4 are all related by the single pseudorotation angle ρ (Section 2.1). Hence, by fixing all covalent bond lengths and angles to their theoretical values, a ribose structure can be built by optimizing a suitable function, $f(\rho, \chi)$. f builds a ribose using torsions ρ and χ and returns the RMSD between the theoretical and the implicit values of the C5′–O5′ and C3′–O3′ bonds (see Figure 23). Equation (7) gives the value of $f(\rho, \chi)$, where l_k are the measured distances and λ_k are the theoretical distances, $k = 5'$ or $k = 3'$, respectively, for the C5′–O5′ or the C3′–O3′ bond

$$f(\rho,\chi) = \sqrt{\frac{(l_{5'} - \lambda_{5'})^2 + (l_{3'} - \lambda_{3'})^2}{2}}\,. \tag{7}$$

Finding the optimal parameters that minimize Eq. (7) builds a ribose attached to its base and interconnecting phosphate groups. The minimization can be solved using classical optimization methods, such as the cyclic coordinate method that does not require derivatives [67]. In this context, each evaluation of the function builds a different ribose conformation. Consequently, the time complexity is proportional to the number of evaluations needed. However,

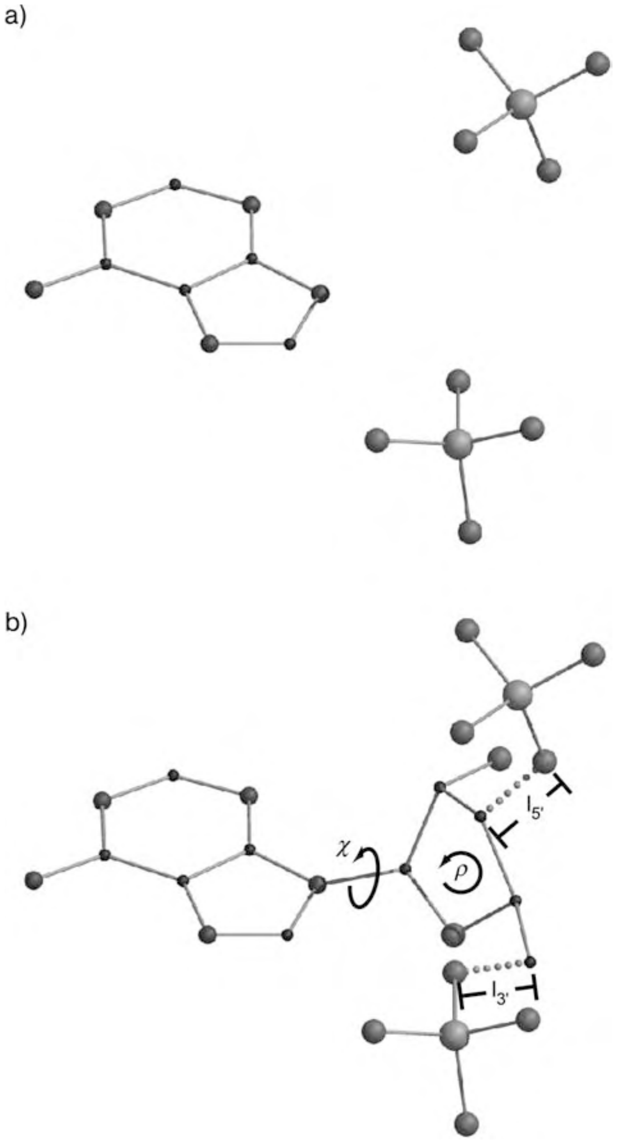

Figure 23 Ribose construction. (a) A base and two phosphate groups. (b) The ribose structure is appended to the base, and is parameterized by ρ and χ. The lengths of the implicit interconnections (shown in dashed lines), $l_{5'}$ and $l_{3'}$, respectively, represent the covalent C5′–O5′ and C3′–O3′ bonds, which quantify the precision of the construction.

we recently derived an optimal parameter estimation of Eq. (7), which solves the ribose optimization in constant time.

Theoretically, the backbone construction can be applied once all variables of the CSP are assigned values – when all bases and phosphate groups are in place. After the backbone construction, however, there is no guarantee that the final model is free from steric conflicts. Therefore, in practice, as soon as the two phosphate groups adjacent to a base are in place, the backbone is built for this nucleotide and the steric clashes verified. This, as in the former backtracking, allows us to prune the search tree.

4.2.2 **Probabilistic Backtracking**

Exhaustive searches for all valid RNA 3-D structures are useful to analyze possible alternative folding of an RNA. However, sometimes only one or few valid models are desired. We recently developed a probabilistic search algorithm that generates valid structures faster and with an increased diversity rate than that of the deterministic backtracking.

We select a random path from the root node of the search tree to any leaf. If at any variable assignment along the random path a constraint is not satisfied, a fixed-size regular backtracking is run until a consistent node is found, which resumes the probabilistic search. If the fixed-size regular backtracking cannot find a consistent node, then a new random path from the root node is selected.

4.2.3 **"Divide and Conquer"**

As for many problems, the "divide and conquer" paradigm has proven useful in RNA tertiary structure prediction as well. A "divide and conquer" algorithm splits a complex problem in many smaller and simpler to resolve subproblems. The solutions of the smaller problems are then combined in complete solutions of the larger problem.

RNA structures can be split into smaller fragments (as we saw in Section 3). Each fragment can be built independently and then merged in complete tertiary structures. In the CSP context, solving a fragment means locally enforcing the constraints in its scope: solving subset $W \subset V$ involves the verification of the constraints defined on W only. The solutions of W become the values of the domain of a new variable, say w, which is added to the CSP. The new CSP, CSP$'$, is defined over the variables $V' = (V \backslash W) \cup \{w\}$, the new domain for w and the new constraints $C' = C \backslash C_w$.

The search space sizes of CSP and CSP$'$ can be compared. Let $D = \{d_1, \ldots, d_n\}$ be the domains for the n variables in V and as defined in the CSP. $E = \{e_1, \ldots, e_k\}$ are the domains for the k variables in W, $E \subset D$. The domain for the new variable, w, is d_w, the solutions of W. If S and S' are, respectively, the search space sizes of CSP and CSP$'$, then from Eq. (4) we obtain:

$$S' < S \Leftrightarrow \frac{\prod_{i=1}^{n} d_i}{\prod_{i=1}^{k} e_i} \times d_w < \prod_{i=1}^{n} d_i \Leftrightarrow d_w < \prod_{i=1}^{k} e_i$$

showing the trivial result that CSP′ has a smaller search space than CSP if the search space size of CSP′ is larger than $|d_w|$, which is generally the case in the presence of actual structural constraints. To save even more time, when fragments of a tertiary structure correspond to RNA motifs, as described in Section 3, their solutions can directly be taken from the X-ray crystal structures [53]. We sometimes refer to this practice as RNA homology modeling.

4.3 MC-Sym at Work

Here we show how MC-Sym can be used to generate RNA tertiary structure models. The input description file has sections to describe the sequence, the nucleotide conformations, the nucleotide interactions, the constraints, and execution arguments.

Figure 24 shows an example for the modeling of a tandem W/W base pairs: C=G stacked with A–U. Figure 24(a) shows the secondary structure of this simple fragment, made of two strands: "a" 5′-AC-3′ and "b" 5′-GU-3′. Figure 24(b) shows the spanning tree of the RNA graph, as chosen by the user, to build the fragment.

In the input (Figure 24c), the "sequence" section defines the two strands and introduces a global numbering system for the nucleotides. The "residue" section defines the nucleotide conformations, D_v, and sampling sizes; here, 10 different C3′-*endo anti* conformations. The nucleotide interactions are defined in the "connect" and "pair" statements, specified using the *LW*+ nomenclature. The "connect" statement is used for adjacent nucleotides in the sequence. In the example, one of the two base stack interactions is included in the spanning tree and five different stacking transformations will be assigned. The "pair" statement is used for the two Watson–Crick base pairs. Here, seven different Watson–Crick transformations will be assigned.

The "backtrack" statement defines the spanning tree, instructing MC-Sym about the order in which the nucleotides will be inserted in the models. Here, a1 is selected as the global referential, then b2 is Watson–Crick to a1, a2 is stacked with a1 and, finally, b1 is Watson–Crick to a2.

The domain specifications are translated by MC-Sym into queries to the appropriate nucleotide conformation or interaction database. The results of the logical queries define the domains. For instance, the query for the conformation of the cytosine a2 could match entries #5 and #8 in the conformation database shown in Table 2, resulting in the conformation domain $\{S_5, S_8\}$. Similarly, the Watson–Crick query for the a2–b1 interaction could match database entries #1, #3 and #8 in Table 3, resulting in the transformation domain $\{T_1, T_3, T_8\}$.

As indicated in Tables 2 and 3, the conformation and transformation domains come from X-ray crystal structures. The atomic coordinates for the

[b] PDB ID and numbering of the two interacting nucleotides.

the global frame, O, then we extract the relative transformation ${}^{A}M_B$ so that ${}^{O}M_B = {}^{O}M_A \times {}^{A}M_B$. Isolating for ${}^{A}M_B$, we obtain ${}^{A}M_B = {}^{O}M_A^{-1} \times {}^{O}M_B$. We save the ${}^{A}M_B$ matrix in the database so that it can be reproduced for any other pair of bases in any local frame.

The MC-Sym database contains nearly 3000 nucleotide conformations and nearly 20 000 base interactions; hence, the domain size argument next to each conformation and interaction. It is the task of the modeler to assign domain sizes so that the conformational space of a given tertiary structure is correctly addressed – not too small to miss valid models and not too large to avoid prohibitive search space sizes.

4.3.1 Modeling a Yeast tRNA-Phe Stem–Loop

In Figure 26, we present a modeling example for the yeast tRNA-Phe T-stem–loop tertiary structure. The secondary structure of the stem–loop is shown in Figure 26(a). The stem and hairpin loop are modeled independently, and the results of each modeling merged. Figure 26(b–d) shows the three inputs. The first describes the structure of the first four base pairs of the stem. The second describes the hairpin loop, closed by the last base pair of the stem. The last merges the resulting fragments and, thus, models the entire stem–loop. Figure 26(e–g) illustrates the spanning trees defined by the three inputs.

The "res_clash" and "adjacency" statements parameterize the steric clashes and adjacency constraints, respectively. The "explore" statement launches the CSP solver. The RNA graph of the loop is divided into two sections by the W/H U54–A58 base pair, leaving the sequence adjacency implicit to the construction between G57 and A58, and between C60 and C61. Figure 26(h) shows one solution.

4.3.2 **Modeling a Pseudoknot**

To model the tertiary structure of the FIV pseudoknot (see Section 3.1.1), a novel methodological protocol based on mass spectroscopy and computer modeling was designed by Fabris and his coworkers. The experimental data were generated using multiplexing solvent-accessibility probes and chemical bifunctional crosslinkers with a characterization by an electrospray ionization Fourier transform mass spectrometry method (ESI-FTMS) [68]. The chemical and enzymatic probes cleave at specific sites or attack specific chemical groups that are exposed to the solvent. The secondary structure, detailed protection maps and inter-nucleotide distance information were then input to MC-Sym, which generated a set of consistent tertiary structures. Finally, the modeled structures were refined by energy minimization using the Crystallography and NMR System (CNS) [69].

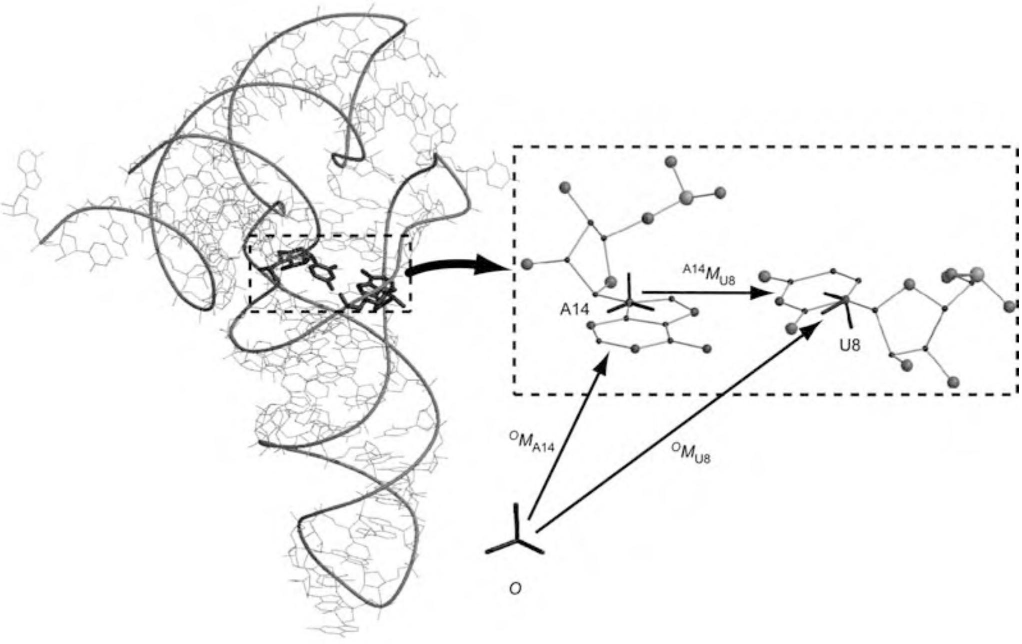

Figure 25 Extraction of the A14–U8 H/W base pair transformation in the yeast tRNA-Phe X-ray crystal structure (PDB ID 1EVV). A thread follows the strands by the phosphorus atoms. Hydrogen atoms are not shown. The base pair is zoomed and shown with the frames ($^{O}M_{A14}$ and $^{O}M_{U8}$) defined in the global frame, O. The transformation $^{A14}M_{U8} = {}^{O}M_{A14}^{-1} \times {}^{O}M_{U8}$ is extracted.

4.3.3 Cycles of Interactions

Traversal of a spanning tree to build tertiary structures implies a conceptual problem, as was pointed out in Section 4.2. A spanning tree does not cover all the arcs of the RNA graph. User constraints must be added to the input to make sure the dropped interactions are satisfied. However, such *ad hoc* constraints are difficult to define and compute. Lemieux and Major have designed a novel building approach to decompose an RNA graph in a series of minimum cycles of interactions [70], whose solutions can be combined by superimposing common arcs. The RNA graph in Figure 24, for instance, is a minimum cycle of four nucleotides. The product of the four transformation matrices is the identity matrix, representing an additional constraint to ensure the consistency of the cycle and the satisfaction of the four interactions.

These minimum interaction cycles could well be used as first-class objects in stochastic graph grammars [71, 72] to represent the tertiary structure of related RNAs and of their sequence alignment. This is similar, but yet more expressive, than stochastic context-free grammars employed to represent RNA secondary structures [73,74].

5 Perspectives

Accurate prediction of RNA tertiary structures from sequence alone is still an unresolved problem. In the meantime, formalizing RNA attributes, searching for higher-order levels of structural organization and modeling their tertiary structure represent current efforts towards better understanding of the RNA architectural principles. In addition, formalizing RNA structural knowledge in computer programs offers the possibility to apply it in a systematic and objective manner, allowing us to generate new and experimentally testable data.

The recent resolution of several RNA structures by X-ray crystallography, NMR, as well as by computer modeling, has allowed us to observe repeated RNA fragments and to infer their function. We are starting to understand the sequence constraints imposed by the tertiary structure of these fragments, and to discover local and global folding rules. In the coming years, as we can

←

expect agreement on an RNA ontology (nomenclatures and formalisms), we might assist in the deployment and implementation of these folding rules into accurate RNA tertiary structure prediction algorithms. An RNA ontology will enable the interoperability of research results. Consequently, as we identify the RNAs of key cellular processes, determine their structure and characterize their role, we will be in a better position to manipulate them. As a result, we should observe an increase in the number and an improvement in the accuracy of RNA-based molecular medicine techniques.

Part 5 Analysis of Molecular Interactions

16
Docking and Scoring for Structure-based Drug Design

Matthias Rarey, Jörg Degen and Ingo Reulecke

1 Introduction

As a result of structural genomics activities, more and more protein structures are becoming available weekly (see also Chapter 13). At the beginning of 2005, more than 29 000 protein structures were deposited in the Protein Data Bank (PDB) [25, 26]. Although experimental structure elucidation via X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy cannot be fully automated at present, it has become a routine task for several protein structural classes. If one excludes complex structures like membrane-bound proteins (e.g. ion channels, G-protein-coupled receptors), one can expect that the three-dimensional (3-D) structure for a protein of interest can be solved with a reasonable chance.

In order to understand a protein's function – or even more challenging to modulate a protein's function – it is important to be able to predict and understand the interactions a protein undergoes with other biomolecules. On the computational side, one has to solve the docking problem: given two molecules, we would like to know whether these molecules will form a complex, how stable this complex is and what it looks like geometrically. Interactions occur between all types of biomolecules – proteins form stable protein–protein complexes, and interact with RNA, DNA and small organic molecules. The interactions between small organic molecules and proteins are of special interest. These interactions often give important hints on the protein's function. Moreover, small molecules can inhibit or activate protein functions and, therefore, play a dominant role in pharmaceutical research. Recently, small molecules have also been applied as a biological tool for revealing

protein function [276]. The focus of this chapter is on reviewing computational methods for predicting interactions between proteins and small molecules, called *ligands* in this context. Chapter 17 concentrates on modeling protein interactions with macromolecular binding partners.

Figure 1 gives an example of a protein–ligand complex. The protein is HIV-protease, a protein from the human immunodeficiency virus (HIV) with the function of cutting a translated multi-protein peptide chain into pieces which fold to HIV proteins (see also Chapter 40). Since this function is not required by the host, i.e. the infected patient, HIV protease is a useful drug target: inhibiting HIV protease prevents the virus from replicating. The ligand molecule is a known inhibitor of HIV protease. The two molecules show a perfect complementarity of the molecule's shapes. In Section 3 we will see that steric as well as physicochemical complementarity is a key aspect in molecular docking calculations.

A computer method for the prediction of protein–ligand complexes has two major ingredients: an algorithm creating potential protein–ligand complex geometries (*pose generation*) and a function predicting the binding affinity of the ligand to the protein based on the complex geometry (*scoring*). Scoring and pose generation both contribute to the difficulty of the docking problem. Several physical effects like electrostatics, van der Waals forces, hydrogen bonding, and hydrophobic and entropic effects influence the binding affinity, some of which can only be estimated roughly. Since these effects can increase or decrease binding affinity, the balance of the terms is of major importance and makes scoring such a difficult task. An introduction to scoring functions will be given in Section 2.

Pose generation involves consideration of several degrees of freedom. The most important ones are the relative orientation of the two molecules and the conformation of the ligand molecule. Apart from these, the protein conformation may also vary, water molecules can be located at the interface between the molecules and the protonation states of the molecules can change. All of these variables are subject to a complicated network of constraints. A small change in one variable may decide whether an overlap between the two molecules occurs or whether a hydrogen bond between two groups can be formed. This implies that the scoring functions for protein–ligand docking typically contain several local minima, and have steep slopes or points of degeneracy and discontinuity. Thus, they are difficult to optimize. Several pose generation methods will be discussed in Section 3.

Although no general solution of the docking problem is available today, several scoring functions and pose generation algorithms for various variants of the docking problem have been developed and successfully applied. This chapter will give an overview of these functions and algorithms. Additional recent review articles on software for structure-based drug design can be found in the literature [42, 110, 115, 152, 168, 187, 209, 243, 265]. Before starting our methods overview, we will summarize the types of docking problems and describe some typical application scenarios.

1.1 A Taxonomy of Docking Problems

Docking problems can best be classified by the type of input molecules. In macromolecular docking, two macromolecules like proteins or DNA are docked. The major characteristics of these problems are that the complex typically has a large contact area and that the molecules, although still flexible, have a fixed overall shape. These features imply that methods based on geometric properties such as shape complementarity alone can already be used efficiently for creating energetically favorable complexes. A survey of methods for protein–protein docking is given in Chapter 17 and elsewhere [197, 275].

The second class contains docking problems in which a small molecule is docked to a macromolecule. The macromolecule can be a DNA fragment or a protein; in the latter case, the problem is called protein–ligand docking. In general, the small molecule is an organic molecule, e.g. a natural substrate or an inhibitor like the protease inhibitor mentioned in the example above.

Small-molecule docking differs substantially from macromolecular docking in the fact that the ligand is typically not fixed in its overall shape. The conformational flexibility of the ligand molecule is of importance and geometric properties alone are often not sufficient to determine low-energy complexes. Even in cases in which the molecule is more or less rigid, the shape of the molecule is not characteristic enough to find low-energy complexes based on shape alone. Therefore, the algorithms that have been developed for small-molecule docking differ from those for macromolecular docking.

For various reasons pertaining to important drug properties, like their bioavailability, most drugs are small molecules. Therefore, small-molecule docking is of great interest in pharmaceutical research. Since pharmaceutical targets are often proteins, most docking algorithms are developed for protein–ligand docking.

In principle, docking of small molecules to DNA can be handled by the same algorithms. Differences occur in the handling of DNA-specific binding mechanisms like covalent binding or binding of so-called intercalators [235]. An intercalator is a small molecule that binds to DNA between two subsequent bases. Since a structural change in the DNA is necessary for binding, conformational flexibility of the DNA must be taken into account. This can be done by docking into a distorted DNA structure [112]. A better alternative is to deal with the DNA flexibility directly. For example, Zacharias and coworkers [305] developed an algorithm based on normal mode analysis for handling structural changes of the DNA during docking calculations.

Protein–ligand docking problems can be further distinguished by the size of the ligand molecule. The typical ligand molecule occurring in drug design docking problems has about five to 12 rotatable bonds. Thus, often the question of placing only a part of the ligand, a fragment, in the active site of the protein arises. In contrast to a typical drug molecule, the conformational space of a fragment is quite small and does not necessarily have to be taken into account explicitly. Therefore, algorithms handling only the relative orientation of the two molecules (rigid-body docking algorithms) can be applied. Docking fragments to proteins is a subproblem handled in several more complex docking algorithms. Some examples are the protein–ligand docking algorithms in which flexibility is handled by dividing the ligand into smaller fragments (see Section 3.2.2), *de novo* design algorithms in which new molecules are created from a fragment database (see Section 5.2) or combinatorial docking algorithms in which combinatorial libraries of molecules are docked by combining placements for individual building blocks of the library (see Section 4.2).

Orthogonal to the classification by the type of input molecules, the second important parameter for categorizing docking algorithms is the time spent per prediction. The number of molecules which have to be processed covers a range from single molecules to several hundred thousands and depends on the specific application scenario.

1.2 Application Scenarios in Structure-based Molecular Design

Molecular docking techniques are frequently used during the lead generation and optimization phase of a drug design project. Most prominent is surely the search for new lead structures in the very early phase of drug design. If the structure of a target protein of interest is available, molecular docking can be used to prioritize compounds in a virtual library [187]. This process, called *structure-based virtual screening*, simply docks each compound of the library into the active site of the target protein and estimates the free binding energy using the scoring function. Virtual screening has a quite long history. Only recently, however, have the methods become applicable due to better docking algorithms and scoring functions as well as fast and cheap computer hardware.

Even with modern scoring functions, virtual screening gives only rough estimates for binding affinities, and is therefore a prefilter used to reduce the number of compounds entering the costly and time-consuming experimental validation. Nevertheless, several case studies have been published in which virtual screening was used to select up to a few hundred compounds which were then experimentally tested [164]. All case studies have two aspects in common: (i) substantial knowledge of the modeler went into the virtual screening process with the consequence that we cannot consider the process as fully automated and (ii) in all cases the authors were able to identify reasonable lead structures. In summary, we can say that although virtual screening is not a fully automated process, it is a very powerful tool in the hands of experienced modelers.

Structure-based virtual screening is often combined with experimental high-throughput screening. For example, virtual screening can be used to preselect promising sublibraries from the compound inventory. Virtual screening may be less reliable than experimental high-throughput screening; however, it gives results which are much better suited for in-depth analysis. Since the proposed complex structure is available, the modeler is able to judge on the basis of this structure, cluster compounds by their binding mode and further reduce the set of solutions by filtering out unwanted geometrical solutions.

The ability to quickly access potential complex geometries makes molecular docking an essential tool for structure-guided lead optimization. Based on a validated lead, focused libraries can be designed and evaluated before the library has to be synthesized. Individual modifications for improving the binding affinity can be suggested much more easily if the complex structure is available. Functional groups in the molecule that are not involved in complex formation can be identified on the basis of the complex geometry. These groups are of major interest in the optimization of second-order drug properties like bioavailability, specificity and synthesizability.

In the near future, we can expect that more and more structures of functionally important human proteins will become available. This will open a new application route for molecular docking tools. With so-called *inverse screening*, we can predict the binding affinity of a lead compound to a large set of protein structures. With such an approach, further proteins interacting with the lead apart from the target protein can be identified. This will give important hints to potential side-effects, toxicity or inappropriate absorption, distribution, metabolism and elimination (ADME) profile of the lead. First publications show that molecular docking can, in principle, be applied in this scenario [223].

In the virtual world we are not limited to existing, already synthesized molecules. Molecular docking can be applied to hypothetical molecules, opening up a completely new route in drug design. In the 1980s, the idea arose of constructing a molecule inside the active site of a protein from scratch (*de novo* ligand design). Today, *de novo* design is an accepted alternative strategy for lead identification, especially if the protein structure is available. The main issue in modern *de novo* design methods is to estimate the synthetic accessibility of a compound. Section 5 summarizes the current strategies for taking synthetic accessibility into account.

2 Scoring Protein–Ligand Complexes

As virtual high-throughput screening is gaining importance in the lead discovery process, the need for a reliable scoring function becomes ever more pressing. Scoring functions have to fulfill three kinds of requirements in docking applications – different poses of a ligand inside a protein binding site have to be compared in order to identify the natural binding mode. Many ligands have to be ranked according to their binding affinity in order to distinguish possible lead structures from nonbinding molecules. Thus, as a scoring function needs to be evaluated very often, it has to be very fast to compute.

Since scoring is such a crucial concern in virtual drug design, a number of review articles deal with this problem in great detail, most recently Refs. [40, 103, 151, 161, 262]. In the following we will give a short overview over the basic features of protein–ligand association and commonly used scoring functions.

2.1 Modeling Protein–Ligand Interactions

A noncovalently bound inhibitor is subject to the dynamic equilibrium between the complex R–L and the uncomplexed state where both the ligand L and the receptor (protein) R are surrounded by solvent molecules (Figure 2). Applying the law of mass action, one can derive a measure of binding free energy from each species' concentration and chemical activity, respectively. Conversely, if we know the binding free energy of a ligand with regard to a certain target protein, we also know if it will bind to the protein or prefers the solvated state. Equation (1) reveals the relationship between the binding-free energy $\Delta G_{\text{binding}}$ and the individual concentrations, which are denoted by the

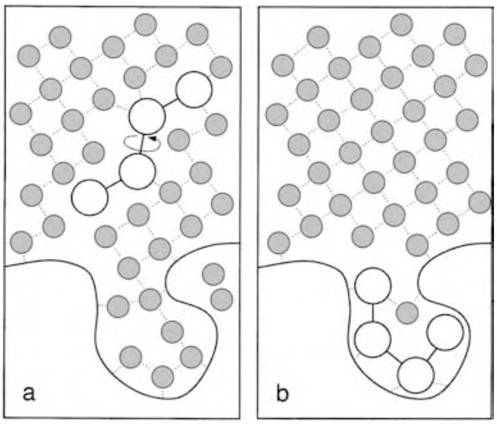

Figure 2 Energetic contributions. Schematic representation of (a) receptor R and ligand L uncomplexed and both surrounded by solvent molecules (shaded circles), and (b) receptor–ligand complex R–L. Hydrogen bonds are represented by dotted lines.

bracket terms.

$$\Delta G_{\text{binding}} = \Delta H_{\text{binding}} - T\Delta S_{\text{binding}} = -RT \ln \frac{[R-L]}{[R] \cdot [L]} , \tag{1}$$

where R is the gas constant and T is the absolute temperature. Binding free energy is composed of enthalpic and entropic contributions: Binding entropy $\Delta S_{\text{binding}}$ is a term derived from a change in the degree of order upon complex formation due to the change in the number of translational, rotational and conformational degrees of freedom, whereas the binding enthalpy $\Delta H_{\text{binding}}$ sums the changes of inter- and intramolecular forces. Typical attractive intermolecular forces are of electrostatic nature, but induction and dispersion effects also play a crucial role. With decreasing distance between the atoms, intermolecular forces become repulsive due to the penetration of the electron shells. A special case of intermolecular force is hydrogen bonding which occurs between a hydrogen atom bound to an electronegative atom and the lone pair of another electronegative atom [44]. Electronegative atoms relevant for protein–ligand docking are mainly oxygen and nitrogen.

When estimating binding free energy, one should also keep in mind that the protein, the ligand and the complex are surrounded by solvent molecules, which also take part in interactions. In particular, water, which is the natural solvent for a protein, has properties which are difficult to take into account [302].

2.2 Scoring Functions based on Force Fields

Force field or first principle type scoring approaches are of the general form

$$\begin{aligned} E_{\text{total}} &= \sum_{\text{bond}} K_r (r - r_{\text{eq}})^2 + \sum_{\text{angles}} K_\theta (\theta - \theta_{\text{eq}})^2 + \sum_{\text{dihedrals}} \frac{V_n}{2} [1 + \cos(n\phi - \gamma)] \\ &\quad + \sum_{i<j} \left[\frac{A_{ij}}{R_{ij}^{12}} - \frac{B_{ij}}{R_{ij}^{6}} + \frac{q_i q_j}{\varepsilon R_{ij}} \right], \end{aligned} \qquad (2)$$

where the energy E_{total} of a system is computed by summing up over inner strain and (noncovalent) binding energy values. Energies resulting from deviations from standard bond lengths r_{eq} and angles θ_{eq} are calculated by simple harmonic potential functions. Out-of-plane deviations ϕ are penalized using a periodic function, and intermolecular forces between the atoms i and j are approximated by Lennard–Jones and Coulomb expressions, which depend on the distance R_{ij} between the atoms. Force field calculations require many parameters which are optimized for specific types of molecular systems. Force fields often used for biomolecular interactions are AMBER [64], OPLS-AA [139], CHARMM [188] and GROMOS [217].

As can be seen in Eq. (2), force field expressions are lacking terms for entropic contributions. Therefore, force fields are mainly used in molecular dynamics (MD) or Monte Carlo (MC) methods. In these methods, free energy and entropy, respectively, are derived from generating an ensemble of states and applying the Boltzmann equation [27]. Solvation effects can be considered in principle, either indirectly by using a distance-dependent dielectric constant (Poisson–Boltzmann model) for simulating electrostatic shielding [130] or by considering the solvent molecules explicitly.

Such simulations can be performed in order to find the natural binding mode and the free energy of the system. In order to rank two compounds against each other a common reference state is required. Figure 3 shows the thermodynamic cycle for calculating the relative binding free energy $\Delta\Delta G_{L \to L*}$ of a ligand L* with respect to another ligand L for a common receptor R. ΔG_3 and ΔG_4 denote the binding free energy of L and L* with respect to R and $\Delta\Delta G_{L \to L*}$ the difference between them. In a thermodynamic cycle the energy is independent from the path it was derived from and thus, if ΔG_3 is known from experiment, ΔG_4 can be calculated from ΔG_1 and ΔG_2. These are the energies needed for transforming L to L* uncomplexed and in complex with R, respectively. They can be computed from stepwise thermodynamic integration over the reaction pathway. In practice, the transformation between the two systems is replaced by a series of transformations between non-physical intermediate states. This method is called free energy perturbation (FEP) (see Ref. [156] for further details).

$$\begin{tikzcd}
\mathbf{R + L} \arrow[r, "\Delta \mathbf{G}_1"] \arrow[d, "\Delta \mathbf{G}_3"'] & \mathbf{R + L^*} \arrow[d, "\Delta \mathbf{G}_4"] \\
\mathbf{R{-}L} \arrow[r, "\Delta \mathbf{G}_2"'] & \mathbf{R{-}L^*}
\end{tikzcd}$$

Figure 3 Thermodynamic cycle. Thermodynamic cycle for calculating the relative binding free energy difference $\Delta\Delta G_{\text{binding}}$ between two ligands L and L^* binding to the same protein R.

$$\Delta\Delta G_{L\rightarrow L^*} = \Delta G_4 - \Delta G_3 = \Delta G_2 - \Delta G_1 \; . \tag{3}$$

It is also possible to calculate the total binding free energy ΔG_4 of L^* by using a "dummy molecule" instead of L. The dummy molecule has no energetic influence on the complex, therefore ΔG_3 is zero. Since ΔG_3 is zero, ΔG_4 is derived directly from the thermodynamic calculations. As this FEP method requires many simulation steps all over the reaction pathway to acquire ensemble averages and according free energy values, it is very time-consuming and not applicable for screening purposes.

Åqvist and coworkers [12] introduced the linear interaction energy method (LIE), by which simulations are carried out only for the corners of the thermodynamic cycle. Rather than integrating over the reaction pathway, binding free energy is linearly approximated depending on the difference in polar and non-polar interaction energy before and after complex formation. The polar and nonpolar free energy contributions are estimated according to:

$$\Delta G_{\text{bind}} = \alpha\Delta \left\langle V_{l-s}^{\text{vdw}} \right\rangle + \beta\Delta\langle V_{l-s}^{\text{el}}\rangle + \gamma \, , \tag{4}$$

where the $\Delta\langle V_{l-s}\rangle$ terms denote the differences in the MD or MC averages between the nonbonded and the complexed state, separated in van der Waals (vdw) and electrostatic (el) interactions of the ligand with the surrounding environment. α, β and γ are constants.

Another method for speeding up force field-based docking calculations is to precalculate energy values for different kinds of atom probes placed at the nodes of a grid which is superposed with the protein's active site. Computing pairwise energies between ligand and protein atoms is therefore reduced to calculations pertaining to the grid points near to the ligand atoms. The historically first and still most frequently used software for this task is the GRID program [106]. Recently, Pearlman [226] introduced the OWFEG (one-window free energy grid) method, by which grid-point energies are derived from FEP calculations and directly related to free energy values.

2.3 Empirical Scoring

Empirical scoring functions are based on correlating geometric parameters of the protein–ligand complex with measured binding free energies. The overall score is a sum of terms representing different physicochemical effects contributing to both entropic and enthalpic energy changes on binding. This approach was pioneered by Böhm [34]. He applied such formula to protein–ligand complexes in the *de novo* design program LUDI [33,35]:

$$\begin{aligned}\Delta G_{\text{binding}} &= \Delta G_0 + \Delta G_{hb} \sum_{\text{H-bonds}} f(\Delta R, \Delta\alpha) + \Delta G_{\text{ionic}} \sum_{\text{ionic int.}} f(\Delta R, \Delta\alpha) \\ &\quad + \Delta G_{\text{lipo}} |A_{\text{lipo}}| + \Delta G_{\text{rot}} NROT \ . \end{aligned} \tag{5}$$

In LUDI, the binding free energy $\Delta G_{\text{binding}}$ is calculated by counting hydrogen bonds, ionic interactions, the lipophilic contact surface area between ligand and receptor, and the number of rotatable bonds in the ligand. Hydrogen bonds and ionic interactions, which diverge from ideal geometry by distance ΔR or angle $\Delta\alpha$, score with a linearly decreasing value. The contact surface is estimated for modeling the hydrophobic effect and the number of rotatable bonds is used to rate the loss of entropy due to freezing the ligand in a specific conformation upon binding. The individual scoring parameters ΔG_i originate from multiple linear regression analysis of 45 receptor–ligand complexes from the PDB with experimental determined binding affinities. The intercept ΔG_0 is regarded as entropic contribution due to the loss of the ligand's degrees of freedom of rotation and translation.

Based on Böhm's work many empirical scoring functions were released which differ mainly in the functional form for the individual terms [37,77,87, 92,99,121,134,148,159,205,242,249,272,279,293,294]. For example, pairwise contact terms or atom-based partial $\log P_{o/w}$ parameters are used instead of surface area terms for incorporating the hydrophobic effect. The term for loss of conformational entropy is also implemented in different ways, accounting for the fact that not all of the ligand's side-chains get stuck in a specific conformation and the rotamers are not independent from each other. Furthermore, with the increasing number of elucidated 3-D structures the parameterization datasets became more voluminous and other regression techniques (partial least squares [93], genetic algorithms [105], neural networks [201]) have been introduced that seem more appropriate for this kind of problem. POEM [8] is a recently published method which combines the design of experiment (DOE) approach [203] with various regressing techniques in order to train an empirical scoring function on a specific target protein.

2.4 Knowledge-based Scoring

Apart from the empirical scoring functions, the so-called knowledge-based approaches or potentials of mean force, originating from protein folding studies [268], have become quite popular. Assuming that an observed crystallographic complex represents the optimum placement of the ligand relative to the protein, protein–ligand atom pair potentials can be derived from the distance distributions of interactions between atoms of specific types found in structural databases. A popular member of this class of scoring functions is the PMF function, introduced by Muegge [208]:

$$A_{ij}(r) = -k_{\mathrm{B}} T \ln \left[f^{j}_{\mathrm{Vol\_corr}}(r) \frac{\rho^{ij}_{\mathrm{seg}}(r)}{\rho^{ij}_{\mathrm{bulk}}} \right] . \tag{6}$$

The potential of mean force A_{ij} between a receptor atom i and a ligand atom j is calculated from a pair-correlation (radial distribution) function, where ρ_{seg} is the number density of pairs ij that occur in a certain radial segment and ρ_{bulk} is the overall distribution when no interaction occurs. $f_{\mathrm{Vol\_corr}}$ is a correction factor for the ligand atom j, which was introduced in order to consider the volume occupied by the ligand itself. k_B is the Boltzmann constant and T is the absolute temperature. The final PMF score is calculated as a sum over all protein–ligand atom pairs ij within a certain cutoff radius.

Other knowledge-based potentials were introduced [70,81,102,133,200,213, 221, 306], mostly differing in the specific functional form of the atom pair potential or the size of the training dataset. Gohlke introduced the DrugScore [102] function with an additional nonpolar surface dependent single atom term to reflect the hydrophobic collapse. Muryshev [213] derived the potential function from pair-correlation studies, but retained some adjustable parameters which were then fitted to experimentally determined binding affinities.

2.5 Evaluation

There are three basic questions to consider when evaluating the reliability of a scoring function:

(i) Is the scoring function able to rate the docking pose most similar to the natural binding mode of a ligand with the best score?

(ii) Can the score of two ligands be used to decide which one binds better to a specific protein?

(iii) Is the score a direct measure for binding affinity such that results from different target proteins can be compared with each other?

As the amount of experimental data grows and becomes available to the scientific community in online databases [52,122,247,291,292,307], an increasing number of evaluation and comparison studies measuring the performance of different scoring functions have been carried out. Several studies on the topic of screening and docking evaluation have been published recently [29,82,146, 194,225,231,232,295,296].

It is a common conviction that there is no scoring function which performs well on all kinds of proteins. Each scoring function is able to account especially well for certain specific types of interaction patterns and protein classes. Furthermore, it is often found that combining the results of different scoring functions leads to more consistent results and the rate of false hits can be reduced by such consensus approaches. Often, a single scoring function is superior for the protein class of interest.

Therefore, a consensus score rarely performs as well as the best scoring function for a specific target, but might be the best choice if there is no additional knowledge about the target protein [51, 56, 273]. It is common sense that actual scoring functions are able to produce satisfying results, in particular, when they are trained to a specific problem. As scoring is such a major concern in computer-aided drug design, there is a great need for further improvements in this field.

3 Methods for Protein–Ligand Docking

The following section contains a survey of algorithms applied to the various types of docking problems as well as a short summary on scoring functions. The methods are typically related to specific software tools also mentioned here.

3.1 Rigid-body Docking Algorithms

Rigid-body docking algorithms have historically been the first approaches to screening sets of ligands with respect to their fit to a given target protein. The protein as well as the ligand is considered rigid, which reduces the problem to the search for the relative orientation of the two molecules with the lowest energy, involving six degrees of freedom.

Reviewing the development of more recent approaches to fragment docking, two enhancements were made. (i) More elaborate algorithms for searching in 3-D space, often adapted from other disciplines, were applied (see, e.g. Sections 3.1.2 and 3.1.3). These methods allow for a reasonable coverage of search space in short computing times. (ii) More information on the physicochemical properties of binding are included directly into the search process. Therefore, energetically unfavorable fragment placements are directly avoided, even if they make sense from a steric point of view. Both enhancements are essential for achieving a high performance for large variety of molecular fragments.

3.1.1 Approaches based on Clique Search

The docking problem can be understood as a problem of matching characteristic local features of the two molecules in 3-D space [165]. A match is an assignment of a ligand feature to a protein feature. Such a feature can either be a piece of volume of the active site of the protein or the ligand or an interaction between the molecules. The search procedure maximizes the number of matches under the constraint that they are compatible in 3-D space, i.e. that they can be realized simultaneously. In other words, compatibility means that a transformation can be found which simultaneously superimposes all ligand features to the matched protein features. In order to search for compatible matches, the following graph G is used: the vertices of $G$are all possible matches between the protein and the ligand; the edges connect pairs of vertices representing compatible matches. Mostly, compatibility means distance compatibility within a fixed tolerance ε: the matches (p_1, h_1),(p_2, h_2) are distance-compatible if and only if $|d(p_1, p_2) - d(l_1, l_2)| < \varepsilon$. A necessary condition for a set of matches to be simultaneously realizable is that all pairs of matches are distance-compatible. Therefore, an algorithm for enumerating cliques (fully connected subgraphs) can be applied to G. By superimposing the matched features of a clique one obtains an initial orientation of the ligand molecule in the active site of the protein.

One of the historically first and today probably most widely used software tool for molecular docking, the DOCK program [166], is based on the idea of searching distance-compatible matches. Starting with the molecular surface of the protein [61, 62, 246], a set of spheres is created inside the active site as shown in Figure 4. The spheres represent the volume which can be occupied by the ligand molecule. The ligand is either represented by spheres inside the ligand or directly by its atoms. In DOCK, an enumeration algorithm searches for sets with up to four distance-compatible matches. Each set is used for an initial fit of the ligand into the active site. Then the set is augmented by further compatible matches and the position of the ligand is optimized and scored. Since its first introduction, the DOCK software has been extended in several directions. The matching spheres can be labeled with chemical properties [267] and distance bins are used to speed up the search process [198, 266]. Recently, the search algorithm for distance-compatible matches changed to the clique-detection algorithm introduced by Kuhl and coworkers [78, 165].

An interesting algorithmic extension was introduced by Knegtel [155]. Instead of using a single protein, an ensemble of protein structures is used for

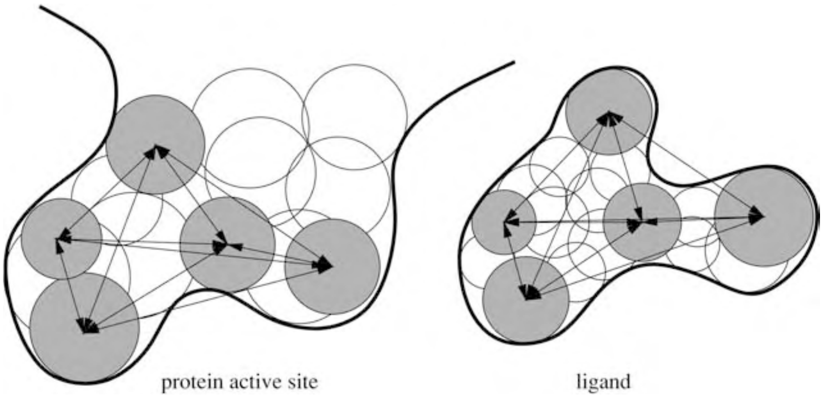

Figure 4 Sphere matching with the DOCK algorithm. (a) A protein active site is shown filled with spheres as they are used in the DOCK algorithm. (b) A ligand covered with spheres is shown. An example for a distance-compatible matching is highlighted in grey. All distances compared are shown by arrows.

the docking calculation. By averaging over the structures, a soft potential representing all structures at the same time can be constructed. With this approach limited protein flexibility can be taken into account. Two of the flexible ligand docking approaches based on DOCK will be introduced below. Furthermore, several scoring functions have been applied in combination with the DOCK algorithm [113, 199, 200, 266].

While the initial DOCK algorithm uses volume as the feature to be matched, other approaches use chemical interactions. Mizutani and coworkers [202] presented the program ADAM in which hydrogen bonding is the feature used for matching. Possible matchings are enumerated and filtered based on distance compatibility.

Further examples for distance-compatibility as an initial screen for fragment orientations are the well-known *de novo* ligand design program LUDI [33, 36] and the rigid-body docking program CLIX [170]. While LUDI's placement is based on matching hydrogen bond vectors and hydrophobic points, CLIX uses energetically favorable regions for functional groups of the ligand for its analysis. These regions are precalculated with the computer program GRID [106] employing a force field potential (see also Section 2). CLIX uses only two points for an initial matching. After fitting the two matched sites, the rotation about the common axis between the matched sites remains as an open degree of freedom. This rotation is then sampled in regular intervals.

3.1.2 Geometric Hashing

Geometric hashing [169] originated from computer vision and was first applied to molecular docking problems by Fischer and coworkers [84, 85]. In computer vision, the geometric hashing scheme was developed for the problem of recognizing (partially occluded) objects in camera scenes. For simplicity, we explain the geometric hashing algorithm for the 2-D case first and describe its application to the 3-D molecular docking afterwards.

Given a picture of a scene and a set of objects which can occur therein (called *models* in this context) both represented by points in 2-D space, the goal is to recognize some of the models in the scene. In a preprocessing phase, a hash table is created from the set of models. For each model, each pair of points defines a so-called *basis*. Then, for each basis, every third point belonging to the model is expressed in coordinates relative to the basis. A *tuple* (model, basis) is stored in a hash table addressed by the relative coordinates of the third point. The reason for having several bases for a model instead of a single one is that it is unknown in advance whether a part of the model is occluded in the scene.

In the recognition phase the scene is analyzed as follows. Every pair of points is considered as a basis. Once the basis is defined, all other points can be expressed by relative coordinates with respect to the basis resulting in a query for the hash table created before. The query votes for all matching tuples (model, basis) stored in the hash table. Finally, models with many votes are extracted, a transformation is calculated from the matching points, and the match is verified.

Two aspects make geometric hashing attractive for molecular docking problems: it is time-efficient and it deals with partial matchings standing for partially occluded objects in the terms of pattern recognition. The latter is extremely important because in most docking applications not all of the ligand features are matched with the protein since parts of the ligand surface are in contact with bulk water.

In order to apply geometric hashing to molecular docking, Fischer and coworkers [84, 85] used the sphere representation of DOCK as the underlying model. As docking is performed in 3-D space, three points (here spheres or atoms) are necessary to define a basis. As a consequence, the number of hash table entries increases with the fourth power of the number of ligand atoms, resulting in unacceptably large hash tables. Therefore, the basis is described by only two points leaving one degree of freedom open (rotation around the axis defined by the two points). With this model in mind, the geometric hashing approach can be directly applied to the molecular docking problem.

3.1.3 Pose Clustering

Pose clustering [181] is a different approach originating from pattern recognition that has been applied to the molecular docking problem [245]. Pose clustering was originally developed for detecting objects in pictures with an unknown camera location. The algorithm matches each triangle of object

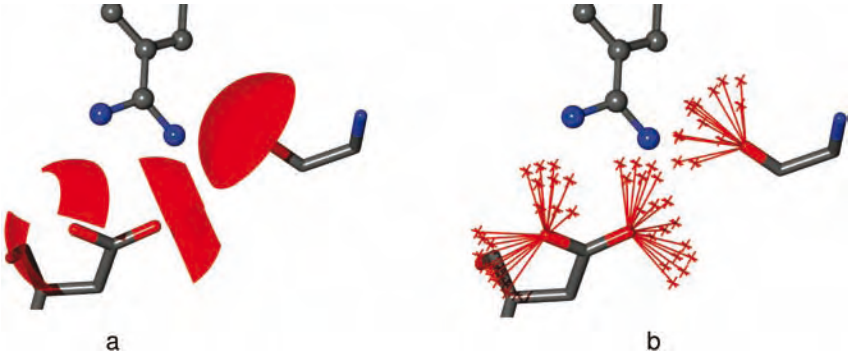

Figure 5 Interaction surfaces and points. Interaction surfaces of three hydrogen-bond acceptors in thrombin (shown in red). Protein atoms are drawn with sticks, ligand atoms with balls and sticks. (a) The interaction surfaces itself and (b) the approximation by interaction points used in the pose clustering algorithm.

points with each triangle of points from the picture. From a match, a camera location can be computed such that the triangles superimpose. The camera locations are stored and clustered. If a large cluster is found, the object is identified and the orientation of the camera with respect to the object is determined.

For applying pose clustering to molecular docking, the LUDI model of molecular interactions [33, 36] is used as the underlying representation. For each interacting group, an interaction center and an interaction surface is defined (see Figure 5). The interaction surfaces of the protein are approximated by discrete points, which then form the scene in the pose clustering algorithm. The centers of the ligand interactions are the object points which have to be matched to the scene.

While in the pattern recognition problem each triangle of object points can be matched to each triangle of picture points, in the docking application the matches are limited in various ways; (i) the interaction types must be compatible and (ii) matching triangle edges must have approximately the same length. A hashing scheme is necessary to efficiently access matching protein interaction surface triangles (picture points) for a given ligand interaction center triangle (object points). The hashing scheme stores edges between two points, and addresses them by the two interaction types of the points and the edge length. A list-merging algorithm then creates all triangles based on lists of fitting triangle edges, for two of the three edges of the query triangle. For a match, additional directionality constraints for the three interactions are checked. Then, a transformation is calculated that superimposes the two triangles. In the original application of pose clustering, the transformation is used to calculate the camera location. In molecular docking, the transformation directly describes the location of the fragment in the active site.

Finally, the transformations must be clustered. We use complete-linkage hierarchical clustering for this task. Up to a user-given distance-threshold, the two closest clusters are merged to a single one. The distance between two clusters is defined as the maximal distance between their objects. As a distance measure between transformations, the root-mean-square deviation (RMSD) of the atoms after applying the transformations is used. After a linear-time preprocessing phase, this quantity can be calculated from the transformations in constant time [245]. For each of the clusters generated, the typical postprocessing steps are performed, like searching for additional interactions, checking for protein–ligand overlap and scoring.

3.1.4 **Fast Shape Comparison**

In molecular similarity, fast methods for comparing molecule shapes are of great interest. A strategy developed in the 1980s is to model atoms by Gaussian functions instead of van der Waals spheres [144, 154]. This method leads to volume-based similarity measures like the Carbo and Hodgkin Indices [49, 126], and allows for fast numerical optimization.

The concept of Gaussian shapes can be adapted to molecular docking [195]. The scoring function measuring the quality of fit consists of two terms. The first quantifies the volume overlap between the protein and the ligand which has to be minimized. The second measures an area intersection which has to be maximized in order to achieve a tight fit. The overall function is differentiable and can therefore be used in combination with fast numerical optimization. Gaussian shapes are the underlying concept of the fast rigid-body docking software FRED which is frequently used [1].

3.1.5 Superposition of Point Sets

In each of the discussed algorithms for rigid-body docking, the superposition of point sets is a fundamental subproblem that has to be solved efficiently and therefore is discussed here briefly.

The superposition problem can be described as follows: Given two sets X,Y with n vectors each, find a transformation $T = \Omega$,t minimizing the root-mean-square deviation between $X$and the transformed vector Y: $RMSD_{X,Y}(T) = \sqrt{(1/n)\sum_i(x_i - \Omega y_i - t)^2}$. Let Ω describe a rotation around the centroid of Y, then $t' = (1/n) * (\sum_i x_i - \sum_i y_i)$ minimizes $RMSD_{X,Y}(T)$ for all rotations Ω.

Optimizing Ω is a more difficult task. Ferro and Hermans [83] and later Sippl and Stegebuchner [269] proposed iterative algorithms rotating subsequently around the x-, y- and z-axes. If the axis is fixed, the optimal rotation angle can be determined analytically.

Kabsch [141, 142] formulated the problem as a constrained optimization problem. Using Lagrange multipliers and the calculation of eigenvectors, Kabsch was able to solve the problem directly. Kabsch's algorithm is very time-efficient and used in several codes for molecular docking today. A recent further development based on Kabsch's ideas combined with quaternions for describing rotations can be found in Ref. [65].

3.2 Flexible Ligand-docking Algorithms

The major limitation of rigid-body docking algorithms is that the conformational flexibility of the ligand molecule is not considered. Often small molecules have large conformational spaces with several low-energy states. Significant differences between the bound conformation and the calculated low energy conformation can occur even for small molecules with only a few rotatable bonds [286].

3.2.1 Conformation Ensembles

In principle, ligand conformational flexibility can be incorporated by applying rigid-body docking algorithms to ensembles of rigid structures, each representing a different conformation of the same ligand. The size of the ensemble is critical, since the computing time increases linearly with the number of conformations, and the quality of the result drops with increasing difference between the most similar conformation of the ensemble and the complex conformation.

Miller and Kearsley developed the Flexibase/FLOG docking algorithm based on conformation ensembles. Flexibases [145] store a small set of diverse conformations for each molecule from a given database. The conformations are created with distance geometry methods [66, 119, 120] which will be introduced later in the context of docking. Then up to 25 conformations per molecule are selected by RMSD dissimilarity criteria. Each conformation of a molecule is then docked using the rigid-body docking tool FLOG [203] which is similar to the DOCK algorithm discussed above.

A different approach based on conformation ensembles was presented by Lorber and Shoichet [184]. Here, about 300 conformations per molecule are created on average for a database of molecules. For each molecule, a rigid part, e.g. an aromatic ring system, is defined. The conformation ensemble is created such that the atoms of this rigid part are superimposed.

Then, the DOCK algorithm is applied to the rigid part and all conformations are subsequently tested for overlap and finally scored. With this method, a significant speedup can be achieved compared to an independent docking of the conformations.

An important point in this scheme is the dependence between the conformation generation algorithm and the docking algorithm: the fewer conformations are created, the higher the tolerance in the matching phase of the docking algorithm must be. Therefore, the algorithms applied to the two subproblems are related making it necessary to tune parameters describing the coverage of conformational space in accord with the tolerance in protein–ligand overlap.

A key element for the success of these methods is obviously the conformation generator. Frequently used are systematic approaches like ROTATE [3] and OMEGA [2]. As a rule of thumb, a few hundred conformations have to be generated in order to have a representative below 1.5 Å RMSD compared to the bound conformation.

The probably most frequently used docking tools based on conformational ensembles are GLIDE [87,114] and FRED [1,195]. GLIDE uses conformational ensembles for fast prescreening of ligand poses. The most promising candidate poses are then numerically optimized and scored. Further examples of software tools following the ensemble strategy are EUDOC [222] and the method by Diller [72].

3.2.2 **Flexible Docking based on Fragmentation**

A possible way to handle conformational flexibility directly in the docking algorithm is by fragmentation. Here, the ligand is divided into several fragments. Each fragment is either rigid or has only a small number of conformations which can be handled by a conformation ensemble. Obviously, the fragment-based docking approaches and *de novo* ligand design are closely related. The major difference is that, while in the docking algorithm the fragments stem from a single molecule, the *de novo* ligand design algorithm picks a fragment out of a database. *De novo* design algorithms will be discussed in Section 5.2.

3.2.2.1 **"Place & Join" Algorithms**

With respect to the way in which the fragments are reconnected during the docking calculation, we can distinguish between two classes of algorithms. In a "place & join" algorithm, each fragment is docked independently. Then, placements for adjacent fragments in which the connecting atoms overlap are identified and reconnected.

The first algorithm of this kind was developed by DesJarlais and coworkers [69]. The ligand is manually divided into two fragments having one atom in common. Then, placement lists are created for each fragment using the docking algorithm DOCK. The algorithm searches through these lists for placement pairs in which the common atom is located approximately at the same point. Finally, the fragments are reconnected, energy minimized, and scored.

Sandak and coworkers [254–256] applied the geometric hashing paradigm to develop a "place & join" algorithm. As before, the ligand is divided into fragments with one overlapping atom, called the *hinge*. For each ligand atom triplet of a fragment, a hash table entry is created and addressed with the pairwise distances between the atoms. The entry contains a fragment identification as well as the location of the hinge. In the matching phase, protein sphere triplets are used to extract ligand atom triplets with similar distances. As a result a vote is counted for a hinge location for each match. Hinge locations with many votes are then selected, and the fragments are reconnected accordingly and finally scored.

"Place & join" algorithms are advantageous in cases in which the molecule consists of a small set of medium-sized rigid fragments. If the fragments are too small, it is difficult to place them independently. Another difficulty is to generate correct bond lengths and angles at the connecting atom without destroying the previously found interactions of the fragments to the protein.

3.2.2.2 **Incremental Construction Algorithms**

The second kind of fragment-based docking algorithms – the one which is used most frequently today – follows the incremental construction method. Instead of placing all fragments of the ligand independently, the incremental construction algorithm starts with placing one fragment (called *base* or *anchor fragment*) into the active site of the protein. Then, the algorithm adds the remaining parts of the ligand to the already placed fragment iteratively. Thus, an incremental construction algorithm has three phases: the selection of base fragments, the placement of base fragments and the incremental construction phase. An incremental construction algorithm can start with several base fragments; however, in contrast to the "place & join" algorithms the placements are not combined, but taken as anchoring orientations to which the remaining parts of the ligand can be added.

Incremental construction originated from the area of *de novo* ligand design. Moon and Howe [204] presented the peptide design tool GROW based on this strategy. The first docking algorithm based on incremental construction was developed by Leach and Kuntz based on the DOCK program [174]. First, a single anchor fragment is selected manually and docked into the active site using a variant of the DOCK algorithm which handles hydrogen-bonding features in the matching phase. A subset of placements is selected for which the incremental construction phase is started. For this phase, a backtracking algorithm is used that enumerates the space of nonoverlapping placements of the whole ligand in the active site. After adding a fragment to the current placement, a refinement routine is used to eliminate steric strain and to improve hydrogen bond geometries. The final placements are then filtered, refined and scored with a force field-based approach. Although there are several manual steps in this procedure, the work demonstrated that the incremental construction idea can be applied to the docking problem.

Leach published a second docking algorithm [172] similar to incremental construction with respect to the way that the degrees of freedom are fixed sequentially. Degrees of freedom considered are the ligand orientation and conformation described by a discrete set as well as a set of rotamers for selected protein side-chains. Leach used a variant of a "branch & bound" scheme, called A* algorithm with dead-end elimination, to search efficiently through the space of possible configurations.

The docking algorithm contained in the FlexX package [**?**, 239, 241] is also based on incremental construction. FlexX is a fully automated approach to molecular docking developed for virtual screening purposes. In the first phase, a small number of base fragments are selected. An efficiently computable scoring function is used to select fragments which are suitable for placement. Base fragments should contain a reasonably large number of interacting groups and at the same time a relatively small number of low-energy conformations. A necessary condition for a successful calculation is that the selected base fragment binds to the protein and is not mostly exposed to water in the final protein–ligand complex. In order to ensure this, a small set of base fragments distributed over the ligand is selected.

For placing the base fragments, the pose clustering algorithm is applied. Base fragment conformations are enumerated within the placement algorithm. The advantage of the pose clustering algorithm is that it is based on the molecular interactions instead of the shape of the fragment. This facilitates the handling of much smaller fragments than in shape-based algorithms, down to the size of a single functional group. All calculated placements up to a given number form the input to the incremental construction phase. In contrast to Leach's algorithm, a greedy strategy is applied always selecting the k placements with the highest estimated score ($k \sim 800$). Each iteration of the incremental construction algorithm contains the following steps: adding the next fragment in all possible conformations to all placements from the previous iteration (or the base placement phase), searching for new protein–ligand interactions, optimizing the ligand position to improve the interaction geometries and reduce steric strain, selecting a subset of placements with high score, and clustering the placements to achieve a reasonable degree of diversity in the solution set. The overall search strategy is shown in Figure 6.

Ligand conformations within FlexX are based on the MIMUMBA model [153]: To each rotatable bond, a set of low-energy torsion angles is assigned, previously derived from a statistical analysis of the Cambridge Structure Database (CSD) [7]. Ring system conformations are precomputed using the 3-D structure generator Corina [89, 252]. For scoring protein–ligand complexes, a variant of Böhms empirical scoring function [34] is used.

Several extensions of the FlexX approach have been developed. The interaction model has been extended such that hydrophobic fragments can be

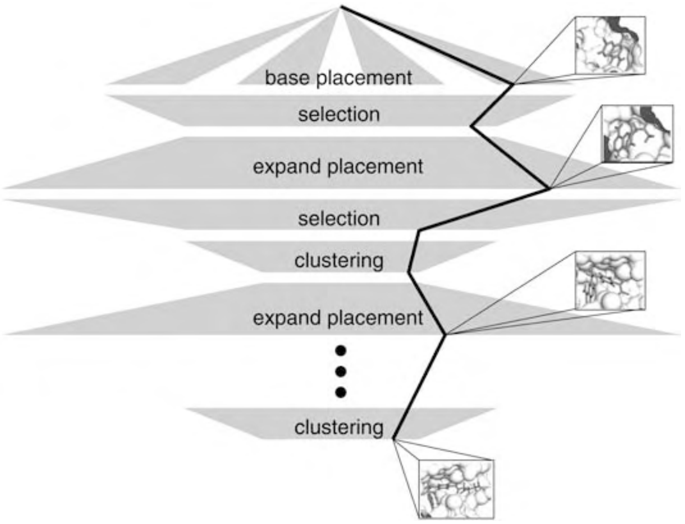

Figure 6 Incremental construction. Flexible ligand docking by incremental construction. The search tree resulting after the steps of the algorithm as described in the text are shown in grey. The black line illustrates the construction process for one placement of the complete ligand.

handled with the pose clustering algorithm [238]. Further development of the interaction scheme allows for even faster virtual screening. FlexX-Scan is a special FlexX variant which makes use of a new interaction scheme resulting in speedups of up to a factor 4 [257]. In order to place critical water molecules and metal ions located in the protein–ligand interface, the "particle concept" has been invented and integrated into the FlexX software. The particle concept allows for automatic placement and energetic consideration of approximately spherical objects during the docking calculation [240]. FlexE is an extension of FlexX regarding the handling of protein flexibility [57, 58]. Similar to Knegtels approach mentioned above, FlexE takes an ensemble of slightly differing protein structures as input. However, the structures are not numerically merged to a single description. FlexE uses various graph algorithms to explicitly consider the different alternative conformations for protein parts like side-chains or small loop fragments and combine them to a single protein conformation which is best suited for the protein–ligand complex created during the docking calculation.

Two other approaches based on incremental construction have been published. The program Hammerhead [300] and its successor Surflex [135] differ from FlexX in the construction strategy. Instead of adding small fragments (cut between each rotatable bond), the ligand is divided into a small set of large fragments. During the construction phase, the next fragment is added such that the connecting atom (or bond) overlaps and interactions to the protein can be formed. Therefore, there is no discrete sampling at the torsion angle of the added fragment. However, since the bond angle at the overlapping atom may vary, high-energy conformations will also be generated and the situation in which a fragment does not interact directly with the protein is more difficult to handle.

Makino and Kuntz [191] and later Ewing and Kuntz [79] presented a fully automated incremental construction docking algorithm based on backtracking. A single anchor fragment is selected maximizing hydrogen bonding features. During the incremental construction phase, the number of conformations for each fragment is limited to reduce the size of the search space. This method is called a limited backtrack search. For scoring, the AMBER force field [224] is used with a modification allowing the handling of multiple protonation states.

Incremental construction algorithms are the basis for widely used docking tools like DOCK and FlexX. The quality of the predicted structures strongly depends on the number of different placements considered in each iteration of the incremental construction process. Therefore, although the overall concept of incremental construction is simple, much effort must be put in the time-efficient analysis of partially placed ligands, e.g. the protein–ligand overlap test, the evaluation of the scoring function and the postoptimization of the ligand placement.

In practice, incremental construction has proved to be a reasonable compromise between accuracy and computing speed. This holds especially for virtual screening applications, in which computing speed is of central importance. For accurate docking, the question about the loss in quality due to the greedy strategy during incremental construction arises. For FlexX, an implementation of an alternative "branch & bound" method shows that for several complexes no significant improvement can be achieved by a full enumeration of the solution space [111].

3.2.3 Genetic Algorithms and Evolutionary Programming

Since the mid-1990s, genetic algorithms have been applied to the molecular docking problem in several approaches [50, 55, 92, 137, 138, 205, 219, 280, 303]. A genetic algorithm [104] is a general-purpose optimization scheme which mimics the process of evolution. The individuals are configurations in the search space. A so-called fitness function is used to decide which individuals survive and produce offspring.

Several elements must be modeled in order to use the idea of genetic algorithms for an application like molecular docking. First of all, a linear description of a configuration (the *chromosome*) is needed describing all degrees of freedom of the problem. Finding the chromosome description is the most difficult modeling part. A suitable description is free of redundancy and models constraints of the configuration space directly such that configurations violating constraints are never generated during the optimization.

Second, a fitness function has to be developed. The fitness function is closely related to scoring functions for molecular docking with one extension. Scoring functions normally work on 3-D coordinates. Therefore, the chromosome of an individual has to be interpreted in order to apply the scoring function. This step is called the *genotype-to-phenotype conversion*. Since most of the computing time is spent on evaluating the fitness function, the conversion and the evaluation have to be done efficiently.

The optimization scheme itself is more or less independent from the application. Typically, several parameters have to be chosen like the population size, the number of generations, crossover and mutation rates, etc. Here, it is important to achieve a reasonable trade-off between optimizing the fitness function and keeping the diversity in the population.

The genetic algorithm which is probably most widely applied for molecular docking today was developed by Jones and coworkers [137, 138] and is implemented in the software tool GOLD. A configuration in GOLD is represented by two strings. The first string stores the conformation of the ligand and selected protein side-chains by defining the torsion angle of each rotatable bond. The second one stores a mapping between hydrogen-bond partners in the protein and the ligand. For fitness evaluation, a 3-D structure is created from the chromosome representation by first generating the ligand conformation. According to the mapping stored in the second string, hydrogen bond atoms are superimposed onto hydrogen-bond site points in the active site. Finally, a scoring function evaluating hydrogen bonds, the ligand internal energy as well as the protein–ligand van der Waals energy is applied as the fitness function. Recently, the Chemscore scoring function was implemented in GOLD, showing an improvement in the virtual screening performance [285].

Oshiro and coworkers [219] developed two variants of a docking method, both based on genetic algorithms and the DOCK approach. The variants differ in the way the relative orientation of the ligand to the protein is described. The first variant is similar to the GOLD algorithm and encodes the matching of ligand atoms to protein spheres in the chromosome. A superposition is used to generate the 3-D orientation of the ligand. The second variant stores the relative orientation directly by a translation vector and three Euler angles. For scoring, a simplified version of the AMBER force field was used.

Gehlhaar and coworkers [92] developed a docking algorithm based on evolutionary programming called EPDOCK. In contrast to a genetic algorithm, offspring are created from one parent by mutation only. Each member of a population is competing for survival in a so-called tournament. EPDOCK contains a self-developed scoring function based on atomic pairwise linear potentials for steric interactions and hydrogen bonding.

3.2.4 Distance Geometry

Distance geometry [119,120] is a well-known technique from the area of structure determination via NMR technology. Instead of describing a molecule by coordinates in Euclidean space, it is described by a so-called *distance matrix* containing all interatomic distances. Based on distance matrices, a set of conformations can be described in a comprehensive form by calculating a distance interval for each atom pair.

The distance geometry methodology can be directly used in the docking algorithm based on clique search and distance compatibility (see Section 3.1.1). Two matches between protein site points and ligand atoms are compatible if the site point distance lies within the distance interval of the ligand atom pair. The drawback of this approach is that the distance matrix with n^2 distances compared to $3n$ atom coordinates is overdetermined: fixing the atom–atom distance between a given atom pair to a single value causes other distance intervals to shrink. Since the exact new interval boundaries are difficult to calculate, the triangle and tetrangle inequality are used to approximate them [74,75]. In other words, only a very limited number of distance matrices can be converted back to 3-D space.

Ghose and Crippen [95] first worked on this approach on a more theoretical basis. Later, Smellie and coworkers [270] applied this methodology to real test cases. Billeter and coworkers [28] combined the description of molecules by distance constraints with an efficient algorithm for constrained optimization.

The screening software Specitope, later versions named SLIDE, developed by Schnecke and coworkers [259] uses distance matrix comparisons as a first filter step. However, the flexibility of molecules is not modeled by distance intervals. Instead, a weighting scheme is defined to scale down the contributions of more flexible atom pairs in the overall score.

3.2.5 Random Search

Once a scoring function for evaluating protein–ligand complexes is available, random search algorithms can be applied to the docking problem. Random placements can be either created directly by randomly fixing all degrees of freedom or they can be derived from a (random) starting structure by random moves. In most cases the structure generation is combined with a numerical optimization driving the placements to the closest local minima. Most approaches of this kind are MC algorithms discussed separately in Section 3.3.3.

Sobolev and coworkers [271] presented a random-search algorithm in their docking program LIGIN. A large set of starting structures is created randomly and then optimized in two steps. The surface complementarity is optimized first, the hydrogen bond geometry in a second step. So far, LIGIN does not include ligand flexibility although the method is in principle able to handle it.

In order to avoid the repeated evaluation of very similar structures, Baxter and coworkers [22] use a method called *tabu search* in their docking software called PRO_LEADS. Starting with an initial random structure, new structures are created by random moves. In tabu search optimization, a list (the tabu list) is maintained containing the best and most recently visited configurations. Moves which result in configurations close to one in the tabu list are rejected except if they are better than the best scoring one. The tabu list technique improves the sampling properties of the random search algorithm in that it avoids revisiting configurations.

3.3 Docking by Simulation

While all previous methods for the docking problem are based on some kind of combinatorial optimization algorithm, there are several approaches tackling the problem by simulation techniques. Instead of trying to enumerate a discrete low-energy subspace of the problem, these approaches begin their calculation with a starting configuration and locally move to configurations with lower energy.

3.3.1 Simulated Annealing

Simulated annealing [150] is a well-known simulation technique which is also frequently used for solving complex optimization problems without any physical interpretation of the simulation itself. The overall simulation routine iterates the following steps. Starting with a configuration A with an energy or score value $E(A)$, a random local move to a new configuration B with energy $E(B)$is calculated. The acceptance of the new configuration is based on the Metropolis criterion, which means that the configuration is accepted if $E(B) \leq E(A)$ or with probability $P = \mathrm{e}^{-(E(B) - E(A))/(kBT)}$ otherwise where k_B is the Boltzmann constant. Over simulation time, the temperature T is reduced based on a so-called cooling schedule such that accepting configurations with increased energy becomes less likely.

The AUTODOCK program for protein–ligand docking developed by Goodsell and coworkers [107,108,206] is based on this strategy. For energy calculation, molecular affinity potentials [106] are precalculated on a grid. Yue developed a program for optimizing distance constraints for rigid-body docking based on simulated annealing [304]. There are several methodical improvements of simulated annealing developed over time. One example which was also used for molecular docking is stochastic tunneling [192,201,202] which rescales the potential energy surface in order to improve the probability of transition between local minima.

3.3.2 MD Simulations

In principle, molecular docking problems can be solved with MD simulations. In fact, the earliest approaches for predicting protein–ligand interactions with the computer were based on MD calculations [234].

In MD, a force field is used to calculate the forces on each atom of the simulated system. Then, following Newtonian mechanics, velocities and accelerations are calculated, and the atoms are moved slightly with respect to a given time step. Introducing MD and force fields is clearly beyond the scope of this chapter. However, some aspects of docking by MD simulations will be mentioned briefly. The simulation becomes more exact, the smaller the time step and the more atoms of the system are taken into account. Thus, MD simulations can become very time consuming and are therefore not appropriate for inspecting large sets of molecules.

In order to avoid very long computing times, methods performing greater moves of the ligand in a single step have been developed. This decreases the dependence of the outcome of the calculation from the starting structure and allows a better sampling of the search space. Di Nola and coworkers [71, 193] developed a technique for this purpose called "helicopter view". For a limited time, the temperature of the system is increased for selected degrees of freedom (protein–ligand relative orientation) and the repulsive terms of the energy function are decreased. This enables the algorithm to escape from local minima in the energy function. A similar effect can be achieved by shrinking and growing the ligand inside the active site of the protein [220].

Given and Gilson have developed a four-phase docking protocol based on MD [100]. First, a set of low-energy ligand conformations is created using MD with alternated heating (in order to perturb the structure) and cooling (in order to minimize the structure). Then, the ligand is placed randomly into the active site and several times minimized. In the final phase, the most stable configurations are investigated further using MD with alternate heating and cooling. The goal of the last phase is to explore the search space around the stable conformations in more detail.

A frequently used technique of speeding up MD simulations is the precalculation of force-field contributions from protein atoms on grids. The force acting upon a ligand atom can then be efficiently calculated by a simple table-lookup instead of summing over all protein atom contributions. The potentials, however, can only be precalculated for atoms which do not change their orientation in space. In order to avoid complete neglect protein flexibility, Luty and coworkers [186,298] divided the protein into a rigid and a flexible part. Every atom sufficiently far away from the active site is considered as fixed in space; all force-field contributions of these atoms can be precalculated on a grid. During the MD simulation, only the active site atoms of the protein and the ligand atoms are allowed to move and have to be considered explicitly in the force-field calculation.

3.3.3 MC Algorithms

In an MD simulation, the local movements of the atoms are performed due to the occurring forces. In contrast, in a MC simulation, the local moves of the atoms are performed randomly. The simulated annealing algorithm discussed above is one special variant of an MC simulation. Two components are of major importance in the development of an MC algorithm: the description of the degrees of freedom and the energy evaluation.

Concerning the degrees of freedom, the aim is a method that avoids sampling high-energy states. A good example of how to realize this concept is the description of the conformational space of a molecule by internal coordinates (bond lengths, bond angles and torsion angles) shown in Figure 7 instead of by Cartesian coordinates for all atoms. With internal coordinates, each type of variable is related to a different energy scale. Changing a bond length is energetically more expensive than changing a bond angle, which in turn is energetically more expensive than changing a torsion angle. Using internal coordinates, it is possible to navigate through the low-energy conformational space by defining the amounts by which the variables of each type are changed. Thus, internal coordinates are the more appropriate description form for MC algorithms.

There are several examples for MC-based docking algorithms. Hart and Read [118] developed an MC scheme combined with simulated annealing. In the MC run, random orientations are created and moved such that protein–ligand overlap is reduced. The results are then optimized in a simulated

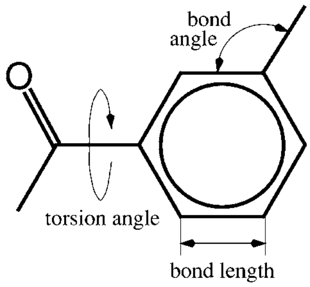

Figure 7 Internal coordinates. Internal coordinate representation of a molecule. The 3-D structure can be constructed from bond lengths, bond angles and torsion angles. Most of the computing time during an MC simulation is spent in the calculation of the energy (or score) of a state. Therefore, this step has to be as time-efficient as possible. Often, energy potentials are precalculated on a grid to speed up this step.

annealing optimization scheme. Protein–ligand overlap and scores are calculated based on precalculated grids. McMartins and Bohaceks QXP program [196] implements a similar approach which can be applied to molecular docking and structural superposition. Wallqvist and Covell [289] also use MC for optimizing the final ligand orientation. Instead of a random set of starting structures, a surface matching algorithm is used.

Abagyan and coworkers [5] developed the software package ICM combining the MC algorithm with an internal coordinate description such as explained above. In contrast to other approaches making purely random moves, ICM is able to make moves based on probability distributions for variable sets. For example, a probability distribution for a torsion angle can be defined such that low-energy torsion angles are more likely to occur than high-energy torsion angles. This biases the MC calculation towards low-energy states.

MC algorithms can be used to overcome the limitation of MD simulations to get stuck in local minima. In order to get low-energy structures, MC can then be combined with energy minimization as described by Apostolakis and coworkers [11]. After a random creation of starting structures, a minimization with a modified van der Waals potential is performed. The energy function for the evaluation of the conformations is a sum of three terms: a force-field energy, a hydrophobic solvation term which is proportional to the SAS of the complex and an electrostatic solvation term obtained from the solution of the linearized Poisson–Boltzmann equation. The best scoring configurations are further analyzed with a MC simulation method called MCM. MCM performs MC interleaved with minimization steps and uses the energy function mentioned above.

PRODOCK is an MC-based docking algorithm developed by Trosset and Scheraga [283, 284]. The software uses either the AMBER IV or ECEPP/3 force field with a grid-based energy evaluation. For calculating energy values within the grid, Bezier splines were used allowing for a more accurate estimation of the energy value as well as information about the derivatives at this point. Like ICM, an internal description of the degrees of freedom is used. The MC simulation is interleaved with energy minimization steps like in Apostolakis' approach.

Brutlag and coworkers proposed a stochastic roadmap simulation (SRS) as an efficient tool for studying molecular motion [9, 10]. A directed graph (*roadmap*) is calculated, where each node represents a randomly sampled conformation of the ligand and the associated protein using internal coordinates. The edges are labeled with transition probabilities, which correspond to the relative motions between such conformations. The probabilities are calculated between every pair of neighboring nodes using Boltzmann statistics. As the roadmap implicitly defines a Markov chain, steady-state occupancies can be calculated without simulating thousands of possible paths through various conformational states.

3.3.4 Hybrid Methods

Due to the complexity of the docking problem, all methods have their pros and cons. Fragment-based approaches and genetic algorithms achieve a wide coverage of the configuration space; however, simulation-based methods outperform others in finding exact local minima, i.e. predicting an exact placement. Combining different methods is therefore a reasonable approach which can result in methods containing the best of each.

Two approaches have been published recently which combine rapid fragment-based searching techniques with sophisticated MD or MC simulations.

Wang and coworkers [290] developed a multistep approach based on rigid-body docking and MD. First, a set of low-energy conformers is created. Each conformer is docked rigid into the active site using DOCK. The high-scoring placements are then optimized using an MD-based simulated annealing optimization in combination with the AMBER force field.

Hoffmann and coworkers [127] combined the incremental construction algorithm in FlexX with an MD-based procedure for postoptimization. First, FlexX is used to create a sample of a few hundred ligand placements. The goal of the second phase is to improve the overall ranking of the solutions and to identify the correct placement. The placements are first energy-minimized using the CHARMM force field. For re-ranking, the software package CAMLab [128] is used. The final score consists of three contributions: a force-field energy, an electrostatic part and a nonpolar part of the solvation energy. The electrostatic part of the solvation energy is calculated by solving the Poisson equation using fast multigrid methods, while the nonpolar part is approximated by the total solvent-accessible surface.

4 Structure-based Virtual Screening

A molecular docking algorithm and a scoring function are obviously the key elements in a structure-based virtual screening software package. In order to make it complete, technical issues like parallel computing on large compute clusters and data management have to be resolved. On a second look, one also identifies slightly different algorithmic problems worthwhile to address: considering pharmacophoric constraints and the exploitation of compound similarity for accelerating the screening process.

4.1 Considering Pharmacophoric Constraints

A frequent scenario for structure-based virtual screening is that, apart from the protein structure, key interacting groups within the active site are known. We would like to guide the docking algorithm to only create poses in which the ligand forms interactions to these key groups. This will focus the resulting compounds to those able to form the interactions requested by the modeler. Since these additional pharmacophoric constraints reduce the number of degrees of freedom, they should also reduce the computational demands as a positive side-effect.

In an early version of DOCK, there was the option to mark some of the protein active site spheres as essential (so-called *red spheres*). The clique detection algorithm can limit its search to those cliques containing the red spheres. If the red spheres are in the clique, they are matched and therefore the required interaction is formed. In addition, less computing time is required for the clique detection.

In a flexible docking algorithm, the situation is more complicated. Obviously, the pharmacophoric constraints can be checked after the pose was generated. This is inefficient, however, since the constraints are applied at a very late phase of the algorithm. The first algorithmic approach for considering pharmacophoric constraints in a flexible docking algorithm was FlexX-Pharm [123, 124]. FlexX-Pharm allows for a variety of pharmacophoric constraints (hydrogen bonding, hydrophobic and steric spots, chemical group locations) combined in a logical expression. During the incremental construction algorithm, for each partially built-up ligand, FlexX-Pharm keeps book about the constraints already obeyed and those which still have to be obeyed in order to achieve a valid solution. FlexX-pharm performs a cascade of fast logical and geometric checks in order to rule out the partial solution which cannot be extended to a valid solution. Today, most molecular docking tools allow for the consideration of pharmacophoric constraints.

4.2 Docking of Combinatorial Libraries

The development of combinatorial chemistry and its application to drug design [88, 109] has led to new search problems in the context of molecular docking. An example of a combinatorial library is given in Figure 8. The number of molecules which can be synthesized on the combinatorial chemistry bases has increased dramatically compared to classical methods. Therefore, any screening methodology has to face many more molecules.

Probably most important for the development of docking methods is the introduction of formal structure into this increased search space. If an unstructured compound collection is given, each molecule has to be analyzed

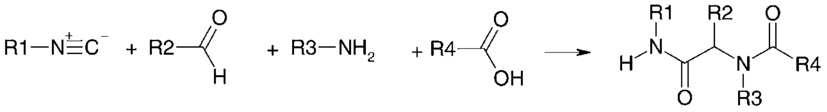

Figure 8 Combinatorial libraries. Based on the Ugi reaction, combinatorial libraries with four different R-groups can be created. After the reaction, all library molecules have the core shown on the right in common, but differ in the four R-groups attached to it.

independently in a screening experiment. Combinatorial libraries, however, follow a systematic build-up law for synthesizing molecules from a limited set of building blocks. This structure can be exploited to drastically reduce the runtime of virtual screening calculations.

In the context of combinatorial libraries, one can distinguish between three kinds of docking problems:

- *Combinatorial docking problem*: given a library, calculate the docking score (and the geometry of the complex) for each molecule of the library.
- *R-group selection problem*: given a library, select molecules for the individual R-groups in order to form a smaller sublibrary with an enriched number of hits for the target protein.
- *De novo library design problem*: given a catalog of molecules, design a library (including the rules of synthesis) optimizing the number of hits for the target protein.

Methods for these problems have emerged from the area of molecular docking and *de novo* ligand design (see Ref. [163] for an early overview on combinatorial docking methods). In the first case, the docking algorithms are applied to individual molecule fragments like R-groups or the core of the library and the resulting information is then combined yielding placements for individual library molecules. The methods for combining the placements differ. As in the case of docking algorithms, they can also be classified as either a "place & join" or an incremental construction method. In the latter case, the *de novo* ligand design is constrained by predefined rules of synthesis.

Early algorithms for the combinatorial docking problem analyzed the similarity in given ligand datasets in order to speed up the search process. The focus in these papers is on structurally relating ligands within the dataset. One approach to do so is to generate a minimal tree structure representing the whole ligand dataset [237]. Another approach is to speed-up conformational searching based on clustering similar molecules [190]. In both cases, the derived hierarchy of molecules can then be used in an incremental construction docking method.

The combinatorial docking tools PRO_SELECT [211] and CombiDOCK [278] are based on the incremental construction method. In both approaches, a library is formed by a template (or core) molecule with a set of attachment points to which one out of a predefined set of substituents can be connected. The template is then positioned inside the active site without considering its substituents. Starting from a few orientations of the template, the substituents are placed into the active site of the protein independently. In case of PRO_SELECT, substituents are then selected based on score and additional criteria like 2-D similarity and feasibility of synthesis. CombiDOCK calculates a final score for whole library molecules by combining fragment scores.

An algorithm that [244] is part of a combinatorial docking extension of FlexX, called FlexX-C, handles the library as a rooted tree in its closed form. Molecules from the library required during the docking calculations are created on the fly. With this method libraries with a few hundred thousand molecules can be handled in main memory during a docking calculation. The tree representation allows for handling complex libraries consisting of several R-groups which can be arbitrarily linked with the one limitation that no ring closures over different R-groups are allowed. The recursive combinatorial library algorithm is a natural extension of the incremental construction method to multiple molecules – in each incremental construction step, all possible R-group molecules are added sequentially [244].

Several approaches based on ligand *de novo* design software have been published for R-group selection problems. Kick and coworkers [149] applied a variant of the BUILDER program [248] to the preselection of substituents for a library targeted to Cathepsin D. Böhm [41] applied the LUDI program to the docking of two groups of fragments which can be connected pairwise in a single-step reaction to search for new thrombin inhibitors. In principle, all programs for fragment-based *de novo* ligand design can be applied in a similar way to the R-group selection problem.

Finally, we mention two methods for *de novo* library design. Caflisch [48] applied the MCSS technique generating fragment placements which are subsequently connected. The DREAM++ software [190] combines tools for fragment placement and selection. The selection process is done such that only a small set of well-characterized organic reactions are needed to create the library.

4.3 Database Approaches

When a large compound library has to be screened, the question arises whether commonalities of compounds can be used, in principle, to speed up the screening process. Like in the case of combinatorial libraries, we would like to perform computations on similar or identical parts of compounds only once in order to improve the efficiency of the overall calculation.

For some docking approaches, the algorithmic idea behind them nicely extends to the case of virtual screening. The probably best example for such a case is geometric hashing (see Section 3.1.2). In this method, multiple compounds can be added to the geometric hash table and will be retrieved by the appropriate protein-based query. The program SLIDE [259] basically follows this strategy for handling multiple compounds.

For fragment-based docking algorithms, a possible strategy would be to avoid the recalculation of poses for common fragments. Lorber and Shoichet demonstrated this approach for a multi-conformation docking tool NWDOCK [184, 277] (see also Section 3.2.1). They extracted rigid fragments from molecules and docked the fragments individually. All molecules containing the fragment are then superimposed on the fragment pose reusing the placement information calculated once for the fragment. With FlexX, we found out that the storage and retrieval of base fragment poses can reduce the required computing time by a factor of 3–4 depending on the library used [258].

Alternatively to looking at common fragments, one can also look for common pharmacophores. The software PHDOCK by Joseph-McCarthy and coworkers [140] follows this idea. A multi-conformer database of compounds is organized by common pharmacophores. The docking algorithm (in this case the DOCK method) can first match pharmacophores. In case of a matching pharmacophore, the compounds containing it are retrieved and further examined. This small selection of methods already shows that understanding virtual screening as an integrated problem is a promising research direction towards even faster methods.

5 From Molecules to Fragment Spaces: Structure-based *De Novo* Design

Instead of moving from single-molecule docking to virtual screening and database approaches to cover a larger part of the chemical universe, a complimentary strategy can be the *de novo* assembly of compounds within an active site of a protein. This has already been mentioned several times throughout this chapter and will be addressed in the following.

A recent review on *de novo* design methods can be found in Ref. [260]. Here, we will focus on summarizing the concept of fragment spaces and algorithms to search them. In addition, the issue of synthetic accessibility will be surveyed and a couple of application scenarios will be described briefly.

5.1 Modeling Fragment Spaces

The difference between a compound library and a fragment space is rather small, but significant. A compound library is basically a collection of molecules, whereas a fragment space contains a collection of fragments. In contrast to the definition given earlier, here, a more general definition of the term fragment is useful. Concerning size, a fragment can be rather large or it can be a single atom only. In addition, a fragment in this context has one or several attachment points, each of a certain type. In some cases, these attachment points are just indicated by missing (hydrogen) atoms and the corresponding chemical environment, therefore, defines the type. In others cases, additional link atoms, sometimes also called *links*, are used which are essentially dummy atoms of certain types connected to the attachment points of the fragment. There, the link itself defines the type.

To make a collection of fragments actually become a fragment space, a set of rules is required determining which of the links are compatible with each other. Fragments that have compatible links can be connected via a new bond between the attachment points to form a larger fragment. Figure 9 shows an example of such a fragment collection. The lines connect fragments with compatible links. In case dummy link atoms are used, as is the case in this example, these will be removed upon fragment connection. The resulting fragment can contain additional links. This depends on the number of links in each of the two fragments that are to be connected. Furthermore, some additional specifications for the modification of the geometry upon fragment connection and the definition of terminal groups for link atoms may be necessary. The fragment space shown was generated by applying the RECAP method [176] to a subset of the WDI. This fragment space was used within the program TOPAS for the first time [261].

The probably most prominent example of a fragment space is a combinatorial library that fulfils all the essential criteria defined above (sees Section 4.2). Other examples for fragment spaces are the use of privileged molecular substructures [23, 24], cyclic and acyclic compounds [13], chemical functional groups [70, 251], building blocks [67], scaffolds and linkers [160], and single atoms [32, 227] or molecular fragments [204, 274].

5.2 *De Novo* Design Algorithms

As we have already outlined earlier, algorithms for docking and structure-based *de novo* design are closely related. Following the docking section above, we will summarize the methods used briefly.

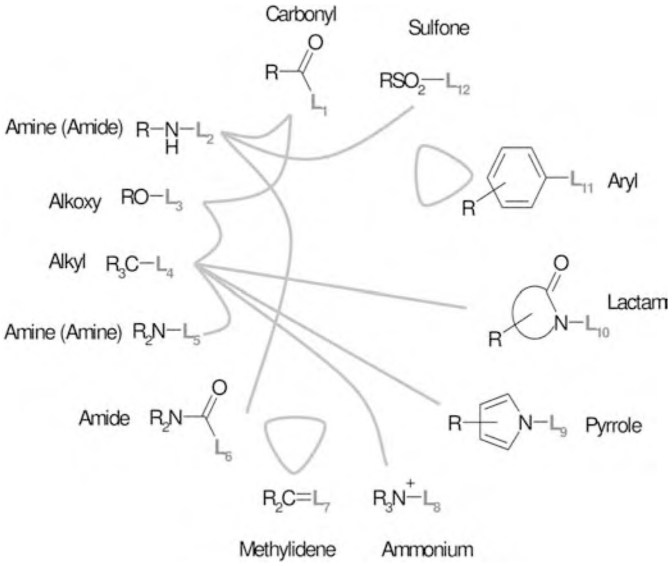

Figure 9 Fragment spaces. Collection of fragment prototypes contained in a fragment space. Each fragment has a (dummy) link atom that represents a corresponding chemical environment (L_1–L_{12}). Fragments can be connected via the formation of a bond between the atoms adjacent to the link atoms. The link atoms themselves will be removed upon fragment connection. The lines connecting the fragments indicate the compatibility of the link atoms. By this, the fragments span up the fragment space.

5.2.1 **Rigid-body Algorithms**

Lewis and Dean published one of the first approaches for *de novo* design more than 15 years ago in the late 1980s. They considered purely geometrical properties and used a collection of 2-D spacer skeletons and rigid-body transformations in order to explore the geometrical constraints of a receptor pocket [179]. The approach was extended to the third dimension in a subsequent publication [178]. Their program BUILDER uses docked molecules for the creation of regular or irregular molecular lattices. Thereon, linear atomic chains are constructed in a partly interactive manner [177, 180]. The amount of chemical knowledge, which could be taken into account for the first approaches, was very limited. That means that for the creation of the atomic chains, for example, only sp^3 carbon atoms were used. Therefore, the chemical models in the BUILDER program were extended in its second version [248].

5.2.2 **Simulation Methods**

One possible first step to take for a structure-based *de novo* design method is exactly the same as for docking calculations, i.e. one has to determine favorable interaction sites in a protein cavity. As mentioned previously, using different kinds of simulation methods can be used for this task. In the case of *de novo* design, the calculation can be carried out, for example, by a grid-based algorithm like in GRID [106], via a MD simulation as in MCSS [205] or by using a fragment-based docking method as done in SEED [189]. This information can then be used in subsequent computational steps. The DLD method, for example, searches a database for appropriate skeletons that can link several MCSS-derived minima [204]. There are a number of other programs that use GRID- or MCSS-derived minima as starting points [76, 170] (for a comparison, see Ref. [31]).

An alternative method is the following. Template structures are combined in a stepwise manner to create molecular skeletons, which satisfy the steric constraints of a given receptor. In a subsequent step, atom-type assignment is then carried out on these molecular skeletons to generate molecules that have complementary chemical properties to the active site. The atom assignment problem has been extensively examined in this context by, for example, Barakat and coworkers [15–19]. Programs based on this kind of approach are SPROUT [96–98, 136], which is based on graph-searching algorithms, and Skelgen [281, 282], which uses a MC-type method.

A third algorithmic alternative is to randomly place fragments in the active site, and assign atom types and connections between these fragments. This can be done by performing a MD simulation as in CONCEPTS [227] or CONCERTS [228], or by using a MC algorithm as implemented in MCDNLG [91], SMoG [70], GrowMol [32] or the method developed by Pellegrini and coworkers which replaces fragments of an already docked compound [230].

The characteristics of MD simulations are the same for *de novo* design as for screening large sets of molecules. Therefore, MD is not an appropriate method for exploring fragment spaces. Nevertheless, it can be of use for optimizing a limited number of solutions that were generated from a *de novo* design method. For the MC-type approaches, the statistical nature of the approach becomes even more apparent in the context of *de novo* design. Whereas this leads "only" to different sets of orientations of the ligand in the case of a docking calculation, for *de novo* design, sets of possibly totally different compounds are generated in each run. This makes it in most cases necessary to perform a multitude of calculations in order to obtain a diverse and probably more comprehensive set of solutions.

5.2.3 "Place & Join" Algorithms

In contrast to the corresponding docking approaches, the number of fragments available in a fragment space is obviously much larger than for a typical ligand molecule. Additionally, there is no information available concerning the topology and the size of the final compound(s). This is of course due to the nature of the fragment space, but has to be pointed out here, since this is a fundamental difference compared to docking methods. There are a couple of *de novo* design programs available which follow this strategy; all of them operate in a very similar way.

LUDI fits molecular fragments onto previously derived interaction sites in the protein cavity. In the first version, these start fragments were then connected by using bridge fragments from a database. Alternatively, LUDI can also be used for adding new substituents to an already existing ligand [33, 34, 38, 39]. Quite similar in concept are the following programs: CLIX [170], which uses fragment energy minima derived from GRID calculations, SPLICE [125], PRO_LIGAND [53, 54, 86, 212, 299, 301] and HOOK, which take fragments derived from MCSS minima as starting positions [76]. Leach and Kilvington used a "tweak" algorithm to generate families of acyclic linkers for combining a set of molecular fragments [173].

One advantage of "place and join" algorithms is that specific key interactions can be accounted for right from the beginning of the calculation. This ensures that all resulting compounds have this specific interaction pattern. However, the main difficulty of all the programs described above is the same as for the corresponding docking approaches. The compounds resulting from the bridging of multiple fragments within an active site are very much dependent on the amount and type of bridge fragments available. In addition, the probability of obtaining strained conformations is relatively high, which means that in most cases an additional energy minimization of the final compounds is necessary. This is then of course more costly in terms of computation time and may also alter the initial fragment positions.

5.2.4 Sequential Growth Algorithms

The use of incremental construction algorithms has originally been invented for *de novo* design and was already covered in Section 3.2. Therefore, the main difference here is the same as already outlined for the "place & join" algorithms, i.e. that the amount of fragments available in a *de novo* design approach is much larger. In principle, two types of sequential growth methods for *de novo* design can be distinguished, those that use atoms as basic building blocks and those that use molecular fragments.

The atom-based programs often involve random elements concerning the selection of atom types and attachment points. In general, only a limited number of atom types, hybridization states and constraints for bond lengths and bond angles are taken into account. Programs using these kinds of approaches include LEGEND [214, 215], GenStar [250] and RASSE [185].

The fragment-based methods can be divided into programs that incrementally build up molecules and those that replace parts of an already docked molecule. Two representatives of the first category are GROW [204], which uses amino acid templates, and COREGEN [13], which uses a ring-linker-based assembly procedure. Programs belonging to the second category are, for example, GroupBuild [251], which replaces individual functional groups for a given compound, and PRO_SELECT [211], which uses a database approach to search for corresponding combinatorial chemistry replacements.

FlexNovo is a fragment-based molecular design program developed by our own group and belongs to the first category. It is based on the FlexX [242] molecular docking software, and therefore uses the same algorithms, chemical models and scoring functions. FlexNovo deals with large fragment spaces, incorporates the concept of pharmacophore type constraints and a large number of additional physicochemical property, geometry and diversity filters [68].

When using incremental construction algorithms, the probability of obtaining strained conformations in the end is probably lower compared to "place & join" algorithms. However, a difficulty that arises especially in the context of *de novo* design is that optimal intermediate solutions might not lead to optimal global solutions. Whereas this does not necessarily have to be the case for docking programs using these kinds of algorithms, which was already mentioned above, for *de novo* design programs the case is more complicated. There, not only the ranking of intermediate solutions for a single compound is important, rather a set of compounds each having totally different intermediate solutions has to be ranked accordingly. In the end, this often results in compounds that are not optimally positioned inside the active site or that lack some key interactions. This can be partially compensated by using pharmacophore type constraints to guide the construction more in the "right" direction, but is of course no guarantee for finding an optimal solution.

5.2.5 **Genetic Algorithms and Evolutionary Programming**

Nondeterministic approaches, such as genetic algorithms or evolutionary programming, have not been used in *de novo* design methods right from the beginning. They became popular approximately a decade ago and are now frequently used in quite a number of programs.

The main difference between all the *de novo* design methods based on these kinds of algorithms is the type of fitness function used for the ranking of solutions. Typically, this is a more or less standard energy function that accounts for the different energetic and geometric contributions to the total energy. Alternatively, scoring functions known from molecular docking programs can also be directly used. This is done for example by the ADAPT program [229], which uses the DOCK scoring function, or LEA3D [73], where the fitness evaluation is based on the FlexX scoring function.

In addition, the employed fragment spaces differ slightly, but not significantly. Glen developed a rather general genetic algorithm procedure that generates molecular structures under different types of constraints, for example a protein cavity, a pharmacophore or certain molecular properties [101]. In most cases, however, different types of molecular fragments are used as done, for example, in LigBuilder [297], ADAPT [229], PEP [45] and LEA3D [73].

Due to the nature of genetic algorithms, the outcome of different calculations will result in different solution sets. Therefore, often not a single, but a couple of program runs are necessary in order to obtain probably a more reasonable set of diverse results, which is especially important in the field of *de novo* design.

5.3 Synthetic Accessibility

Synthetic accessibility has always been and still is one of the key issues in the computational *de novo* design area as shown by Stahl and coworkers [274] and recently surveyed by Baber and Feher [14]. Obviously, this is not the only criterion that a proposed lead or drug candidate has to fulfill. There are a number of at least equally important prerequisites, such as pharmacological activity and ADME toxicology properties [175,236]. The coverage of the latter is clearly beyond the scope of this chapter and is described in Chapter 19.

One way to incorporate synthetic accessibility in a *de novo* design approach is to encode it directly in the fragment space. This can be done by carefully choosing the set of fragments and by using well-defined connection rules. The (justified) assumption here is that compounds created from this fragment space will have a high probability on being synthetically tractable [23,24,67, 171,233,261].

5.3.1 Fragment Selection

There are quite a number of publications that deal with the issue of fragment selection. Each of them tries to identify and select common molecular substructures or functional groups in known drugs. This has been done, for example, for molecular frameworks [23] and side-chains [24], privileged molecular fragments [176], frequently replaced chemical groups [264], multi-activity substructures in molecules which show different biological activities [263], and heterocycles [43].

A complementary approach is to select fragments according to specific property ranges. The underlying assumption here is that there is a drug-like subspace in the vastness of the chemical universe that can be described by a limited number of easy accessible physicochemical properties [117,182,218]. Obviously, not all of the approaches for property prediction and selection can be directly applied to fragments as well. Nevertheless, there are some publications, which deal especially with the problem of fragment properties. A couple of them will be described below.

Following Lipinski's "Rule of Five" [183] (see also Chapter 18), Congreve and coworkers proposed a "Rule of Three" for fragment-based lead discovery and indicated that these property ranges might be useful for fragment selection [60]. Vieth and coworkers performed a survey on characteristic physical properties and the corresponding structural fragments for marketed oral drugs [287]. Hopkins and coworkers suggested the term "ligand efficiency" as an estimate of the binding energy of a compound on a per atom basis [132], which makes this approach in principle also applicable for fragments. This concept has been recently reviewed and extended by Abad-Zapatero and Metz [4].

Additionally, the exclusion of specific substructures could be a desirable task. Baurin and coworkers formulated a medicinal chemistry tractability filter for reactive or unwanted chemical features [20, 21]. Kazius and coworkers derived a set of toxicophores for mutagenicity prediction [143]. These filters have to be handled with care though [162], but can be of use for fragment-based drug discovery in principle [80].

5.3.2 Virtual Synthesis

The definition of the compatibility of fragments is essential when working with fragment spaces. There are several approaches for performing virtual synthesis of molecules. Each of the *de novo* design methods described above has its own definition of fragment compatibility. This ranges from the construction of molecules on an atom-per-atom basis to the connection of very specific substructures. Therefore, the methods differ mainly with respect to the level of sophistication they use for the evaluation carried out upon the formation of new bonds. In the following, a couple of approaches will be described which perform virtual synthesis in a more elaborate and, therefore, in a probably more accurate way.

The compatibility of fragments generated by the RECAP method, for example, is defined following the same rules for the connection of fragments that were used for cleaving compounds in the first place [176]. A more sophisticated evaluation is performed by the program package WODCA [90] and especially in a specific part of this package, the EROS program. This approach incorporates more elaborate physicochemical concepts and therefore tries to model a broad scope of organic reactions [129]. SYNOPSIS simulates organic reaction steps in a different way. For each compound, appropriate functional groups are detected and then different reactions are chosen from a collection of 70 different reaction types [288].

5.3.3 Compound Analysis

The use of drug-like fragments and the definition of a drug-like property range can be beneficial for the outcome of a *de novo* design approach for obvious reasons, but it is by no means sufficient to guarantee the synthetic accessibility of a certain compound [162]. There are a couple of other methods available which take more information into account than just molecular substructures. For example, neural nets have been used for distinguishing between drug-like and nondrug-like compounds [6, 47, 253], Muegge and coworkers used a pharmacophore point filter [207], and Byvatov and coworkers and Müller and coworkers used a support vector machine approach [47, 210]. It has been shown that each of these methods can be used for classifying compounds according to their similarity to known drugs or another training set of compounds with reasonable accuracy (see also Chapter 18).

Another possibility is to do an exhaustive retrosynthetic analysis for a given compound. The first attempts in doing this with computers were published in 1969 by Corey and Wipke [63]. Since then, a couple of related approaches have been published. Again, the coverage of all the information is beyond the scope of this article, but this subject has been excellently reviewed recently by Hanessian [116]. Such programs can identify possible synthesis pathways and appropriate starting chemicals from compound catalogues. Due to the fact that these are knowledge-based approaches, the outcome is very much dependent on the chemistry actually implemented in the program and the level of sophistication with which the analysis is done. The outcome of such an analysis can be of great help in the decision making process. However, still, it seems that the issue of synthetic accessibility cannot be described in a simple and consistent manner, as was recently investigated by Lajiness [167].

6 Structure-based Drug Design at Work: Validation Studies and Applications

Every computational tool for structure-based drug design is published with an initial validation of the method. Basically, we have to distinguish retrospective from prospective validation. In a retrospective study, previously collected experimental data, either X-ray crystal structures or binding affinities, are used to design a test scenario. In a prospective study, the calculated structures or binding affinities are validated afterwards by experiment.

A necessary condition for the applicability of a docking algorithm is its ability to reproduce X-ray structures of the molecular complexes. Usually, a few tenths of these structures are considered and most docking tools are able to reproduce roughly 70% of them within an error margin of 2 Å RMSD. The selection of these test cases is not a simple task: structures may be inappropriate (covalently bound ligands, ligand binding influenced by crystal contacts, etc.), of low resolution or even contain errors. A very good collection of protein–ligand complexes can be found in Ref. [216] and an alternative set has been published in Ref. [158]. When considering these redocking experiments, one has to keep in mind that the protein structure is usually taken from the bound conformation which makes redocking of X-ray structures to an easier problem than performing true predictions.

Several comparison studies have been published with the last 5 years (see, e.g. Refs. [29, 46, 87, 146, 157]). These comparisons have to be read with care because the results are influenced by many hidden parameters like the composition of the test cases, the preparation of the ligand and especially the protein, the selection of the active site, and the personal experience with the software tools just to name a view (see Ref. [59] for an excellent review on fallbacks in comparison studies).

Since most docking tools are applied for virtual screening, the question of whether the programs are able to extract bioactive compounds from large libraries has to be addressed. Obviously, predicting the complex structures correctly is necessary; however, it is not sufficient for virtual screening. In particular, the scoring function plays a more dominant role in virtual screening. While in redocking the scoring function has to select the right pose only, in virtual screening it has to distinguish between different ligand molecules. In retrospective screening studies, a set of known actives is mixed with other molecules having similar physicochemical properties than the known active ones. Literature containing retrospective virtual screening analysis is given in Ref. [59]. Chapter 18 gives a comprehensive review of structure-based virtual screening applications.

The ultimate test for a molecular docking or *de novo* design engine is a prospective study. Here, the experiments for structure determination or binding affinity measurement are done after the prediction. There are excellent reviews summarizing practical applications and success stories of structure-based virtual screening [164]. Chapter 18 further discusses these applications. Concerning *de novo* design, the field is not examined and reviewed in such great detail, as is the case for docking or virtual screening. Nevertheless, there have been a couple of more comprehensive studies for the use of such methods in drug discovery [131, 160, 274].

7 Concluding Remarks

The development of computational approaches for the prediction of protein–ligand interactions has a history lasting more than 30 years. Retrospectively, we can associate key developments with every decade. The 1970s were dominated by the simulation approach. In the 1980s, the first algorithmic approaches were presented. At this time, it was firstly possible to perform screening, i.e. to prioritize a large collection of compounds instead of looking at individual compounds only. Most approaches presented at that time were rigid-body docking algorithms. In the 1990s, docking tools began to consider ligand flexibility while maintaining the efficiency necessary for virtual screening. In parallel, several methods and software tools for structure-based *de novo* design were developed. The question arises as to what the current decade, once behind us, will stand for?

With no doubt, the most challenging problems in molecular docking are the consideration of protein flexibility during ligand binding (modeling the induced fit) and an accurate prediction of free binding energies. First algorithmic approaches dealing with protein flexibility can be found in the literature, some of them are covered in this chapter. These algorithms are able to deal with special cases like side-chain flexibility. However, none of them has yet been applied successfully in a virtual screening exercise. So far, the increasing number of false positives is the major stumbling block. Concerning scoring functions, we notice a continuous development of new and improvement of existing scoring functions. However, none of these developments can be considered as a big step forward. So for both fields, no satisfactory solution is in sight and it remains questionable whether these problems will be solved soon.

Although the scientific achievements for these two major problems in structure-based drug design are small, we can surely say that currently a big step is being made concerning the technology, applicability and acceptance of structure-based molecular design techniques. While the end of the 1990s was dominated by interest in (experimental) high-throughput screening, nowadays we recognize great interest in virtual screening techniques. Virtual screening facilities were established in nearly every large pharmaceutical company. According to PubMed, in 2004 about 400 papers related to virtual screening were published, compared to 134 in 1999. *De novo* design is not yet an established procedure in pharmaceutical industry, but is considered a complementary technique. In particular, in cases where virtual screening fails, *de novo* design can be of use as a generator of ideas for the identification of new chemotypes or for increasing the potency of a known inhibitor. Despite known deficiencies of the existing methods, they prove to be useful and belong today to the methodical standard repertoire for drug design.

Modeling Protein–Protein and Protein–DNA Docking

Andreas Hildebrandt, Oliver Kohlbacher and Hans-Peter Lenhof

1 Introduction

Since Paul Ehrlich formulated his famous principle *corpora non agunt nisi fixata* [meaning that a substance is not (biologically) active unless it is bound] at the beginning of the 20th century [32], physical interaction has been known as the key step in most biochemical processes. Direct physical interaction (*binding*) between an enzyme and a ligand is required as an initial step in metabolic reactions. Similarly, protein–protein interactions are crucial in signal transduction and protein–DNA interactions are the key events in gene regulation.

With the availability of a sufficient number of protein structures from X-ray crystallography in the 1980s it became feasible to predict the structure of protein–protein complexes from the structures of the unbound proteins. This prediction problem, known as the protein–protein docking problem (PPD), has since been tackled using a wide range of computational techniques. More recently, the intense research in protein–protein interaction networks has sparked renewed interest in docking techniques to predict or validate these networks from a structural perspective and to aid in the understanding of the fundamentals of these interactions. In addition, the understanding of protein–protein interactions and protein–DNA interactions is essential for the study of gene regulatory networks (GRNs). While most of the research in protein–protein docking is thus still basic research, biomedical applications are rapidly gaining interest. In contrast to protein–ligand docking, these applications are less direct. In particular with complex multicausal diseases the understanding of the interactions of potential targets with other proteins is pivotal during the target identification phase of modern drug design. Computational validation of regulatory and interaction networks can provide useful insights during this phase. Another application exists at the interface between protein–protein and protein–ligand docking. Small molecules inhibiting protein–protein association are hard to identify using ligand-docking approaches, because they usually do not bind to well-defined, deep binding pockets. Instead, association inhibitors can form their own binding sites in the protein interface

[8]. Techniques from protein–protein docking might be more appropriate than techniques from protein–ligand docking to handle such cases.

Algorithms to model biomolecular interactions have to solve two problems: they have to predict both the *binding mode* (i.e. the relative orientation of the partners binding) and the *binding affinity* (i.e. their binding free energy ΔG) as precisely as possible. Obviously, these two goals go hand in hand: no accurate estimation of the binding free energy is possible if the binding mode is not correct and without a decent energy function the identification of the correct binding mode is impossible. Many algorithms address the first issue, the identification of the binding mode, based on the lock-and-key principle proposed by Emil Fischer in 1894 [39]. The lock-and-key principle implies a strong geometric complementarity of the binding partners. Rigid-body docking (RBD) algorithms exploit this principle to identify complementary regions of the two partners and thus deduce possible binding sites. Unfortunately, there are many examples where the molecules experience significant changes in their geometry upon binding – a mechanism known as *induced fit* [65]. This is one of the two most serious problems in protein docking today.

The second important issue in protein docking is the accurate estimation of the binding affinity. All docking algorithms employ a scoring function or energy function of some kind to identify good approximations of the "true" complex structure observed in nature *(true positives)* from incorrect complex structures (*false positives* or *decoys*). An ideal energy function would cleanly separate structures close to the true structure from these decoys. The problem of predicting the binding free energy turns out to be quite complex. It requires the modeling of numerous physical interactions, some of which are still not understood in their entirety. Particularly troublesome is the modeling of the effects of water on the biomolecular interactions. Water is responsible for the hydrophobic interaction and has a strong influence on the electrostatic interaction.

It is beyond the scope of this chapter to review every aspect of protein–protein and protein–DNA docking in detail. Instead, we want to focus on a spectrum of sophisticated docking techniques. Section 2 discusses protein–protein docking while Section 3 describes protein–DNA docking. For those readers who want to learn more, we want to point out several recent reviews. Two comprehensive reviews [103, 108] cover the majority of relevant techniques and a number of interesting new developments in protein–protein docking. Correlation-based protein–protein docking has been reviewed at length by Eisenstein and Katchalski-Katzir [33]. The review by Russell and coworkers [100] briefly discusses protein–protein docking in the context of protein–protein interactions.

2 Protein–Protein Interactions

2.1 Basic Concepts of Docking

Numerous methodologies have been developed to predict the three-dimensional (3-D) structure of a protein complex AB from the structures of its unbound components A and B. Most methods follow the general algorithmic scheme described below (see also Figure 1).

(i) *Preprocessing.* The 3-D structures of A and B are read from files. If the hydrogen atoms are not contained in the imported structure files, they are usually added to the structures. Depending on the method, atom radii and charges have to be assigned, and representations of the protein surfaces of A and B have to be calculated. The calculated molecular surfaces represent artificial boundaries between the interior and the exterior of the proteins.

(ii) *Generation of putative complex structures.* The majority of docking approaches are based on the assumption that the two proteins A and B undergo only limited conformational change during the docking process. RBD techniques treat the proteins A and B as completely rigid 3-D objects. Usually, an RBD approach scans the conformation space and generates a very large number of putative complex conformations (*candidates*) that are stored in a list. If the complex generation procedure is successful, the candidate list contains a sufficient number of true positives. Candidate structures are often generated by matching procedures that map regions of the surface of B onto geometrically and chemically 'compatible' regions of the surface of A.

(iii) *Filtering steps.* The generated putative complex conformations are evaluated with respect to shape and chemical complementarity using scoring functions. Candidate conformations with low scores are removed from the candidate list. The filtering procedure can be repeated with different scoring functions, starting with functions that can be computed efficiently. Apart from geometric and energetic scoring functions, distance constraints and other experimental data of the complex structure can be used to filter out decoys.

(iv) *Realizing protein flexibility.* RBD approaches usually succeed in the correct prediction of the protein complexes if the bound structures of A and B are sufficiently close to their unbound, native structures. However, small conformational changes involving only a few side-chains can cause RBD approaches to fail. In order to realize protein flexibility, docking algorithms thus optimize the conformations of the remaining candidates.

Generation of Putative Complex Structures
Filtering Steps
Realizing Protein Flexibility
Clustering and Reranking
<
<

Figure 1 Schematic overview of the major steps in protein–protein docking algorithms.

Some algorithms account for the flexibility of the amino acid side-chains at the binding site or of backbone hinges only, while other approaches optimize the coordinates of all atoms in the complex.

(v) *Clustering and re-ranking.* Candidate lists produced by docking algorithms often include families of similar structures. Consequently, many algorithms include a clustering step to reduce redundancy. In the last step, docking algorithms re-rank the remaining candidates or clusters of conformations using a more sophisticated energy or scoring function and return the best conformations.

The above scheme is only a broad outline of a typical docking algorithm. Individual algorithms can lack some of these components or differ in the underlying techniques. Key differences often are the structure generation, the scoring functions and the models of flexibility employed.

When comparing different algorithms, the two most obvious performance measures are "quality of the result" and "computational speed". However, the evaluation of the quality of docking results is almost as challenging as the docking problem itself. Typically, docking approaches are validated using X-ray or nuclear magnetic resonance structures of protein complexes. The algorithms usually output large lists of putative complex conformations sorted with respect to some scoring function. Successful algorithms will place true positives at the top of the list.

One widely used quality measure is the rank of the *first* true positive found in the candidate list (the lower the rank, the better the performance). Whether a structure is a true positive can be decided via structural similarity measures, e.g. the root-mean-square deviation (RMSD), or the fraction of native contacts formed in the protein–protein interface. A second important measure is the similarity of the *best true positive* contained in the list.

The performance of docking algorithms can be evaluated based on the bound structures of the proteins A and B or on their native structures. Both types of tests use protein complexes whose structures have been elucidated experimentally. In the first kind of tests, which we will call *bound tests* or *redocking*, the docking problem is simplified by ignoring all conformational changes that take place during the docking process. Here, the bound structures of A and B are taken from the protein complex AB, a random rigid transformation t is applied to one of the two proteins, e.g. to B, and the docking algorithm to be tested is then run on the structures A and $t(B)$. Bound tests are the simplest of all tests. Algorithms performing poorly in these tests will clearly fail in real-life examples as well. The RBD techniques presented in Section 2.2 that treat the proteins A and B as entirely rigid 3-D objects usually show excellent performance in bound tests.

In the second, more realistic kind of tests, which we will call *native test*, the algorithms are applied to native structures of A and B that may differ considerably from the bound structures. Since even small conformational changes can lead to the failure of RBD approaches, numerous techniques for realizing protein flexibility have been developed. A selection of sophisticated approaches for modeling protein flexibility will be presented in Section 2.3.

A series of "blind" prediction experiments with the goal to identify the strengths and weaknesses of existing docking approaches was initiated in 2001/2002. In these blind tests, docking algorithms have been applied to protein complexes whose structures have been elucidated, but not yet published. The results of the so-called CAPRI (Critical Assessment of PRediction of Interactions) competitions will be discussed in Section 2.6. These experiments have revealed that one of the key problems of the docking algorithms is the choice of an appropriate scoring function. A spectrum of widely used scoring functions will be discussed in Section 2.4. The integration of experimental data into docking algorithms is a way to improve the quality and reliability of docking results. In Section 2.5, we will present data-driven approaches to protein docking.

2.2 Rigid Body Docking

RBD approaches are based on Emil Fischer's lock-and-key principle, which implies local shape complementarity of the proteins at the binding site. In the case of RBD, it is assumed that the two proteins *A* and *B* show only a limited conformational change during the docking process. They can thus be treated as rigid 3-D objects.

Typically, RBD algorithms try to identify conformations with large contact areas between the surfaces of *A* and *B* that exhibit no or only small overlaps between the interiors. In order to test this condition for given candidates, we have to define and calculate artificial protein surfaces that allow for differentiation between the interior, the surface and the exterior of the proteins.

Almost any kind of established surface definition has been used for this purpose. In particular, van der Waals, solvent-excluded and solvent-accessible surfaces have been employed in different representations. Typically, RBD approaches try to identify putative complex conformations by keeping one protein fixed in space while moving the second around. The resulting candidates can then be uniquely represented by six parameters describing the relative translation and rotation of the mobile protein from the reference position. In the following, we will generally denote the static protein by *A* and the mobile protein by *B*.

2.2.1 Correlation Techniques

An important type of RBD docking techniques, so-called *correlation docking*, was introduced by Katchalski-Katzir and coworkers [58]. In their classical formulation, correlation-based docking algorithms use a purely geometric score to generate conformations featuring a large number of surface contacts and no significant overlap.

In order to identify candidates with this property, the molecular geometries are represented by piecewise constant functions on a 3-D grid (Figure 2). Let $\vec{r}_{ijk} \in \mathbb{R}^3$, $i, j, k \in \{1, \ldots, N\}$ denote a set of evenly spaced points in a box containing the molecules A and B, where $\vec{r}_{111}$ corresponds to the "lower left front" corner of the box and $\vec{r}_{NNN}$ to the "upper right back" corner.

The structures of A and B can be represented by two grids $\mathcal{A}$ and $\mathcal{B}$ with values a_{ijk} and b_{ijk} that depend on whether the point $\vec{r}_{ijk}$ is on the inside, the surface (to achieve a certain softness of the molecules, the surface is represented by a surface layer of finite thickness) or the outside of the respective molecule:

$$a_{ijk} = \begin{cases} 1 & \text{on the surface of molecule A} \\ \rho & \text{inside molecule A} \\ 0 & \text{outside molecule A} \end{cases} \tag{1}$$

$$b_{ijk} = \begin{cases} 1 & \text{on the surface of molecule B} \\ \delta & \text{inside molecule B} \\ 0 & \text{outside molecule B.} \end{cases} \tag{2}$$

At each point $\vec{r}_{ijk}$, the local fit of A and B in their current relative orientation can then be assessed by computing the score:

$$c_{ijk} := a_{ijk} b_{ijk}$$

and the geometric fitness value (Score) for a conformation represented by the grids $\mathcal{A}$ and $\mathcal{B}$ is computed as:

$$\text{Score} := \sum_{i,j,k=1}^{N} c_{ijk}$$

Depending on the shape, location and relative orientation of A and B, c_{ijk} can assume the values given in Table 1. Thus, each point on the surfaces of both molecules contributes with a value of 1 to the total score. To penalize overlap between A and B, ρ is set to a large negative value and δ to a small positive one, such that $\delta\rho$ results in a negative contribution to the geometric fitness for each point of overlap. Tuning the values of δ and ρ allows to adjust

Table 1

	Surface point of A	Interior point of A	Outside A
Surface point of B	1	$\rho \ll 0$	0
Interior point of B	$\delta > 0$	$\rho\,\delta \ll 0$	0
Outside B	0	0	0

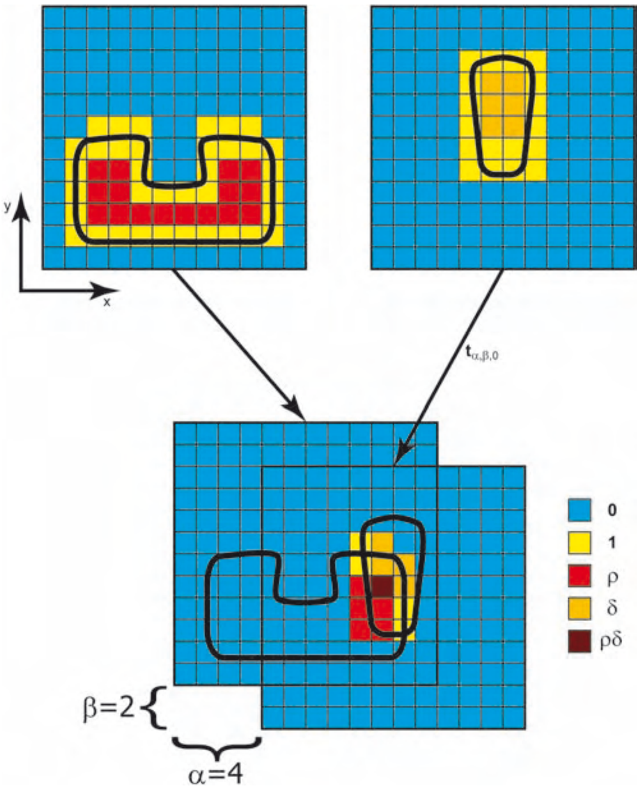

Figure 2 Schematic illustration of the grids used for correlation-based docking. First, each protein is mapped onto a grid describing its inside, outside, and surface. Afterwards, the two grids are correlated to determine the geometric fit between the two proteins in their current relative orientation.

for the degree of penetration that will be tolerated. This choice also strongly discourages the contact of the surface points of *B* and interior points of *A* with a contribution of $\rho \ll 0$, while penetration of *A*'s surface into the interior of *B* is allowed. This can be considered as an additional "softening" of the molecular surfaces.

To determine the complex structure leading to the largest geometric score, the larger of the two molecules, *A*, is kept fixed in its position while the smaller one, *B*, is rotated and translated to sample the configuration space. Correlation-based approaches only consider a discrete subset of the possible rotations of molecule *B*. For each of these possible rotations of *B*, the algorithms try to identify the optimal translations. Since the molecules themselves are represented by discrete grids, it is natural to restrict the translational degree of freedom to integral multiples of the grid spacing, i.e. given a certain rotation of molecule *B*, instead of scanning the whole translational space for the optimal conformation, we only test N^3 translations of molecule B, which are of the form $t_{\alpha\beta\gamma} := (\alpha\Delta_x, \beta\Delta_y, \gamma\Delta_z)$, where $\Delta_x, \Delta_y, \Delta_z$ denote the grid spacing of a_{ijk} and b_{ijk} in the x, y, and z directions. To simplify the notation, we will assume that $\Delta := \Delta_x = \Delta_y = \Delta_z$.

Translating the molecule B by a transformation $t_{\alpha\beta\gamma}$, with $\alpha, \beta, \gamma \in \mathbb{Z}$, corresponds to shifting the grid indices of $\mathcal{B}$. This implies that it is *not* necessary to introduce a different grid for each translation of molecule B. Instead, it suffices to read off the values from the non-translated grid $\mathcal{B}$ at the shifted position as follows:

$$t_{\alpha\beta\gamma}(b_{ijk}) = b_{i+\alpha,j+\beta,k+\gamma}$$

Thus, for each rotated conformation of molecule B, we can compute a grid of geometric scores for each of its translations $t_{\alpha\beta\gamma}$ from:

$$c_{\alpha\beta\gamma} = \sum_{i,j,k=1}^{N} a_{ijk} b_{i+\alpha,j+\beta,k+\gamma}$$

The values $c_{\alpha\beta\gamma}$ for all translations of B build a grid of scores which we denote by $\mathcal{C}$.

Let $\mathcal{R}$ be the set of all possible rotations of molecule B. The general scheme of correlation-based docking algorithms then looks as follows [33]:

- Compute the grid $\mathcal{A}$ for molecule A
- For each rotation $r \in \mathcal{R}$:
  - apply r to molecule B
  - compute the grid $\mathcal{B}$ corresponding to the current rotation state of B
  - compute the grid $\mathcal{C}$
  - store the m largest values of $\mathcal{C}$, corresponding to the m translations of the current rotation state of B with the largest geometric scores
- Sort the resulting $m|\mathcal{R}|$ conformations with respect to their scores and return them.

A direct naive implementation of this algorithm would result in $\mathcal{O}(N^3)$ time for each value $c_{\alpha\beta\gamma}$, leading to a total of $\mathcal{O}(N^6)$ time for the computation of $\mathcal{C}$ and a total of $\mathcal{O}(|\mathcal{R}|N^6)$ for the complete algorithm.

Fortunately, the runtime can be drastically decreased by noting that the grid $c_{\alpha\beta\gamma}$ is the discrete correlation of the grids $\mathcal{A}$ and $\mathcal{B}$. It can thus be computed efficiently using the fast Fourier transform (FFT) due to the *correlation theorem*:

$$\mathcal{FT}\left(\sum_{i,j,k=1}^{N} a_{ijk} b_{i+\alpha,j+\beta,k+\gamma}\right) = \mathcal{FT}^*(a_{ijk})\mathcal{FT}(b_{ijk})$$

Here, $\mathcal{FT}$ denotes the Fourier transform and $\mathcal{FT}^*$ its complex conjugate. This yields

$$c_{\alpha\beta\gamma} = \mathcal{FT}^{-1}(\mathcal{FT}^*(a_{ijk})\mathcal{FT}(b_{ijk}))$$

where $\mathcal{FT}^{-1}$ denotes the inverse Fourier transform.

Since the Fourier transform of a discrete grid of size N^3 can be computed in $\mathcal{O}(N^3 \log(N))$ time using the FFT, we can thus compute $\mathcal{C}$ in $\mathcal{O}(N^3 \log(N))$ time, leading to the total runtime of $\mathcal{O}(|\mathcal{R}|N^3 \log(N))$.

Even though this algorithm generates candidate structures based on *geometric* matching alone and thus neglects energetic aspects like electrostatic compatibility, it works quite well in *bound* docking experiments. A variety of improvements to this scheme has been proposed in the literature. In principle, two different techniques can be used to improve the scoring of the candidate structures. The first option is the re-evaluation of the candidate structures using more sophisticated scoring functions. In this case it is important to ensure that the initial geometry-based docking algorithm produces a sufficient number of near-native structures. A typical example of this approach is the docking programm BiGGER by Palma and coworkers [95], where electrostatic energy and desolvation are used as post-scan filters.

The second option is the modification of the filtering process to include energetic contributions in addition to geometric complementarity. A straightforward approach to this problem introduces additional grids. Gabb and coworkers [40] employ one grid for the electrostatic potential of protein A and one grid for the partial charges of B to obtain an estimate of the electrostatic energy of the complex, and use the result to filter out conformations with unfavorable interaction energies. Mandell and coworkers [81] propose a similar technique, but compute the potential of A using continuum electrostatics. The resulting interaction energy estimates are then added to the geometric fit of the candidate. An elegant alternative to introducing additional grids was pointed out by Heifetz and coworkers [48], who use grids of *complex* numbers and store the non-geometric information in the imaginary part. Rather than correlating electrostatic potentials and charges to obtain an estimate of the electrostatic interaction energies, they make use of the observed anticorrelation of the electrostatic potentials of docking partners at the binding site [82]. Similarly, hydrophobic interactions can be accounted for, e.g. in the imaginary part of $\mathcal{C}$. For a recent review on correlation-based docking techniques, see Ref. [33].

2.2.2 Graph-based Structure Generation Methods

In contrast to grid-based correlation techniques, graph-based approaches allow for accurate but compact representations of the protein structures or

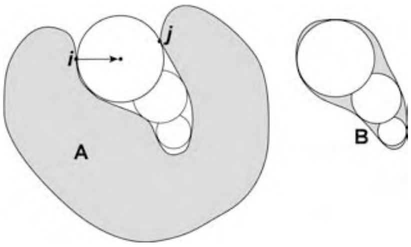

Figure 3 DOCK represents the binding pockets of protein A and the interior of protein B by sets of spheres and searches for good superpositions of these sets.

their surfaces. Kuntz and coworkers [66,105,106] developed DOCK (see also Chapter 16), a method that describes the geometry of the putative binding sites of A and the shape of B by sets of spheres. The union of spheres that belong to a pocket of A represents the empty volume of this putative binding site and builds a negative image of A at that site. The DOCK approach tries to identify the best superposition of B and the negative images of A by searching for cliques in a graph representing all possible matchings of spheres.

DOCK starts by computing discrete sets of points on the molecular surfaces of A and B. In the second step, the algorithm computes sets of spheres for A and B with the following properties (Figure 3):

(i) Each sphere touches the molecular surface at two points (i, j) and has its center on the surface normal of point i.

(ii) Each sphere of protein A lies on the outside of the surface of A.

(iii) Each sphere of protein B lies on the inside of the surface of B.

This procedure usually generates a large number of spheres, which can be reduced by applying additional constraints. The remaining spheres are clustered into “small” sets. Ideally, the sphere sets of A should represent the different pockets and tentative binding sites on the surface of A, while the clusters of B should form the set of possible docking interfaces of B.

The actual structure generation can be formulated as a *clique* (a completely connected subgraph) search problem in a graph that represents the putative pairwise matchings of spheres of A and B as nodes. For each pair (i, j), where i is a sphere of A and j is a sphere of B, a node v_{ij} is added to the graph. Two nodes v_{ij} and v_{kl} are connected by an edge if and only if the Euclidean distance $d(i, k)$ of the sphere centers i and k belonging to A is almost equal to the Euclidean distance $d(j, l)$ of the sphere centers j and l of B, i.e.:

$$\|d(i,k) - d(j,l)\| \leq \varepsilon \tag{3}$$

where ε is a user-defined parameter. Hence, edges connect pairs of spheres whose centers have almost the same distances and hence can be mapped onto each other by a suitable rigid transformation. Each clique of size four in the graph defines a possible transformation. Therefore, the algorithm calculates the tentative complex conformations by carrying out a straightforward incremental search for cliques of size four, by computing the respective transformations, and by applying the transformations to all atoms of protein B.

Kasinos and coworkers [57] presented another graph-based approach that applies graph-matching techniques to identify tentative complex conformations. They calculate points on the surfaces of A and B and two graphs that represent the surfaces. The points on the surfaces build the vertex sets of the respective graphs. Pairs of points are connected by edges that are labeled with the Euclidean distances between the points. The algorithm calculates maximal matchings of the two graphs and the transformations that map the respective point sets onto each other.

2.2.3 **Slice Decomposition and Polygon Descriptors**

A few docking algorithms use slice decompositions of the protein surfaces to identify complementary surface regions. The first such algorithm was published by Walls and Sternberg [112] in 1992. In this section, we will summarize an approach by Helmer-Citterich and coworkers [9, 49], which decomposes the proteins into parallel slices whose boundaries are represented by polygons. The approach determines conformations that exhibit a good match between the polygonal chains of the slices of A and B.

The structure generation procedure, called SHAPES, freezes the conformation of protein A and cuts its solvent accessible surface into parallel slices 1.5 Å thick, orthogonal to the z-axis. Each slice is represented by a 2-D polygon (defined by the intersection of the molecular surface with a plane parallel to the x–y plane) that approximates the protein surface. This is illustrated in Figure 4.

The algorithm considers a discrete set of orientations of protein B that are generated by rotations (R_x, R_y) of B around the x- and y-axes. Each such orientation $(r_x, r_y) \in (R_x, R_y)$ of B is tested in the following way:

(i) For each orientation of protein B, SHAPES calculates the slice decomposition of the solvent accessible surface of protein B, orthogonal to the z-axis, and the respective polygon representations of the slices.

(ii) The algorithm scans a set of possible translations of B along the z-axis. Only translations T_z that map the z-plane of at least one slice polygon of B onto the plane of a slice polygon of A are evaluated using polygon-matching techniques. The algorithm starts with the translation that maps

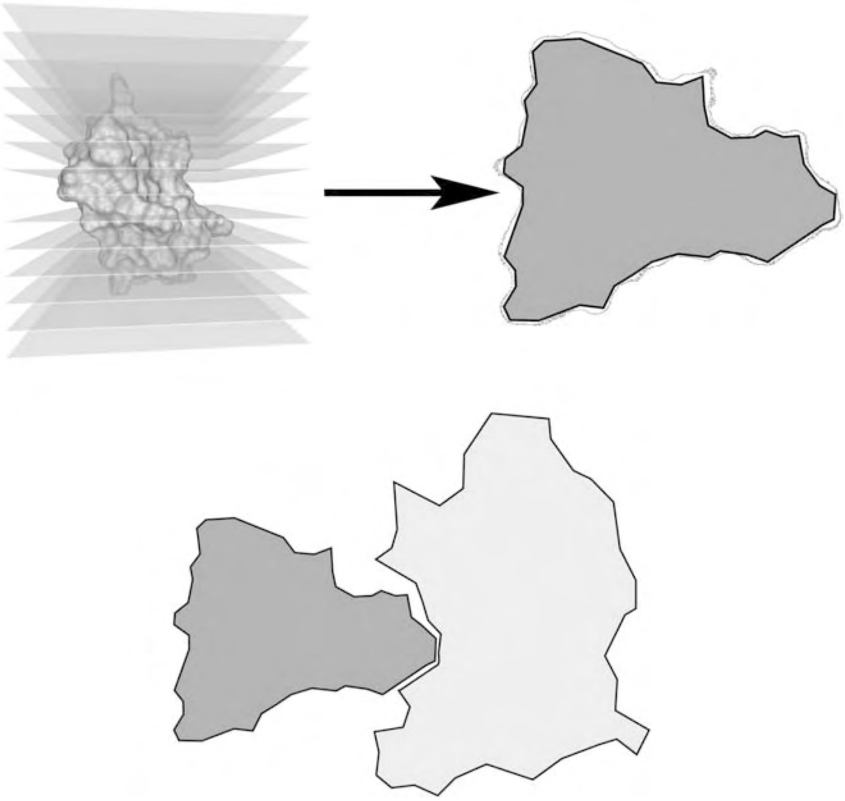

Figure 4 Slice decomposition approaches consider parallel equidistant planes cutting the protein surface. The contour of a surface cut is approximated by a polygon. The algorithm then searches for pairs of compatible polygons of A and B.

the z-plane of the top polygon of B onto the z-plane of the bottom polygon of A. Repeated shifts of 1.5 Å along the z-axis generate the other possible z-translations of B. For each such translation $t_z \in T_z$ of B, the pairs of slice polygons on all different matching z-planes are tested by the polygon-matching technique described below.

(iii) Given a polygon P_A of A and a polygon P_B of B on the same z-plane/slice, the algorithm superimposes each of the m polygon sides of P_B with each of the n polygon sides of P_A by calculating a translation t_x, t_y and a rotation r_z around the z-axis that maps the side of P_B onto the side of P_A. For each such transformation (t_x, t_y, r_z), a complementarity value is calculated.

(iv) The protein–protein interface is a sufficiently large region of complementarity spread across several z-planes. It can thus be found by searching for a set of compatible transformations, both within a single z-plane or across multiple z-planes. This search can be done efficiently by clustering the calculated transformations (t_x, t_y, r_z) of all planes using a 3-D grid with cell size of 3 Å for the translations along the x- and y-axes and 12° for the rotations around the z-axis. The "complementarity values" of all transformations that belong to one cell of the transformation grid are added up. Thus, the cells with the highest complementarity values represent the best partial transformations. The combination of each of these partial transformations (t_x, t_y, r_z) with the current transformation (r_x, r_y, t_z) of B defines a rigid transformation generating a candidate.

The conformation of protein A is fixed during the whole procedure described above. Since protein A is decomposed into slices orthogonal to the z-axis, the poles of A with respect to the z-axis are poorly described. To solve this problem, Helmer-Citterich and coworkers propose to repeat the above procedure with a slice decomposition of A along either the x- or y-axis, orthogonal to the first slice decomposition along the z-axis.

2.2.4 Critical Surface Points and Geometric Hashing

Many docking algorithms determine putative complex conformations by investigating the topological properties of the surfaces of the proteins and by identifying geometrically complementary surface regions. Some of these algorithms apply the following docking strategy: based on their curvature properties, the surfaces are decomposed into patches which are classified as either convex (*knob*), concave (*hole*) or flat (*saddle*). Each surface domain is represented by a central point located on the respective domain or face. These sets of so-called critical points or interest points are sparse representations of the molecular surface. The algorithms determine candidates by searching for matching complementary point sets.

In 1986, Connolly [22] presented the first docking approach matching knobs and holes on the so-called molecular surfaces (solvent excluded surface) [21, 23] of the proteins A and B. Connolly's algorithm generates tentative complex conformations by searching for a rigid transformation that maps four knobs/holes on the surface of A onto four complementary holes/knobs with similar distances on the surface of B.

Wang [113] modified the definition of critical points slightly and matched only one knob/hole on surface A with a complementary hole/knob on the surface of B. The matching of two critical points defines the required translation. Two vectors pointing towards the respective centroids of the local volumes of the hole and the knob are used to fix two rotational degrees of freedom. Furthermore, the approach considers a discrete set of rotations around the axis passing through the centroids to fix the last rotational degree of freedom.

Nussinov and coworkers [38,76] presented a docking algorithm that matches pairs of critical points along with their surface normals. They introduced an elegant and efficient technique for identifying matching pairs of critical points, the geometric hashing technique, developed originally for computer vision applications. The hashing technique is based on a transformation invariant representation of the surface descriptors. Lenhof [73] also applied geometric hashing techniques to generate tentative complex conformations by matching similar triangles of surface points. Geometric hashing is described in more detail in Chapter 16.

2.2.5 Other Approaches

Numerous sophisticated geometric-matching methods have been published in the last two decades. Since a detailed discussion of these methods would go beyond the scope of this work, we will briefly summarize the main ideas behind the matching techniques.

Ackermann and coworkers [2] use geometric and chemical features to decompose the surfaces into domains. An approach based on semantic nets is applied to study the sizes and shapes of the surface domains and to match complementary surface regions. Exner and Brickmann [14,36] compare topographical properties of surface domains using fuzzy logics strategies. Levine and coworkers [74] combine techniques from genetic algorithms, parallel and distributed computing, and virtual reality in the docking program STALK. Gardiner and coworkers [41] propose a genetic algorithm for identifying the areas of greatest surface complementarity. The *soft docking* approach developed by Jiang and Kim [56] integrates dot and cube representation of the molecular surfaces. Cherfils and coworkers [20] calculate putative conformations using a simulated annealing method. In 1992, Bacon and Moult [10] published an approach for protein–protein and protein–ligand docking that uses surface complementarity and electrostatic energy to assess candidate conformations. The algorithm generates candidate conformations by matching patterns of points on the surfaces using McLachlan's [83] least-squares best-fit algorithm.

2.3 Realizing Protein Flexibility

RBD approaches usually succeed in predicting the complex conformations if the bound structures of A and B are sufficiently close to the native, unbound structures. However, even small changes in the conformation of a few side-chains may cause RBD approaches to fail. Although the algorithms will usually still generate approximations of the complex structure, these will be assigned poor scores as they contain physically impossible overlaps between the two proteins. The challenge is now to identify the true positives among the candidates.

The general strategy for realizing protein flexibility is to reconstruct a physically meaningful complex structure. All conformations in the candidate list have to be perturbed and optimized to remove overlaps and to re-establish native contacts in the docking interface. This process requires both an efficient optimization method and a reliable scoring function. As a result of this structural optimization and a subsequent re-scoring, the rank of the true positives will improve.

Studies of the differences between bound and unbound structures indicate that in many cases the protein backbones change only slightly [13, 94]. However, significant conformational changes of side-chains at the docking interface may accompany complex formation. Many docking algorithms thus consider the protein backbones as rigid and simply optimize (demangle) the side-chains of the protein–protein interface.

In contrast to side-chain rearrangements, hinge-bending is the result of conformational changes in the protein backbone. This frequently occurs for multidomain proteins. In these cases, domains of the protein are connected by flexible loop regions. These regions serve as hinges around which the domains may swivel. In some cases, this results in quite complex movements. In the case shown in Figure 6 the two domains of calmodulin can perform a gripper-like movement and close around a possible ligand.

Even more challenging cases of protein flexibility have been described in the literature. In 2000, Shoemaker and coworkers [104] presented a possible answer to the question of why so many proteins in the cell seem to be unfolded most of the time. They proposed a new binding mechanism, the so-called "fly-casting", where binding and folding occur simultaneously. Furthermore, Shoemaker and coworkers argue that a relatively unstructured protein molecule can have a greater capture radius for a specific binding site than the folded state with its restricted conformational freedom. This binding mechanism defines a new grand challenge with respect to the development of structure prediction methods because binding and folding occur more or less simultaneously. While force field-based molecular dynamics methods should in principle be able to handle these cases of full flexibility, these techniques are prohibitively expensive in terms of CPU time.

In the following, we will first discuss approaches for side-chain placement (SCP), then an algorithm for handling hinge-bending by Sandak and coworkers [102], and finally a technique that allows for realizing backbone and side-chain flexibility simultaneously developed by Abagyan and Totrov [1, 109].

2.3.1 Side Chain Placement

The main goal of SCP algorithms is to find the global minimum-energy conformation of the side-chains at the protein–protein interface with respect to a given energy function E. For each given conformation in the candidate list, the placement algorithms determine the side-chains near the contact site and optimize the side-chain conformations. Finally, the optimized conformations are re-ranked with respect to their energy values.

Since side-chain optimization techniques can also be applied to modeling and predicting protein structures, a wide range of methods is available today. Simulated annealing [51, 53, 72], Monte Carlo methods [24, 25, 52, 75, 118], mean-field optimization [62, 71, 84, 85], artificial neural networks [53, 62] and local homology modeling [68] have been applied to this problem.

A large number of techniques for SCP are based on a discretization of conformational space. Ponder and Richards [97] observed that the side-chain conformations occurring in proteins can be adequately described by a rather small, discrete set of rotamers for each residue (for a detailed discussion of rotamers, see also Chapter 10). This discretization results in a combinatorial optimization problem: identify the set of rotamers with the minimal energy, the so-called *global minimum-energy conformation* (GMEC). We will now discuss some of the techniques that have been proposed for identifying the GMEC.

Given a putative complex conformation, SCP methods start by identifying all residues in the protein interface. A residue is considered to be part of the interface, if any of its atoms is within a cutoff distance, e.g. 6.0 Å, from any of the atoms of the other protein.

Let R denote the set of residues that belong to the interface. Note that we do not distinguish between residues of A and B because it is not required for the presentation of the algorithmic techniques. For each residue i, we determine its set R_i of possible rotameric states i_r from a given rotamer library, e.g. the rotamer library of Dunbrack and coworkers [31] (see also Chapter 10). The remaining residues and the backbone of the proteins A and B, which will be kept rigid, are called the template t.

Each possible conformation of the side-chains in R can be described by a binary incidence vector:

$$X = (x_1^1, x_2^1, \cdots, x_r^i, \cdots), \tag{4}$$

where x_r^i equals 1 if residue i is in state r and 0 otherwise. Since "allowed" conformations assign exactly one rotameric state to each residue, the following equations must hold for all possible binary solution vectors X:

$$\sum_r x_r^i = 1 \quad \text{for all residues } i. \tag{5}$$

The GMEC is the combination X of rotamers that fulfills constraint (5) and yields the lowest total energy with respect to a potential energy function

E (note that we restrict ourselves to the typical case of energy functions containing at most pairwise interaction terms):

$$E(X) = E_\mathrm{t} + \sum_{i,r} x_r^i E(i_r) + \sum_{i,r} \sum_{j<i,s} x_r^i x_s^j E(i_r, j_s), \tag{6}$$

where E_t is the potential energy of the template, $E(i_r)$ is the potential energy of side-chain i in state r interacting with the atoms of the template and $E(i_r, j_s)$ is the pairwise potential energy of side-chain i in state r with side-chain j in state s. The GMEC problem is not only NP-complete [96], but also inapproximable [18].

Note that the potential energy of the template E_t is a constant that does not depend on the side-chain rotamers chosen. In a first preprocessing step, the algorithms calculate and store the template energy E_t and the rotamer energies $E(i_r)$. Similarly, all pairwise interaction energies $E(i_r, j_s)$ are calculated.

Typical protein interfaces consist of 40–60 side-chains, yielding up to 10^{60} rotamer combinations. Hence, exhaustive search [16,114,115] is only tractable for very small examples with few side-chains. In the following we will discuss several important techniques for solving the GMEC problem: the *dead-end elimination* (DEE) technique introduced by Desmet and coworkers [27], an A^* algorithm developed by Leach and Lemon [69, 70], and integer linear programming (ILP) techniques.

2.3.1.1 **Dead End Elimination** The DEE method developed by Desmet and coworkers [27] reduces the size of the search space by eliminating side-chain rotamers that are incompatible with the GMEC. A rotamer i_r can be safely ignored in the search for the GMEC, if a second rotamer i_u of side-chain i exists such that the following inequality is fulfilled:

$$E(i_r) + \sum_{j \neq i} \min_s E(i_r, j_s) > E(i_u) + \sum_{j \neq i} \max_s E(i_u, j_s). \tag{7}$$

This so-called DEE theorem states that the rotamer i_r cannot be part of the GMEC if its "best" (i.e. lowest) energy is still larger than the "worst" (i.e. highest) energy of i_u. Desmet and coworkers proved an analogous theorem for rotamer pairs and successively applied the two theorems in an iterative fashion as long as the number of rotamers could be reduced. Applying DEE will usually not result in a single solution for the GMEC, but it drastically reduces the search space. The remaining search space can then be more effectively searched using one of the techniques described below.
A more effective variant of the DEE theorem has been formulated by Goldstein [44]: a rotamer i_r cannot be part of the GMEC, if a second rotamer i_u of side-chain i exists such that the following inequality holds:

$$E(i_r) - E(i_u) + \sum_{j \neq i} \min_s \{E(i_r, j_s) - E(i_u, j_s)\} > 0. \tag{8}$$

In the last decade, a series of papers on variants of the DEE theorem has been published [28, 29, 44–46, 67, 78]. Desmet and coworkers [29] discuss further variants of the DEE theorem and summarize algorithms for implementing these inequalities efficiently.

2.3.1.2 **"Branch & Bound" and the A^* Algorithm** In principle, all possible solutions to the GMEC can be represented by an enumeration tree. Each path from the root to a leaf of the tree describes a feasible rotamer combination. The i-th layer of the tree represents the rotamers of the i-th side-chain and each node is labeled with a rotameric state i_r of i. Hence, the number of layers equals the number of side-chains (Figure 5). A path $P(v)$ from the root to a node v in layer m visits exactly one node in each layer. If the node in layer i is labeled i_r, then $P(v)$ assigns rotameric state i_r to residue i. Hence, $P(v)$ fixes the rotameric states of the first m side-chains. The subtree $T(v)$ of node v represents all possible rotamer combinations of the remaining side-chains.
During the construction of the tree, the potential energies of the different paths are calculated and stored in the tree nodes where the paths end. Hence, the root of the tree stores the template energy E_t while the other nodes v store the total potential energy of all rotamers that lie on the path $P(v)$ from v to the root:

$$E(v) = E_\mathrm{t} + \sum_{i_r \in P(v)} E(i_r) + \sum_{i_r \in P(v)} \sum_{\substack{j_s \in P(v) \\ j<i}} E(i_r, j_s) \tag{9}$$

The GMEC can then be determined by constructing the whole tree and by searching for the leaf with the lowest energy. The path from this leaf to the root describes the rotamer combination with minimal potential energy. Since the number of rotamer combinations grows exponentially with the number of side-chains, building the whole enumeration tree is not feasible for typical

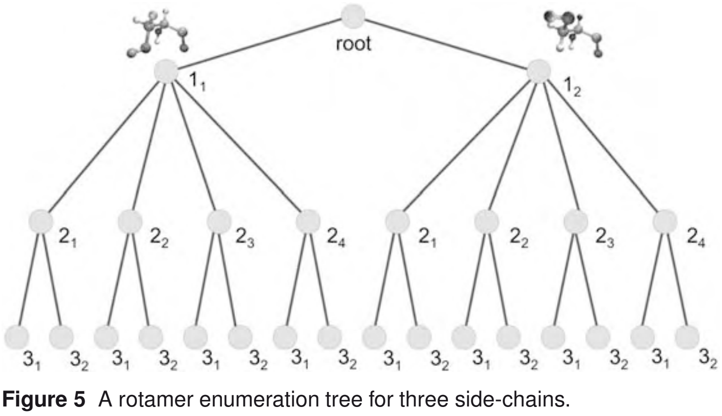

Figure 5 A rotamer enumeration tree for three side-chains.

problem sizes. "Branch & bound" approaches are widely used methods for solving high-dimensional optimization problems. These algorithms try to avoid the exploration of subtrees that cannot contain a minimal conformation.

Let U be an upper bound for the energy value of the GMEC and $E_{\mathrm{L}}(v)$ a lower bound for the energetic contribution of the best path from a node v to any of the leaves in the subtree $T(v)$ of v, then the subtree $T(v)$ can be safely ignored if the following inequality holds:

$$E(v) + E_{\mathrm{L}}(v) > U \tag{10}$$

The upper bound U can be obtained using a greedy or multi-greedy heuristic (see, e.g. Refs. [89, 98]) that usually generate good approximations of the optimal solution. A reasonable lower bound $E_{\mathrm{L}}(v)$ for the potential energy of the optimal path in $T(v)$ can be calculated as follows. We have to add up lower bounds $L(j)$ for the energetic contribution of the side-chains j that have not yet been assigned a rotameric state, i.e. the side-chains not represented by the nodes in $P(v)$:

$$E_{\mathrm{L}}(v) = \sum_{j \notin P(v)} L(j) \tag{11}$$

Suitable lower bounds $L(j)$ can be determined as follows:

$$L(j) = \min_{s} \left\{ E(j_s) + \sum_{i_r \in P(v)} E(j_s, i_r) + \sum_{k \notin (P(v) \cup j)} \min_{l} E(j_s, k_l) \right\} \tag{12}$$

The first sum in the above definition describes the pairwise interaction energies of rotamer j_s with the side-chains on the path $P(v)$ that have already been assigned a rotameric state, whereas the last sum in Eq. (12) is a lower bound for the pairwise interaction energies of j_s with the other side-chains that have not yet been assigned a rotameric state.

"Branch & bound" approaches usually build the tree layer by layer in a breadth-first search manner. Before adding the children of node v and starting the construction of the subtree of node v, the algorithm calculates $E_{\mathrm{L}}(v)$ and applies inequality (10) to test if the subtree $T(v)$ can be safely ignored.

An alternative to "Branch & bound" is the A^* algorithm introduced by Hart and coworkers [47]. It has been applied to SCP for protein–ligand docking by Leach and Lemon [69, 70]. The A^* algorithm is a heuristic procedure for searching an optimal path in a graph or tree that allows to explore deeper layers of the tree before completing upper layers, if promising paths have been detected. The algorithm first visits the children v of the root, and calculates the potential energies $E(v)$ and the lower bounds $E_{\mathrm{L}}(v)$ for the best possible path in the corresponding subtrees $T(v)$. For each child v of the root, the sum of

$E(v)$ and $E_{\mathrm{L}}(v)$ serves as an estimator:

$$BP(v) := E(v) + E_{\mathrm{L}}(v) \tag{13}$$

for the best possible energy. These estimators are stored in a priority queue together with their nodes such that the first element v is the most promising node with the smallest estimator $BP(v)$.

In the next step, the A^* algorithm further explores the tree by adding new nodes representing the children w of the node v with the best estimator $BP(v)$. Then, the estimator $BP(v)$ is removed and the estimators $BP(w)$ of the new nodes are computed and added to the priority queue. The algorithm stops if an optimal solution has been found. An optimal solution is one that assigns a rotameric state to each of the side-chains and has an energy that is lower than the best estimator stored.

2.3.1.3 **Integer Linear Programming** ILP techniques have been very successfully applied to many high-dimensional optimization problems. We will now derive an ILP formulation for the GMEC problem.

If we combine Eqs. (5) and (6) for the GMEC problem, we arrive at:

$$\begin{aligned}
\min_X E(X) \quad &= \quad \min_X \left\{ E_{\mathrm{t}} + \sum_{i,r} x_r^i E(i_r) + \sum_{i,r} \sum_{j<i,s} x_r^i x_s^j E(i_r, j_s) \right\} && (14)\\
\text{s.t.} \quad & \quad \sum_r x_r^i = 1 \quad \text{for all } i \in R && (15)\\
& \quad x_r^i \in \{0,1\} \quad \text{for all } i \in R \text{ and } r \in R_i && (16)
\end{aligned}$$

This is an integer quadratic programming problem, since the solutions are integer and since the energy function contains products of the form $x_r^i x_s^j$. It can be transformed into an ILP problem using the following procedure:

(i) We determine the largest pairwise interaction energy $E_{\max}$ of any pair of rotamers.

(ii) We substitute the pairwise interaction energy $E(i_r, j_s)$ of each rotamer pair by $E(i_r, j_s) - (E_{\max} + \varepsilon)$ where ε is a small positive constant.

(iii) For each pair of variables $x_r^i x_s^j$, we introduce a new binary variable y_{rs}^{ij} that takes the value 1 if and only if x_r^i and x_s^j are 1.

The first two steps are necessary to ensure that all pairwise interaction energies are negative. The above transformation shifts the solutions of the GMEC problem only by a constant. Hence, the minima of the transformed problem are identical to the minima of the untransformed problem:

$$\begin{aligned}
\min_X E(X) &= \min_X \left\{ E_\mathrm{t} + \sum_{i,r} x_r^i E(i_r) + \sum_{i,r} \sum_{j<i,s} y_{rs}^{ij} E(i_r, j_s) \right\} && (17)\\
\text{s.t.} \quad & \sum_r x_r^i = 1 \qquad \text{for all } i \in R && (18)\\
& y_{rs}^{ij} \le x_r^i \qquad \text{for all } i, j \ne i \in R, r \in R_i, s \in R_j && (19)\\
& y_{rs}^{ij} \le x_s^j \qquad \text{for all } i, j \ne i \in R, r \in R_i, s \in R_j && (20)\\
& x_r^i \in \{0,1\} \qquad \text{for all } i \in R, r \in R_i && (21)\\
& y_{rs}^{ij} \in \{0,1\} \qquad \text{for all } i, j \ne i \in R, r \in R_i, s \in R_j && (22)
\end{aligned}$$

The linear constraints (19) and (20) guarantee that the variable y_{rs}^{ij} can take the value 1 only if x_r^i and x_s^j are 1. If, in addition, $x_r^i = x_s^j = 1$, then the fact that $E(i_r, j_s)$ is negative forces the variable y_{rs}^{ij} to take the value 1 because we are dealing with a minimization problem. In other words, if $y_{rs}^{ij} = 0$ held for a minimal conformation, setting $y_{rs}^{ij} = 1$ would not violate any of the above constraints. However, it would generate a new solution whose energy is smaller than the energy of the supposed minimal conformation by a factor of $E(i_r, j_s)$, thus contradicting the above assumption.

Althaus and coworkers [5, 6] presented the first ILP formulation of the GMEC problem and a "Branch & cut" algorithm. "Branch & cut" is the most common technique for solving ILP problems. For details on "Branch & cut" and integer linear programming, we refer to the book by Wolsey [117]. The scheme of standard "Branch & cut" approaches can be summarized as follows. We relax the ILP by dropping the integer condition – we allow the variables x_r^i to take any real value in the interval $[0,1]$ – and solve the resulting linear program (LP). If the solution $\bar{X}$ is integral we have found the GMEC. Otherwise, we search for a valid linear inequality $f(X) \le f_0$ that cuts off the solution $\bar{X}$, i.e. $f(X) \le f_0$ for all feasible solutions X of the ILP problem and $f(\bar{X}) > f_0$. The set $\{X | f(X) = f_0\}$ is called a cutting plane. Any cutting plane found is added to the LP and the resulting LP is solved again. The generation of cutting planes is repeated until either an optimal solution is found or the search for a cutting plane fails. In the second case a branch step follows, i.e. we generate two subproblems by setting one fractional variable x_r^i of the last solution to 0 in the first subproblem and to 1 in the second subproblem. We then start the "Branch & cut" algorithm for the two subproblems recursively. This recursion gives rise to an enumeration tree of subproblems, where the minimum of the solutions of the two subtrees represents the optimal solution of our primal ILP problem.

The search for cutting planes is called the separation problem. The most promising cutting planes are the facets of the convex hull of all feasible solutions. In order to find good cutting planes, Althaus and coworkers [5] studied the convex hull of the feasible solutions, the so-called GMEC polyhedron, and identified a few classes of facet-defining inequalities.

Other ILP formulations of the GMEC problem have been presented by Eriksson and coworkers [34] and by Kingsford and coworkers [59]. The compact graph-theoretic ILP formulation of Kingsford and coworkers can be summarized as follows:

Let G be an undirected $|R|$-partite graph with node set:

$$V := V_1 \cup V_2 \cup \cdots \cup V_{|R|}, \tag{23}$$

where V_i contains a node u for each rotamer i_r of side-chain i. The potential energy $E_{uu} := E(i_r)$ is assigned to the node $u \in V_i$ that represents the rotamer i_r. Each pair $(u, v) = (i_r, j_s)$ of rotamers with $i \neq j$ is connected by an edge with weight $E_{uv} = E(i_r, j_s)$. A feasible solution of the GMEC problem has to pick exactly one node per node set V_i. The energy of the feasible solution is the sum of the template energy E_t, the node weights and the weights of the edges that connect the selected nodes. We introduce binary decision variables x_{uu} and x_{uv} for each node $u \in V$ and for each edge (u, v) of the graph:

$$\begin{aligned}
\min_X E(X) &= \min_X \left\{ E_\mathrm{t} + \sum_{u \in V} x_{uu} E_{uu} + \sum_{(u,v) \in G} x_{uv} E_{uv} \right\} && (24)\\
\text{s.t.} \quad & \sum_{u \in V_i} x_{uu} = 1 \qquad \text{for all } i \in R && (25)\\
& \sum_{u \in V_i} x_{uv} = x_{vv} \qquad \text{for all } i \in R \text{ and } v \notin V_i && (26)\\
& x_{uu}, x_{uv} \in \{0, 1\} \quad \text{for all } u, v \in V. && (27)
\end{aligned}$$

The constraints (26) ensure that exactly those edge weights E_{uv} are added to the energy function for which both end nodes u and v are selected, i.e. $x_{uu} = 1$ and $x_{vv} = 1$.

Kingsford and coworkers [59] show that their ILP formulation allows for solving large problem instances. They propose to relax the ILP to an LP. If the solution of the LP is integral, the SCP problem has been solved in polynomial time. Otherwise, they start the computationally more expensive ILP procedure. Surprisingly, they show that optimal solutions can almost always be obtained directly by solving the respective LP when placing side-chains on native or homologous backbones, whereas the design problem often cannot be solved using LP. These results have been obtained with an energy function based on van der Waals interactions and a statistical rotamer self-energy term. Kingsford and coworkers also found that small modifications of

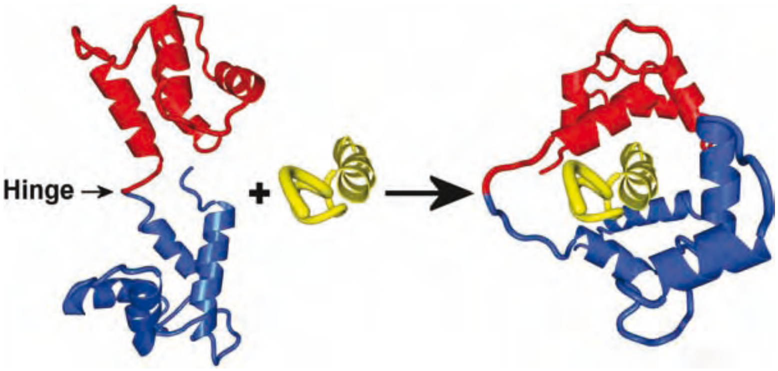

Figure 6 Hinge-bending accompanies the binding of calmodulin and to a peptide. The two terminal domains of calmodulin "wrap" around the peptide by a movement around the hinge region marked by the arrow (PDB IDs 1CFF and 1BBM).

the energy function may lead to an increase of examples for which the more expensive ILP procedure is required.

2.3.2 **Hinge-bending**

Sandak and coworkers [101, 102] published the first algorithm for handling hinge-bending. To accurately predict the structure of protein–protein and protein–ligand complexes, they adapted a technique developed in computer vision and robotics for the efficient recognition of partially articulated objects. These objects consist of rigid parts connected by rotary joints. The approach is based on an extension and generalisation of the Hough transform and the geometric hashing paradigm for rigid objects.

Since a detailed description of this sophisticated algorithm would go beyond the scope of this work, we focus on the core ideas of the method. To simplify matters, we assume that

(i) The ligand B is built of two "rigid" domains B_1 and B_2 connected by a short flexible hinge.

(ii) The position of the hinge in protein B is known and can be described by a point H.

(iii) Apart from the six degrees of motional freedom of B as a whole, independent rotations of B_1 and B_2 around the hinge are allowed as additional conformational changes.

The algorithm starts by applying a slightly modified version of the RBD scheme based on geometric hashing as described in Refs. [38, 76] (see also

Chapter 16). Triplets of points on the surfaces of A and B are used to calculate all rigid transformations T of B that result in interesting contacts between the surfaces of A and B. If a transformation t is generated by a surface matching between B_1 and A, t is associated with the domain B_1 and with B_2 otherwise.

The hinge-bending algorithm is based on the following concept (see Figure 7): hopefully, the set T of possible transformations contains a transformation t_1 placing B_1 close to the correct position, but not necessarily B_2, and a transformation t_2 placing B_2 correctly, but not necessarily B_1. Both transformations share a common feature: when applied to their respective domains, they will place the hinge at the same position. The algorithm thus tries to identify pairs of transformations associated with both domains that would place the hinge at approximately the same position using a grid-based technique.

Sandak and coworkers apply all transformations in T to H resulting in a set $T(H)$ of possible locations of the hinge. These putative hinge locations are clustered using a 3-D grid. For each grid cell, a vote accumulator counts the number of transformations that map H into this cell. The algorithm considers a cell as interesting if it receives a large number of votes from transformations associated with both domains. The high-scoring cells and the associated transformations are selected, while the other transformations are removed. Each of the remaining transformations is applied to its domain and checked for collisions with A. Transformations that yield large overlaps are removed from the candidate list, similarly those yielding an insufficient number of

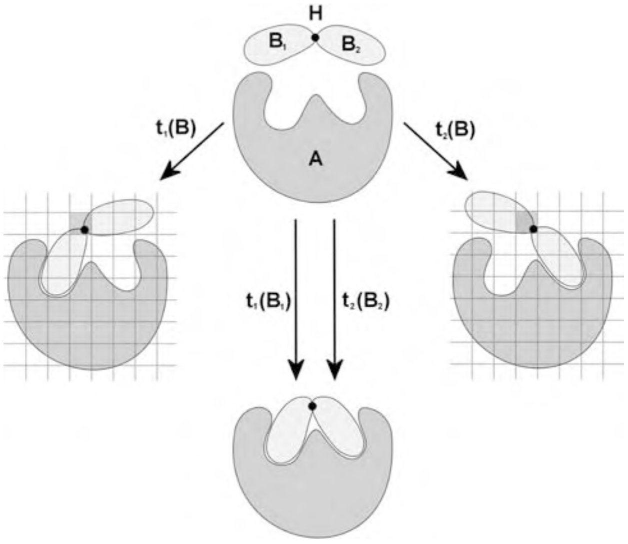

Figure 7 Schematic illustration of protein-docking with hinge-bending: the two domains B_1 and B_2 have to swivel around their joint hinge H to fit into the binding site of A.

favorable van der Waals contacts with A. In a following self-collision test, the remaining possible pairs (t_1, t_2) of transformations belonging to high-scoring cells where t_1 is associated with B_1 and t_2 with B_2 are applied to their respective domains. If the transformed domains $t_1(B_1)$ and $t_2(B_2)$ do not show a forbidden self-collision, the pair of transformations (t_1, t_2) is added to the set of possible solutions together with a geometric score, the sum of the van der Waals contacts of $t_1(B_1)$ with A and $t_2(B_2)$ with A.

2.3.3 **Biased Probability Monte Carlo (BPMC) Conformational Search**

Abagyan and Totrov [1, 109] suggested an efficient and effective method for optimizing the backbone conformation and the side-chain positions simultaneously. The modified Monte Carlo method, called the BPMC approach, operates in torsion angle space. To simplify matters, we will sketch the BPMC algorithm using structure prediction of peptides as an application example.

In torsion angle space, the conformation of a peptide can be described by the backbone torsion angles ϕ, ψ and the torsion angles $\chi_\alpha, \chi_\beta, \cdots$ of the side-chains. Abagyan and Totrov combine the two torsion angles ϕ, ψ of each residue to one "subspace" or internal variable of the optimization problem such that the number of internal variables representing the backbone is equal to the number of residues. The torsion angles of individual residues can also be combined to one subspace or internal variable.

The BPMC approach is based on the idea "to sample with larger probability those regions of the conformational space which we know *a priori* are, on the average, highly populated and to sample with less probability regions known to be less populated" [1]. Abagyan and Totrov prove that random steps chosen according to the expected probability distribution of the "subspace" parameters should be preferred over any other way to make a random move. Therefore, they carry out a statistical analysis of the local conformational preferences of a representative set of protein structures to identify preferred zones in ϕ–ψ and χ subspaces. The calculated ϕ–ψ and χ maps are divided into regions by visual inspection or according to the maxima of the torsion potential. Each region defines a preferred zone z that is approximately described by an ellipse. These zones are also associated with probabililties $P(z)$, which are derived from the number of points contained in the zones.

The BPMC iteration scheme can be summarized as follows:

(i) The BPMC procedure randomly selects a subspace or internal variable, i.e. it chooses a backbone or side-chain torsion angle belonging to one residue and the respective subspace.

(ii) It randomly selects one zone z_k according to the probability $P(z_k)$ out of the set of all high-probability zones $z_1, z_2, \cdots, z_m$ of the selected internal variable or subspace.

(iii) It makes a normally distributed step in the vicinity of the z_k-th zone.

(iv) A local minimization of the new conformation is carried out using the ECEPP/2 energy function [37, 92].

(v) The total energy of the optimized conformation is calculated by adding additional energy terms for solvation energy, electrostatic free energy and entropy.

(vi) The conformation is accepted if the Metropolis criterion [86], which is the normal acceptance criterion for a move in the simulated-annealing procedure, is fulfilled.

The BPMC approach has been successfully applied to a number of different optimization and structure prediction problems, ranging from *ab initio* prediction of peptide structures to protein–protein docking.

2.4 Scoring Functions

To distinguish the native structure from decoys, the generated candidates are usually evaluated using some kind of scoring function. The number of different scoring functions that have been used in protein–protein docking is very large. Therefore, we will discuss some general requirements for these functions first and then describe selected scoring functions in more detail. (For a discussion of scoring functions in the context of protein–ligand docking, please refer to Chapter 16.)

The ideal scoring function is (i) highly accurate, (ii) computationally efficient and (iii) robust with respect to small deviations from the native structure. Such an ideal function would allow us to easily compute the interaction free energies of all candidates and then pick the one with the lowest score/energy, which is hopefully close to the native structure.

Unfortunately, the prediction of binding free energies is a challenging problem. While the biophysical effects contributing to the binding free energy ΔG_{bind} are well known, they are not yet understood to the extent necessary to construct an accurate scoring function. It is thus difficult to model these effects adequately. This is particularly true for entropic contributions and solvation effects. However, even for the well-understood contributions like hydrogen bonds or van der Waals interactions it is hard to find sufficiently accurate, albeit computationally efficient, models.

Over the years, different classes of scoring functions have been developed, each with its own strengths and weaknesses. All these approaches share one major simplification: while the thermodynamic properties we try to predict (free energies in particular) are defined as ensemble properties, all scoring functions try to deduce this property based on a single structure only. There has been some effort to predict binding free energies for small molecule ligands using ensemble techniques (free energy perturbation and thermodynamic integration), however these methods are not applicable to large protein–protein complexes.

Most scoring functions fall into one of three categories: (i) *ab initio* models, (ii) empirical models and (iii) knowledge-based models. The first category is based on first principles, i.e. on solid physical theories like quantum mechanics. These models require no additional parameterization besides physical constants. While they are theoretically elegant, they are often computationally intractable for the large systems considered in protein–protein docking. Current scoring functions thus mostly fall into the latter two categories (empirical and knowledge-based), which we will discuss below. A comprehensive review of the different types of scoring functions in the context of protein–ligand docking can be found in [15].

2.4.1 Empirical Potentials

Empirical potentials decompose the overall binding free energy into individual independent contributions, which are then approximated by separate models. Many simple scoring functions described for RBD approaches fall into this category. Empirical models are often, but not always, based on solid theoretical models. In particular, some of these potentials are derived from or inspired by molecular mechanics force fields (AMBER or CHARMM in most cases). These force fields are also empirical scoring functions in a broader sense and have been used for scoring in protein–protein docking as well.

Empirical scoring functions use varying decompositions of the total binding free energy into individual contributions. The decompositions aim at being sufficiently *complete*, *accurate* and *orthogonal*. Sufficient completeness implies that all major effects governing protein association are covered. If this is not the case, then sufficient accuracy cannot be achieved. Orthogonality implies that each effect is covered by one contribution of the decomposition only, thus simplifying the validation of the scoring function and yielding a minimal and concise decomposition.

Obviously, there are numerous possible contributions to the total binding free energy. A reasonably complete decomposition of the binding free energy ΔG_{bind} could, for example, include the following contributions:

$$\begin{aligned}\Delta G_{\text{bind}} = \Delta G_{\text{vdW}} + \Delta G_{\text{es}} + \Delta G_{\text{hp}} + \Delta G_{\text{hb}} \\ + \Delta G_{\text{solv}} + \Delta G_{\text{int}} + \Delta G_{conf} - T\Delta S_{\text{tr/rot}}\end{aligned} \tag{28}$$

where ΔG_{vdW} are the van der Waals contributions, ΔG_{es} is the change in electrostatic free energy, ΔG_{hp} accounts for the hydrophobic interaction, ΔG_{hb} accounts for the hydrogen bond energy, ΔG_{solv} accounts for the change in solvation free energy, ΔG_{int} accounts for the change in the internal energy of the two proteins (e.g. conformational changes), ΔG_{conf} accounts for the loss of side-chain torsional degrees of freedom, and $T\Delta S_{\text{tr/rot}}$ accounts for the loss of translational and rotational degrees of freedom upon association. Clearly, this decomposition is neither entirely orthogonal nor entirely complete. Hydrogen bonds and solvation effects also have an electrostatic contribution, and the hydrophobic effect is not completely separable from van der Waals and solvation effects. Nevertheless, this decomposition accounts for the major interactions occuring between proteins. The art of constructing an empirical scoring function lies in the choice of good approximations for each of these effects and in knowing which of these contributions can be neglected for the problem at hand.

In the simplest case, an empirical scoring function accounts for a single effect only, e.g., for hydrophobic interactions or electrostatic contributions. Surface overlaps used as score in correlation-based approaches can be regarded as simple empirical scoring functions accounting for the hydrophobic effect and van der Waals interactions only. While these trivial scoring functions will work readily for certain types of protein–protein interactions (e.g. large hydrophobic interfaces for correlation approaches), they will fail as soon as the total binding free energy is dominated by other effects. Sophisticated scoring functions thus aim at modeling as many of the effects as accurately as possible.

The scoring function used by Jackson and Sternberg [54] in their RBD approach is an example of a more sophisticated empirical scoring function. The approach relies on a subset of the above decomposition:

$$\Delta G_{\text{bind}} = \Delta G_{\text{es}} + \Delta G_{\text{solv}} + \Delta G_{\text{hp}}. \tag{29}$$

Solvation and electrostatics are handled by the same approach – continuum electrostatics. This approach models the solutes (the proteins) as regions of low dielectric constant immersed in a continuum of high dielectric constant – the solvent (water). The overall electrostatics of this system can be readily solved using the Poisson or Poisson–Boltzmann equation by standard numerical techniques (e.g. finite difference methods, e.g. Ref. [43]). Solving the (linearized) Poisson–Boltzmann equation on a sufficiently fine 3-D grid yields the electrostatic potential for each grid point. Using a quite elaborate scheme, Jackson and Sternberg compute the change in solvation free energies of the two proteins upon association ($\Delta\Delta G^{A}_{\text{solv}}$ and $\Delta\Delta G^{B}_{\text{solv}}$) and their electrostatic interaction energy ($\Delta G^{AB}_{\text{es}}$) from these potentials.

The hydrophobic effect is estimated as the cavitation free energy, i.e. the energy required to form a protein-shaped cavity in the surrounding water. This energy is thought to be roughly proportional to the molecular surface area. Binding of the two proteins obviously reduces surface area, as the protein binding interface is no longer exposed to the solvent. This results in a negative cavitation-free energy. The hydrophobic effect is thus estimated as:

$$\Delta G_{\text{hp}} = \gamma \Delta A = \gamma \quad (A_{AB} - A_A - A_B), \tag{30}$$

where A_{AB}, A_A and A_B are the molecular surface areas of the complex and the proteins, respectively, and γ is a constant.

The full model thus looks as follows:

$$\Delta G_{\text{bind}} = \Delta\Delta G^{A}_{\text{solv}} + \Delta\Delta G^{B}_{\text{solv}} + \Delta G^{AB}_{\text{es}} + \gamma(A_{AB} - A_A - A_B). \tag{31}$$

While the model turned out to be successful for scoring protein–protein complexes, the use of the finite-difference Poisson–Boltzmann equation results in quite long running times. This scoring function is thus viable for the final re-ranking stage of the docking algorithm only.

It should be remarked that the energies predicted by most empirical scoring functions are not able to reproduce the absolute value of the binding free energy with reasonable accuracy. The reason is often to be found in the nonorthogonality of the overall decomposition, in the insufficient accuracy of the individual contributions, but also in the overall balance of these contributions. However, this does not impede the usefulness of these scoring functions for protein–protein docking, where a proper separation of the native structure from the decoys (i.e. a correct relative *ranking* of the energies) is sufficient.

2.4.2 **Knowledge-based Potentials**

In contrast to empirical scoring functions, knowledge-based scoring functions do not explicitly model individual contributions to the binding free energy. Instead, they are based on the frequencies of residue–residue or atom–atom contacts observed in X-ray structures of protein–protein complexes. Those interactions occuring frequently are counted as energetically favorable, whereas interactions observed rarely in complexes are considered less favorable. The frequencies observed can be converted to pseudo-energies assuming a Boltzmann distribution (the so-called *inverse Boltzmann law* [107]). In this case, the potentials are often called *potentials of mean force* (PMFs).

Knowledge-based potentials can be constructed for different model resolutions. The potentials initially developed for protein structure prediction are typically residue-based potentials, i.e. two amino acids are considered to be in contact and thus to contribute to the total energy, if they are within a given threshold distance. In its simplest form, the computation of the interaction free energy reduces to a summation over all pairs in contact across the protein interface:

$$\begin{aligned} &\Delta G_{\text{bind}} = \sum_{(i,j)} e_{t(i)t(j)} \quad \text{for all} \quad i \in A, j \in B \\ &\text{with} \quad r_{ij} := |\vec{r}_i - \vec{r}_j| \leq r_{\text{cutoff}}, \end{aligned} \tag{32}$$

where $t(i)$ denotes the atom/residue type of i, $e_{t(i)t(j)}$ are the statistically derived interaction energies, $\vec{r}_i$ and $\vec{r}_j$ are the positions of i and j, and r_{cutoff} is the cutoff distance, i.e. the maximum distance for which the pair (i, j) is still considered to be in contact (usually $6 - 7$ Å). Less coarse scoring functions compute these $e_{t(i)t(j)}$ as a function of the distance. The above equation then becomes:

$$\Delta G_{\text{bind}} = \sum_{(i,j)} e_{t(i)t(j)}(r_{ij}). \tag{33}$$

Deriving these $e_{t(i)t(j)}$ from a structural database typically involves counting of the individual pairs. The different knowledge-based potentials differ in the way this counting is done (e.g. the assignment of atom/residue types) and, more importantly, they differ in the choice of a reference state. The issue of reference states is beyond the scope of this paper. A recent discussion of the problem can be found in Refs. [77, 122].

The key step in all these approaches is relating the e_{ab} to the number of observed contacts between atoms/residues of type a and b in the database for a given distance. The inverse Boltzmann law yields:

$$e_{ab}(r) = -k_B T \ln \frac{g_{ab}(r)}{g(r)}, \tag{34}$$

where $g_{ab}(r)$ is the probability of finding a pair of types a and b in distance r, and $g(r)$ is some normalized reference probability. These probabilities are approximated by counting contacts in the structural database.

Both, atom contact potentials (ACPs) and residue contact potentials (RCPs) have been used extensively in protein–protein docking with significant success. In theory, knowledge-based potentials account for all effects contributing to the binding affinity; however, some of these effects tend to be underestimated. In particular, the repulsive part of the van der Waals contribution and solvation effects are often added to yield a more reliable scoring function.

The *atomic contact energy* (ACE) proposed by Zhang and coworkers [121] is one of these potentials. It is based on a classification into 18 distinct atom types. For each of these types, the number of contacts was determined from a database of 89 homology-reduced protein structures with a single cutoff radius of 6 Å. Interaction scores can thus be readily computed using Eq. (32). ACE is typically augmented with additional Coulomb electrostatics and entropic contributions to predict protein binding free energies [119].

An example for a residue-based contact potential is RPScore, developed by Moont and coworkers [90]. RPScore considers two residues to be in contact if their C_β atoms are within 6 Å of each other. Counting these contacts across the interface of a set of protein complexes and applying the inverse Boltzmann law to these counts, normalized with the expected number of contacts, results in relative preferences for amino acid contacts. Moont and coworkers used this type of potential and similar atom-based potentials for rescoring docking candidates obtained through correlation docking and yielded very good results.

Murphy and coworkers [91] used RCPs (RPScore) and ACPs (ACE) in subsequent filtering and scoring steps. They found that both types of potentials are good for discriminating native structures from decoys. The performance increases if both methods are combined, i.e. if RPScore is used for an initial filtering and ACE for a final scoring or *vice versa*. In order to account for overlaps, both potentials had to be augmented by an additional van der Waals energy term.

2.5 Data-driven Docking

Today, protein complexes are studied with a wide variety of experimental techniques. Not all of these experiments yield enough information to allow a direct structure elucidation, but nonetheless they often allow to draw useful conclusions about the properties of the complex. Indeed, integrating such experimental data into protein-docking procedures has been consistently reported to improve prediction accuracy. This approach of integrating experimental results into the docking process is commonly known as *constrained* or *data-driven* docking.

A large number of different experimental techniques has been used in the context of data-driven docking. Here, we will focus on select approaches and refer the interested reader to the recent review of the field by van Dijk and coworkers [111]. At this point we would like to emphasize that for many data-driven docking approaches, the experimental origin of the constraints is of no importance. If the docking algorithm is able to use "generic" distance or angle constraints, it can utilize information from the most diverse experimental techniques in a unified framework.

2.5.1 Experimental Techniques

Site-directed mutagenesis of individual amino acids in the complex provides information on the involvement of the mutated residue in the binding interface. If a certain point mutation influences the binding in any way, the residue is considered part of the complex interface. If, on the other hand, replacing a residue does not influence the binding, this can at least be taken as a hint that it is not part of the interface. This information can be exploited in data-driven docking. In the structure generation stage, e.g., we restrict the search to those candidates where the experimentally identified residues are indeed part of the binding interface.

Mass Spectrometry (MS) techniques have become a popular tool for many biological applications, particularly in proteomics. Even though it might not be obvious at first glance, MS experiments can also be used to provide constraints for the protein-docking problem. This can be achieved in two different ways. The first technique is the measurement of H/D exchange rates, where the proteins are immersed in heavy water (D_2O). In this situation, hydrogen atoms on the surface of the protein can be exchanged by deuterium atoms from the heavy water, perturbing the mass of the protein. Measuring these mass differences yields information about the exchange rates. Residues in the protein–protein interface are shielded from H/D exchange and thus experience lower exchange rates in the complex. A second type of constraint can be derived from MS experiments on cross-linked proteins. A reactive bifunctional cross-linker covalently binds to two residues. The chemistry of the functional groups determines at which sites the cross-linking occurs. The protein complexes are then fragmented (e.g. through tryptic digest) and the resulting peptides are investigated using MS techniques. If this reveals a fragment with a mass equal to the sum of the masses of two peptides occuring in the complex plus the mass of the cross-linker, one can derive a simple distance constraint: in the complex, the two peptides occuring in the cross-linked fragment cannot be farther away than the distance of the two functional groups of the cross-linker. Thus, cross-linked pairs of peptides from A and B yield an upper bound on the distance of pairs of residues in the complex.

NMR spectroscopy measures the electromagnetic absorption properties of nuclear spins subjected to a strong magnetic field. These effects sensitively depend on the chemical environment of the absorbing atom and can be used to derive distance and orientational constraints between atom pairs in the complex. The most commonly used constraints are distance constraints based on nuclear Overhauser enhancements (NOE) and orientational constraints based on residual dipolar coupling (RDC). In addition, NMR can be used to determine which residues undergo conformational changes during complex formation by H/D exchange measurements, cross-saturation transfer or chemical shift perturbation. Using NMR to derive distance or angle constraints has become a popular technique for protein docking. Unfortunately, most techniques require time-consuming manual annotation of the NMR spectra (resonance assignment).

2.5.2 **Algorithmic Approaches**

In principle, experimental information can be introduced into the docking process at three different stages: the structure generation stage, the filtering stage or the scoring stage. If experimental data is used in the filtering stage, it is often used in the form of geometric constraints. Candidate structures violating too many of these constraints are removed and the search space is thus reduced. In the scoring stage, the candidate structures can be used to predict an experimental property. The similarity between predicted and experimental data can then serve as a scoring function. Since most of the algorithmic techniques are very similar to the techniques already described above, we will only discuss a few select examples.

In general, the structure generation itself is driven by some kind of energy or scoring function. To integrate experimental data, additional scoring terms can be introduced to penalize deviation from the measured values. A typical example for such an approach is implemented in the docking program HADDOCK [30], which integrates information about interfacial residues by adding distance penalties. Since not all interface residues may be detected, neighboring residues on the protein surface will be added to those validated experimentally. Given a candidate structure, effective distances are calculated for each interface residues. The effective distance measures a residue's proximity to the interface. Candidates where the interface largely coincides with the experimentally determined interface will have low effective distances, resulting in good scores.

Experimental information can also be used for correlation-based docking techniques by weighting different parts of the protein differently, according to the experimental data at hand [11, 12]. For example, the contribution of residues known to be part of the binding site can be increased by assigning their surface regions a larger value. Anand and coworkers [7] used MS H/D data to filter candidates generated with the docking program DOT [81]. NMR data was used as a post-scan filter [95] in the correlation-based program FTDOCK [40].

Integrating experimental data in the scoring phase can be achieved in numerous ways. Kohlbacher and coworkers [63] used unassigned ^{1}H-NMR spectra of complexes to re-score the candidates. In an initial phase, they generate candidates by RBD based on geometric hashing [73]. With an empirical model, they predict the chemical shift of every proton in the candidate structure. The sum of these shifts yields a theoretical spectrum for each candidate. These spectra are then compared to the NMR spectrum of the native structure and the resulting similarities are used to score the candidates. Based on this score alone they achieved very good rankings of several protein–protein complexes.

2.6 Assessment of Docking Predictions

At first glance, assessing the quality of protein-docking algorithms seems straightforward. In principle, it would suffice to apply the docking algorithm to a number of test cases for which the complex structure has been determined experimentally and compare the generated conformations with the known

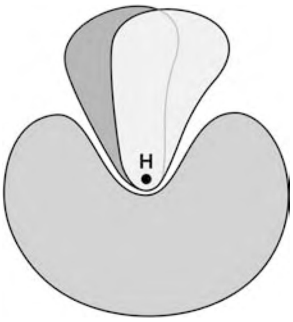

Figure 8 RMSD is not a well-suited measure for the similarity of protein–protein complexes. Small rotations of one of the proteins about a point close to the interface can lead to large changes in RMSD, although most of the interface contacts are conserved.

complex structures. Unfortunately, two problems arise. First, the choice of the test complexes has an enormous influence on the quality of the result. Some protein complexes are inherently "simple" and others inherently "hard", typically due to the degree of flexibility. Second, there is no canonical measure for the deviation of the generated structures from the native ones [110]. The most popular method is the computation of the RMSD of a certain set of atoms, e.g. the C_α atoms of the backbone. The usefulness of the RMSD for docking evaluation has been questioned in the literature [119]. One of the problems associated with RMSD is illustrated in Figure 8. While a small rotation of one of the proteins about a point close to the interface preserves most of the interface contacts, it results in a large change in RMSD. Alternative quality measures thus often focus in some way on the interface region. The interfacial RMSD, for example, computes the RMSD only for binding site residues. A conceptually different measure is the fraction of native contacts, which tends to be more stable for partially correct predictions [119]. It counts the number of native contacts present in the candidate structure.

Assessing the quality of docking predictions is further complicated by the relatively low number of protein complexes with known bound and unbound structures. Since a considerable number of docking examples is typically needed to tune the docking algorithm and fit its parameters, the real *test set* is usually quite small. It is thus often unclear how well the predictions of a given algorithm generalize to completely unknown complexes. Apart from the above-mentioned more technical aspects, comparing the results of different docking algorithms and assessing their quality is severely complicated by a further, more subtle difficulty: typically, during the development and testing of protein-docking algorithms, no clear distinction is made between test and training sets. This means that in many cases, the structures that are used to evaluate the quality of a given docking algorithm were also employed during its development. Hence, it cannot be ruled out that the algorithm has been overtrained, i.e. that it shows good performance on the training set only.

To overcome these difficulties, the protein-docking community has established a regular blind prediction challenge called CAPRI which is similar in spirit to the CASP competition in protein structure prediction. CAPRI is organized in so-called rounds. For each round, crystallographers provide possible docking targets, the structures of which they have already determined, but not published. The organizers choose an interesting subset of these targets and forward the structures of the individual proteins – either in their bound or unbound (for some cases, only a homologous unbound structure is used as input, further complicating the prediction) conformation, depending on the target – to the participating groups. Each group may then submit a certain number of predictions for each target. Finally, the predictions are evaluated by the organizers and the results are published.

Detailed evaluations of the different CAPRI rounds can be found in the corresponding papers and on the CAPRI website [35]. Here, we will exemplarily discuss the evaluation of round three as taken from [116]. CAPRI round three presented only two different targets: an epidermal growth factor-like domain of laminin and nidogen-G3 and a wild-type homodimer of the phosphoenolpyruvate:sugar phosphotransferase system (PTS) regulation domain from LicT [55]. Of these two targets, the first one was considered the easier problem: nidogen was used in its bound form (but randomly oriented) and laminin, even though used in the unbound form, was very similar in structure to the bound conformation. Out of the 179 submitted predictions for this target, 27 were of acceptable or better quality. Only two models out of these 27 were considered high quality, i.e. they had more than 50% of the native contacts correctly predicted. The second target was considerably more difficult. Here, the challenge consisted in predicting the wild-type homodimer from the structure of the subunit of a double mutant, which produces an activated form of the homodimer with widely different backbone (RMSD of around 12 Å). This large degree of flexibility posed severe difficulties to the docking algorithms and, indeed, the prediction score in general was quite poor [116], with only one acceptable prediction.

These results already indicate that for certain complex structures, protein–protein docking is still a major challenge. In fact, the level of difficulty depends mostly on the type of structure considered. Vajda and Camacho [110] analyzed strengths and weaknesses of current docking techniques on a benchmark set of 52 different complexes [19] (this benchmark set has since been extended in Ref. [87]). Interestingly, it turned out that the complexes in the test set can be assigned a degree of difficulty that is independent of the docking algorithm applied. The whole test set decomposes into five categories of increasing difficulty based on three structural properties: the degree of flexibility, the area of the complex interface (ΔSASA, the change in solvent accessible surface area during complex separation) and the magnitude of the desolvation effect upon complex formation. The simplest class of docking examples, the so-called type I complexes, is composed of protein–protein complexes with low degree of flexibility, a relatively large interface area of $1400 < \Delta\text{SASA} < 2000$ Å^2 and a strong desolvation effect below -4 kcal mol^{-1}. This class consists almost completely of enzyme-inhibitor complexes. If the hydrophobic effect is weaker than for the complexes of type I, protein–protein docking can still be expected to work successfully as long as the interface area is large, $\Delta\text{SASA} > 2000$ Å^2, and the conformational changes during docking are only moderate. These complexes form class II, which consists mainly of protein pairs with strong functional coupling and of enzyme–inhibitor complexes.

The docking problem becomes more difficult if neither the hydrophobic effect nor the interface area are particularly large. In this case, which is called type III, the docking results often depend sensitively on the coordinates of the input structures. An important type of complexes that often falls into this class is antibody–antigen pairs. If in addition the interface area is particularly small, $\Delta\text{SASA} < 1400$ Å^2, docking can no longer be expected to work successfully. Indeed, the results of all docking algorithms for this type IV complexes are generally poor. Interestingly, Vajda and Camacho noticed that many docking algorithms still produce several true positives in the structure generation stage for type IV complexes. However, these are usually lost in the filtering or scoring steps of the algorithm.

The hardest problem for all current docking algorithms, though, is those complexes which undergo large conformational changes during docking. This effect often occurs if the interface area is larger than $\Delta\text{SASA} > 2000$ Å^2: large contact areas give rise to a large number of interactions and these interactions are able to induce massive conformational changes. Thus, it is sometimes hard to distinguish between the relatively easy type II complexes and the extremely hard type V complexes. Transient protein complexes involved in signal transduction typically fall into this class.

Having defined these five classes of increasing difficulty, Vajda and Camacho evaluated whether the results of the CAPRI competition fit into this scheme. Indeed, it turned out that the decomposition of the CAPRI targets into classes I–V explained the performance of the different algorithms very well. In general, all algorithms predict the correct structure for type I and II complexes. The results for type III complexes varied, but were consistently better for those with negative desolvation energy, hence for complexes closer to class I. Type IV complexes lead to poor docking results, while docking seems to fail for type V. This study shows an important difference in the source of error for the different types of complexes: while for class III and

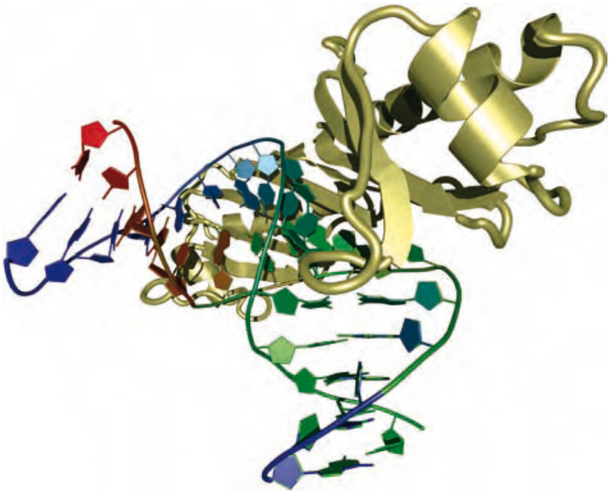

Figure 9 As can be seen from this crystal structure of the TATA box-binding protein bound to double-stranded DNA (PDB ID 1CDW [93]), proteins can induce massive conformational changes of the DNA. In this case, the DNA is nearly bent to a right angle.

IV, we can expect major improvements by changing scoring functions and SCP algorithms, type V complexes will need new techniques for handling flexibility. Since in these cases a rigid structure generation phase will typically not produce approximations to the native structure, improved re-ranking methods in the later stages will come too late. The only possible remedy to this shortcoming would be the flexibilization of the structure generation phase.

3 Protein–DNA Interactions

3.1 Peculiarities of Protein–DNA Binding

Interactions of proteins with nucleic acids differ in some fundamental aspects from protein–protein interactions. The most prominent structural peculiarity is the negatively charged phosphodiester backbone of nucleic acids. Proteins binding to DNA have to compensate this charge, which typically results in a large number of positively charged lysine and arginine residues in the protein–DNA interface. Hence, electrostatics, solvent effects and counterions play a much more important role in modeling protein–DNA interactions than they do in protein–protein interactions.

The second key difference lies in the flexibility of nucleic acids. DNA and, in particular, RNA have quite flexible backbones, which often undergo bending or unwinding upon binding (Figure 9). Apart from changes in the backbone conformation, individual bases or base pairs can flip out of the double helix and interact directly with the protein. To date, no algorithm is truly able to handle this degree of flexibility. However, there are some proteins, e.g. zinc finger proteins, that bind to DNA without inducing significant changes in DNA structure. In these cases, complex structures can be successfully predicted with approaches quite similar to those applicable to protein–protein docking. However, scoring functions used in protein–protein docking have to be adapted to the different types of interactions present in the protein–DNA case. The construction of knowledge-based potentials for protein–DNA interactions is further complicated by the comparatively small number of crystal structures available; only a minor fraction of the complex structures found in the Protein Data Bank (PDB) contains nucleic acids (about 900 structures as of early 2006).

While the electrostatic interaction of the protein with the DNA backbone is the major contributing factor towards protein–DNA complex stability, specificity is mostly conveyed through hydrogen bonds between protein side-chains and bases. This makes the prediction of the exact binding position, i.e. the sequence motif a specific protein binds to, much harder than the prediction of the binding site of the protein. This difficulty is based on two facts. (i) The relative differences in binding free energy between two DNA sequences are often quite low with differences in the range of a few $\mathrm{kcal\,mol^{-1}}$. Hence, very accurate scoring functions are required. (ii) The hydrogen bond patterns conveying specificity often include water-mediated hydrogen bonds, which are difficult to predict and to model.

The ability to accurately predict relative binding affinities for different sequences (i.e. the specificity) is an important goal in protein–DNA docking. This allows the development of rapid sequence-based prediction methods based on structural data and is also an essential tool for the design of tailor-made transcription factors [50].

3.2 Algorithmic Techniques

As protein–DNA docking is currently restricted to complexes with little conformational flexibility, it basically employs the same techniques used in rigid-body protein–protein docking. We will now describe some of these docking techniques together with the scoring functions.

3.2.1 Correlation Techniques

Several approaches have been proposed that use correlation techniques for protein–DNA docking [3, 99]. These approaches use established tools from protein–protein docking to perform a RBD, and then filter and refine the results. We will discuss the work by Aloy and coworkers [3] in more detail.

Their docking algorithm applies a standard correlation-based RBD method (FTDOCK) used with slightly different parameters and electrostatics. As has been mentioned above, the binding specificity for many protein–DNA complexes is only marginally influenced by the DNA backbone charges. Aloy and coworkers account for this by dampening the backbone charges. The correlation docking results in a set of initial candidate structures, which are then filtered with respect to geometric constraints. These constraints are derived from experimentally determined DNA–protein contacts. The remaining candidates are finally re-scored using a knowledge-based potential. Although the docking does not account for flexibility, it turns out to be quite successful even when used with unbound protein structures. Of a test set of eight complexes, two complexes were indeed predicted correctly (below 4 Å RMSD for the structure on rank one) and for five out of the eight a good approximation was at least among the top ten structures.

3.2.2 Monte Carlo Techniques

Knegtel and coworkers [60] proposed a Monte Carlo algorithm for protein–DNA docking. MONTY uses a simple scoring function considering hydrogen bonds, salt bridges, van der Waals contacts and steric collisions. This scoring function is used in a Monte Carlo framework to identify minimum energy conformations. MONTY considers the six degrees of freedom arising from protein rotation and translation, and additional degrees of freedom representing flexible side-chains. Repeated runs of the Monte Carlo simulation yield different candidate structures. The approach was tested on the complex of 434 Cro and double-stranded DNA. For three different X-ray structures, MONTY was able to identify a good approximation of the true complex structure (below 4 Å RMSD). However, the algorithm started from the bound structures and did not account for DNA flexibility.

In a second study, Knegtel and coworkers [61] extended MONTY to include DNA backbone flexibility as well. They describe the DNA backbone through a parametric equation and allow for unwinding or tightening of the helix during the simulation. Helix flexibility is achieved by changing the parameters of the parametric equation in small steps. Base pairs are then relaxed to adjust to the new backbone conformation. It turns out that adding DNA backbone flexibility indeed increases the number of correctly retrieved hydrogen bonds. It was also shown that inclusion of experimental data improves the predictions. To this end, Knegtel and coworkers included harmonic potentials for NOE pairs or energy bonuses for correctly retrieved experimentally confirmed contacts. These contacts can be obtained from arbitrary experiments, e.g. from mutagenesis.

A hybrid geometric hashing, minimization, and Monte Carlo approach was proposed by Deng and coworkers [17, 26]. Their algorithm is based on the assumption that the hydrogen bonding is the key factor in protein–DNA interaction. Hence, they designed an interaction potential accounting for hydrogen bonding and van der Waals interactions only. The piecewise defined function resembles a Lennard–Jones potential, but also includes angular contributions for hydrogen bonds. The different phases of the algorithm use different levels of approximation for this potential. In the initial geometric hashing phase of the algorithm, the potential is approximated as a square-well potential, which in fact just counts hydrogen bonds between DNA and protein. Matching quadruples of interaction points between protein and DNA creates a list of transformations ensuring at least four hydrogen bond matches between protein and DNA. The second phase of the algorithm refines the square-well approximation to a harmonic potential. For this quadratic approximation one can easily derive a closed-form solution for the optimal transformation minimizing the interaction energy. The optimal solution for the quadratic scoring function is then used as the starting point for a Monte Carlo minimization using the full Lennard–Jones potential in the third phase. For a number of well-known DNA-binding proteins they could predict the correct (i.e. highest binding) sequence motif.

3.3 Scoring Functions

Mandel-Gutfreund and coworkers [79, 80] proposed a simple residue-based contact potential based on a set of 53 protein–DNA structures. They applied this potential to sequence variants of a DNA–zinc finger complex. To identify binding motifs, they scanned the upstream regions of a number of genes. The sequence of the DNA was changed to all potential motifs occuring in these upstream regions and these motifs were then scored with the contact potential. Although the potential is quite simple, it allows structure-based predictions of the binding sites with reasonable chance of success.

Zhang and coworkers [120] proposed a knowledge-based energy function for protein–DNA and protein–ligand complexes. The potential differs from other knowledge-based approaches through the choice of the reference state. The distance-scaled, finite, ideal-gas references state (DFIRE [122, 123]) avoids some the problems related to other commonly used reference states. As in similar knowledge-based potentials, the DFIRE potential is derived from binned contact frequencies in a database of 200 protein–ligand complexes. The potential was validated on 45 protein–DNA complexes from the PDB with known binding free energies. On this data set the scoring function yielded an excellent agreement of predicted and experimental binding free energies, although no protein–protein and protein–DNA complexes were used to derive the potential. The potential is thus very robust and generalizes well to other types of structures.

Several authors have suggested that the directionality of the hydrogen bonds is an essential feature, which is not properly captured by these simple potentials. They thus extend the idea of knowledge-based potentials to include angular contributions besides the radial contributions as well. Kono and Sarai [64] proposed a potential based on the spatial distribution of amino acid atoms around the base pair. They analyzed 52 protein–DNA complex structures and counted the frequency of occurence of hydrogen bond donors and acceptors in defined spatial positions (relative to the fixed base) by summing up observations on a 3-D cubic grid. This type of potential contains an angular contribution through the relative position of a grid point with respect to the base. The potential was shown to successfully predict the DNA target sequences for the MATα1/α2 transcription factor.

Another knowledge-based potential was proposed by Ge and coworkers [42]. It is specific for the interaction with base pairs in the DNA major and minor grooves. Following a similar idea as Kono & Sarai, they superimpose DNA base pairs from high-quality crystallographic data. From this data, they compile a set of observed positions for water molecules and amino acid atoms relative to the base pairs. This set of points is then approximated by 3-D ellipsoids, which represent areas of favorable interaction with the base pair. Interaction energies with the base pairs are estimated as simple harmonic potentials between protein atoms and DNA ellipsoids. This energy function is complemented by a simple steric clash test (overlapping conformations are excluded) and performed quite well for a number of ligand–DNA complexes.

4 Conclusion

Protein–protein docking has seen many improvements over the last decade, which are highlighted by the results of blind predictions in the CAPRI competition. At the same time, the blind prediction experiments proved that protein–protein docking is still a largely unsolved problem. A careful review of the failings and problems of the numerous techniques and applications described above reveals some fundamental problems that need to be addressed in the future.

The first key problem still is *protein flexibility*. There are now several techniques available for handling flexible side-chains and domain movements in protein docking. Despite the progress made, none of these approaches addresses protein flexibility in its entirety. Except for a few stochastic approaches, e.g. Monte Carlo approaches, we have not yet managed to fuse the two first steps of the docking – structure generation and realizing flexibility – into a single combined step.

Scoring functions are the second key problem in protein–protein docking. In particular, solvent effects and entropic contributions remain challenging problems. We have seen many improvements in this area, but successful scoring functions are still computationally quite demanding. Over recent years, scoring functions have continually improved. Nevertheless, we are far from the point where one single scoring function can reliably distinguish the native complex structure from decoys.

If protein–protein docking is a difficult problem, then DNA–protein docking is much more difficult by far. While the fundamental problem is nearly identical, the development in this area is still a few years behind in every aspect. Fewer crystal structures are available, therefore our understanding of the protein–DNA interaction is not yet as far advanced as our understanding of the protein–protein interaction. The two key problems of protein–protein docking, i.e. flexibility and accurate scoring, occur in protein–DNA docking as well. In fact, both problems are more severe in this case. The huge conformational changes induced to DNA upon protein binding are still beyond what any docking algorithm is able to handle. The same is true for the accurate scoring, where the peculiar effects of DNA backbone charges and the effect of counterions are still major problems.

Protein–protein and protein–DNA docking will clearly remain exciting and important topics in the future. The rising interest in a structure-based understanding of protein interaction networks has given the field new impulses. Structure-based systems biology tries to understand large, complex systems based on molecular interactions [4, 100]. While the new data obtained from structural genomics initiatives has taught us a lot about interactions, this way of thinking opened up new application areas for protein–protein docking. For example, protein–protein docking can help to validate or predict protein interaction networks. Protein–DNA docking might play a similar role for GRNs, however, we are still a long way from being able to predict these networks based on structure alone.

The key challenges of the next years lie in the development of improved scoring functions and full flexibility for both proteins and DNA. Better scoring functions would not only yield an accurate ranking of the candidate structures, but also a good prediction of the absolute value of the binding free energy. This is a challenging task indeed. It remains to be seen whether it can be reached through any of the current methods. All thermodynamic quantities, including the binding free energy, are defined for an ensemble of structures. It would thus seem obvious that simulation-based methods are more approriate for predicting these quantities than the current methods based on a single structure only. However, this implies massive investments in terms of compute power. An interesting alternative to more accurate scoring is “data-driven docking”. Here, we can expect numerous new techniques to be integrated into docking over the next years. Basically any technique producing structure-based information of some kind can be integrated into docking approaches. Hopefully, these different efforts will converge into one consistent framework for data-driven docking in the future. Future algorithms will also have to account for side-chain and backbone flexibility simultaneously. For the case of protein–DNA docking we will probably need entirely different approaches to account for full flexiblity. These challenges will clearly keep the docking community busy for the next years and keep the CAPRI competitions exciting.

Acknowledgments

The authors wish to thank Andreas Moll, Anne Dehof and Bettina Leonhardt for their assistance with preparing the figures, and Pierre Dönnes, Annette Höglund and Dr. Dirk Neumann for critical reading of the manuscript. All images of molecular structures were generated using BALLView [88].

Lead Identification by Virtual Screening

Andreas Kämper, Didier Rognan and Thomas Lengauer

1 Introduction

The identification of new drugs is a research topic of outstanding interest. Due to recent progress in the determination of several complete genome sequences, including the human genome, the structural genomics projects aiming for structure determination of all naturally occurring protein folds, new techniques for target validation and the advances in bioinformatics, our understanding of the nature of many diseases and their causative facts is constantly increasing. These efforts help to achieve the goal to identify novel small molecules interacting with proteins and in this way find new drug targets. In 2000 it was anticipated that the number of potential drug targets would increase 10-fold [47], which was too optimistic from todays view [177]. The number of druggable proteins is more likely to be around 2200–3000 [81, 174]. Of them, around 600–1500 are disease-related and thus are putative drug targets for small-molecule drugs [81].

The availability of new targets calls for effective systematic procedures for finding putative drugs that bind to these targets. The process of searching through a collection of compounds for molecules showing biological activity against a given target is called *lead identification*. This lead identification is a *screening* procedure (Section 1.1) and part of the overall drug discovery process. It can be subdivided into several individual steps (Section 1.2). As a prerequisite for screening, the molecules which are tested against the target, the *screening compounds* (Section 1.3), have to be preprocessed (Section 2). The actual screening can be performed with a variety of methods outlined in Section 3. The results obtained from these methods need to be analyzed and interpreted (Section 4). The final Sections 5 and 6 of this chapter provide recent case studies and critical evaluations of structure-based and ligand-based virtual screening techniques.

Bioinformatics – From Genomes to Therapies Vol. 2. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

1.1 Screening Techniques

Until a few decades ago, the search for drugs was a trial-end-error procedure, with the target proteins being mostly unknown. In the last few decades of the 20th century, two different systematic techniques for searching for drugs have become accessible. Both of them are based on the fact that, increasingly, the target proteins for drugs or putative drugs have been identified. The two approaches are:

- High-throughput screening (HTS) is an experimental technique, where in a fully automated fashion a robot tests all molecules from a library against a molecular test system [78].
- Virtual screening (VS), on the other hand, is a pure computational technique. Here, the computer is used to estimate biological activities, e.g. binding affinities. This includes one or more computational techniques.

These techniques can complement each other in the sense that VS guides the experimental setup of HTS, but recently VS is more and more being seen as an alternative to HTS [101]. There are many concepts for the integration of both approaches [7, 69], showing the benefit of including experimental and *in silico* methods in drug discovery. As an example, VS methods can be used to select a subset of compounds for HTS or to analyze the results of a HTS experiment.

Due to their different nature, VS and HTS techniques have different advantages and disadvantages. For HTS, the major drawback is the cost of the experiments. The cost is mainly determined by the purchase of compounds of about US$1.00 per compound [198]. This has to be multiplied by the number of compounds used per HTS run, typically on the order of a few hundred thousands. In addition, supplies and an assay are needed. For both, the cost is highly dependent on the type of target. On the other hand, the major limitation for VS is the need for prerequisite knowledge about the binding process. If there are neither known actives which can serve as templates nor a three-dimensional (3-D) structure of the target protein, VS cannot be used. If the 3-D structure of the target is known, then methods of structure-based design can be used (see Chapter 16). The other possibility is that at least one ligand is known that binds to the target, such as the natural substrate or another inhibitor. In the latter case, methods of ligand-based design can be applied. A substantial advantage of VS is its applicability to not yet synthesized, *virtual* compounds. This facilitates screening of virtual combinatorial libraries with up to billions of molecules. It is obvious that VS methods must be very efficient to deal with such large numbers of compounds. Thus, often not only a single technique is used for VS. Instead, screening proceeds in a sequence of steps, each of which reduces the number of considered compounds, starting with very fast techniques, followed by more advanced, computationally more expensive techniques.

Within this chapter we will cover all computational aspects of VS. The sections on preprocessing of libraries (Section 2) and postprocessing of hit lists (Section 4) are also valid for HTS. However, we will exclude the more technical aspects of data handling and information storage of HTS. Furthermore, the structure-based design techniques covered in detail in Chapter 16 will not be included here.

1.2 Drug Discovery Process

Drug discovery is a time-consuming and expensive process [44] which involves a number of steps. Although the process is not linear – several of the steps have to be repeated iteratively – it is often represented as a pipeline (Figure 1). Within the pipeline, screening is performed during hit identification after a suitable drug target has been identified and validated. A hit can be defined as a compound which exhibits a strong binding affinity to the target. In order to perform a screening run, first a collection of compounds (Section 1.3) is submitted to the pipeline. This collection has to be prepared for screening using a number of preprocessing steps (Section 2.1). Specifically, unsuitable compounds are discarded by filtering steps. Next, within the pipeline a structure- or ligand-based technique is applied to further restrict the number of compounds (for ligand-based methods, see Section 3; for structure-based methods, see Chapter 16). This is not necessarily performed in a single step. It is quite common to use several cascading techniques, starting with a fast but inaccurate method to exclude many compounds, ending with a slow, but better method to screen the most promising compounds (see Sections 5

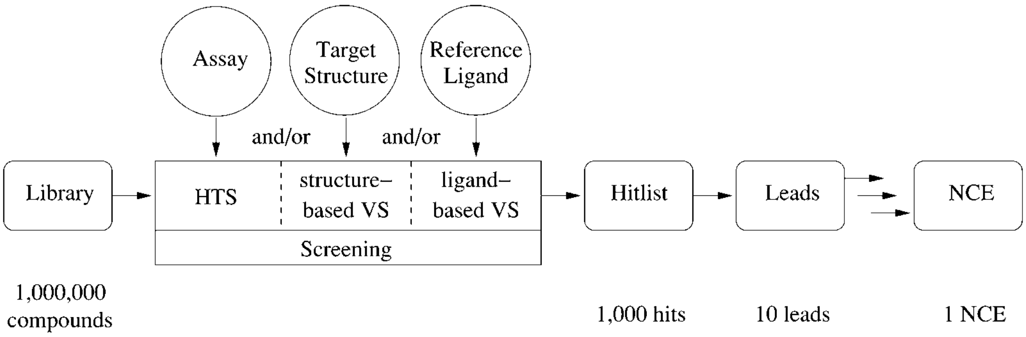

Figure 1 The drug development process. Screening is applied for reducing the number of initial compounds to a hitlist of molecules with a high binding affinity. Compounds from the hitlist are subsequently optimized to leads. The final steps (not shown) are then the finding of candidate structures, clinical trials and, finally, the approval of the new chemical entity (NCE) by the authorities.

and 6 for recent examples). Finally, a number of molecules exhibiting a strong binding affinity to the target are obtained – the *hits*. The crude hitlist obtained by these methods needs to be analyzed and compounds need to be sorted to prioritize subsequent lead selection (Section 4). In further steps of drug development, top-ranking compounds of the hitlist are refined and a small number of lead structures exhibiting promising properties are obtained (*hit-to-lead*) which may be optimized further to finally become *candidates* used in clinical trials. The respective drug optimization techniques are described in Chapter 19 of this volume.

1.3 Compound Collections

The number of all possible drug-sized molecules, the virtual chemistry space, is huge. A systematic exploration of a small part of this space with molecules up to 11 heavy atoms was recently performed [57]. After exclusion of unsuitable chemicals with many small rings, over 13 million different compounds remained. A typical drug molecule can be up to twice as large as the compounds investigated in this study (average mass of 340 Da [55], about 24 heavy atoms). Estimates of the number of "drug-like" molecules accessible to current synthesis procedures are of the order of 10^{60} [18] to 10^{100} [200]. These numbers indicate that even when combining all compounds ever synthesized (estimated 10^{8} molecules), we cover an almost negligible fraction of the virtual chemical space.

Compounds for screening can be obtained from databases of known structures, from combinatorial libraries or from *de novo* design programs. Due to problems with synthesizability, often only known structures are considered. Typical databases with organic laboratory compounds [e.g. MDL Available Chemicals Directory (ACD, http://www.mdli.com/products/experiment/available_chem_dir) or SPRESI (http://www.spresi.com)] are not suitable sources for screening compounds due to the nondrug-like properties of most of the entries. (In fact, these databases are used as references for nondrugs, see below.) Much better sources are collections available in-house to pharmaceutical companies or offered by screening compound vendors, containing historical compounds and combinatorial libraries. Within the MDL Screening Compounds Directory (SCD, http://www.mdli.com/products/experiment/screening_compounds) database, over 3 million screening compounds are listed together with supplier information. Unfortunately, all these compound databases need extensive cleanup to be suitable for drug screening. Very recently, ZINC, a curated large screening library of purchasable compounds has become available [85], in which all the necessary preprocessing steps (Section 2.1) have been performed.

Reference data on pharmaceutical compounds at various stages of development can be taken from the MDL Drug Data Report (MDDR, http://www.mdli.com/products/knowledge/drug_data_report), the World Drug Index (WDI, http://scientific.thomson.com/products/wdi), or the MDL Comprehensive Medicinal Chemistry (CMC, http://www.mdli.com/products/knowledge/medicinal_chem) database.

2 Filtering and Preparation of Ligands

The data from screening compound collections are usually not suitable for VS off the shelf. On the one hand, this is due to incomplete information (often missing 3-D coordinates, stereochemistry, hydrogen atoms). On the other hand, chemical libraries tend to contain a number of undesired compounds and a lot of duplicates. Thus, before a library of compounds can be used in VS, a number of preparatory and filtering steps (Section 2.1) have to be applied. Among these filters, bioavailability (Section 2.2) and drug-likeness (Section 2.3) of the compounds are of special relevance. The overall preparation process is summarized in Figure 2.

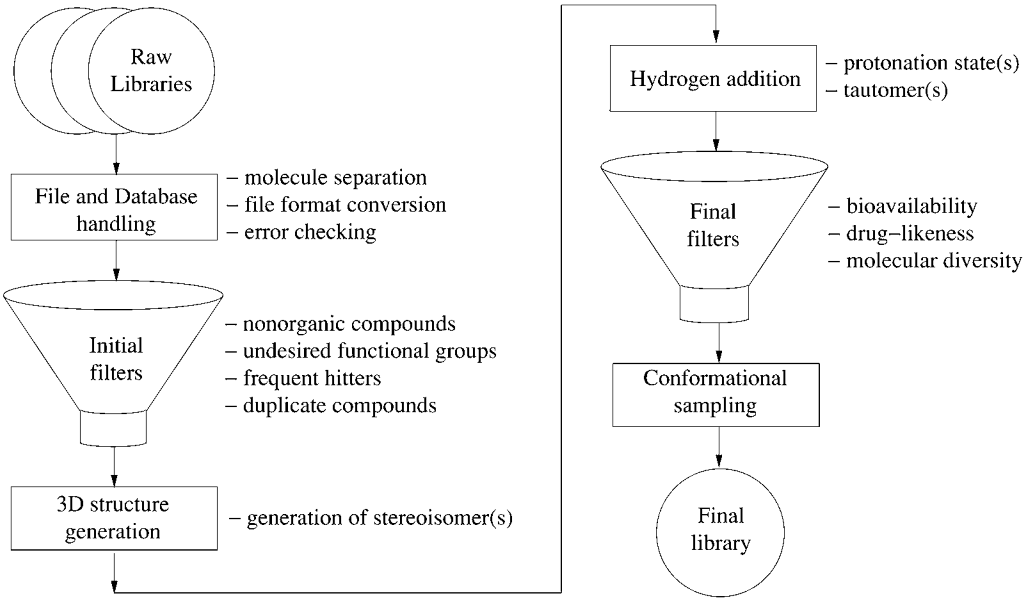

Figure 2 Example preprocessing workflow for chemical libraries (see text for details).

2.1 Library Preprocessing

An initial preprocessing step comprises the separation of entries with more than a single molecule (e.g. containing a charged species and its counterions) into their constituent entries. Next, all nonorganic molecules (e.g. chloride ions, water) must be removed. The most obvious and easiest method is the removal of all molecules without any carbon atom. Alternatively, as almost all drugs contain a bond between carbon and a hetero-atom, another strategy is to remove molecules without any of these bonds.

Then the library is subjected to a functional group filter. Here substructure search is performed in order to identify and discard compounds with known undesired groups in the library. This technique can be applied to reactive functional groups [170], groups unlikely to be leads, promiscuous binders and even functional groups classified as toxic [201]. Strategic pooling, a technique proposed by Hann and coworkers [75], can also be applied by using functional group filters. For instance, if the ligand is required to contain an acidic group, only compounds with this function are integrated into the final library.

A common problem of HTS and VS consists of small molecules binding to many different proteins, resulting in false-positive results (so called "frequent hitters" or "promiscuous binders") [135, 172]. By statistical methods based on substructures, Roche and coworkers [172] developed a scoring scheme based on a neural network to classify molecules as frequent hitters. Merkwirth and coworkers [141] use an ensemble model for this classification. Molecules covalently binding to proteins can be filtered out using reactive functional group filters (see above).

Finding duplicates in screening libraries significantly reduces the number of compounds to be tested. A one-by-one subgraph matching of connection tables for all pairs of compounds is too expensive for collections with more than a few thousand molecules. Instead, a representation of the molecular structure which can be compared easily is generated. Often chemical hash codes like those provided by Ihlenfeldt and Gasteiger [84] are used. Here, the molecular topology is encoded in a single number – the *hash value*. If two hash values are different, the molecules are different. If the hash values are identical, the two compounds are most likely identical. Only in extremely rare cases do two different compounds exhibit the same hash code. To be sure, a substructure matching has to be performed if two identical hash codes have been found. An alternative to hash codes is the generation of a unique string for every molecule. This can be done by using the SMILES (Simplified Molecular Input Line Entry System) representation after Weininger [210]. An enhancement of the SMILES representation can generate unique strings [209] by using an atom-ordering scheme, which is suitable for molecular comparison.

The methods described so far need the 2-D representation of the molecule in form of a connection table only. If 3-D information is needed further in the screening pipeline then, as a next step, this information must be generated from either 2-D coordinates [e.g. most structure data files (SDFs)] or connection tables [e.g. structures in 1-D string representations, like SMILES or Sybyl Line Notation (SLN)]. Due to the still large amount of data this can only be done efficiently by structure generation programs. These convert the connection table into a single low-energy conformation. The two most widely applied tools of this kind are CONCORD [157] and CORINA [176]. CONCORD uses rule sets based on literature values of bond lengths and torsion angles to construct the molecule. Based on these values, acyclic parts of the molecule are constructed. For cyclic parts special rules pertaining to ring geometries are applied. Ring systems are obtained by merging conformations of the individual rings and optimizing the geometry such as to minimize the strain. CORINA works similarly, but includes more literature data and has a backtracking algorithm for generation of strained ring systems.

While the 3-D structure is generated, information on the stereochemistry of the compound has to be included. The often incomplete annotation of the stereocenters is a pervasive problem with current compound collections. Each stereocenter offers a choice of two stereoisomers (for the relevant cases asymmetrical carbons and *cis–trans* isomerism). Which of these alternatives are explored is up to the user. An exhaustive generation of all possible stereoisomers of the compounds is one extreme, discarding the molecule due to incomplete information is the other. Typically, only a small number of stereoisomers are generated at this stage. Some programs even allow to handle stereocenters as variable during the calculation [62].

Next step in preprocessing, although often combined with structure generation, is the addition of missing hydrogens. This includes the assignment of a protonation state and an assessment of the tautomerism of the molecule. Depending on the application, either the most likely or all protonation states/tautomers are generated. A typical approach for assignment is the use of empirical rules. For example, carbonic acids are usually kept deprotonated and primary aliphatic amines are protonated. A program for generation of protonated forms is LigPrep from Schrödinger LLC (http://www.schroedinger.com). Tautomers can be generated with TAUTOMER (http://www.mol-net.de/software/tautomer) by Molecular Networks.

Depending on the methods used for screening, often the conformational space of a molecule needs to be explored by a VS program. While the structure generation programs (see above) produce a single structure only, the conformational analysis programs produce a set of alternative low-energy conformations for a molecule. Leach has reviewed the available techniques [119] and several available programs have been compared [20] whether they predict bioactive conformations correctly. The OMEGA program (http://www.eyesopen.com/products/applications/omega.html) by OpenEye, using a rule-based algorithm, currently seems to provide the best trade-off between accuracy and speed [19, 20].

During all the steps of the screening procedure the identity of the molecules (e.g. their registry numbers, order information) has to be maintained and stored, typically in a relational database system.

2.2 Bioavailability

It is highly desirable for a drug to be administered by oral ingestion in order to be easily utilized by the patient. Thus, the molecule must have reasonable aqueous solubility and has to pass the intestinal membrane in order to enter blood circulation. Bioavailability – a transport phenomenon – is often confused with drug-likeness. Here we keep these two entirely different subjects separate. We discuss bioavailability in this section and drug-likeness in Section 2.3.

By analysis of molecules that have entered clinical trials (and, thus, are bioavailable), Lipinski and coworkers established the "Rule of Five", which provides a simple heuristic rule for oral bioavailability [128]. It is likely that a molecule exhibits poor absorption, if two or more of the following criteria are fulfilled:

- Number of hydrogen bond donors (counted as number of O–H and N–H groups) > 5
- Number of hydrogen bond acceptors (counted as number of any O or N atom) > 10
- Molecular weight > 500
- Calculated $\log P > 5$ (if $C \log P$ is used, see below)

Here, $\log P$ represents the logarithm base 10 of the octanol–water partitioning coefficient, a property which can easily be calculated by property estimation techniques [143]. Among the estimation techniques for $\log P$, $C \log P$ introduced by Hansch and Leo [76] and available from BioByte (http://www.biobyte.com) is widely accepted. The idea of simple property-based rules as rejection criteria for bioavailability was extended by Ghose and coworkers [64]. Here, ranges were calculated for $\log P$, molar refractivity, molecular weight and number of atoms.

After development of fast estimation methods for the polar surface area (PSA) by Clark [31] and Ertl and coworkers [50], rejection of molecules with a PSA $>$ 140 Å was proposed as the only rejection criterion. Veber and coworkers [193] analyzed a database with drug candidates. They classified compounds as bioavailable, if the PSA $<$140 Å and the number of rotatable bonds less than 12. More detail on bioavailability and, more generally, on absorption, dissipation, metabolism and excretion (ADME) properties is provided in Chapter 19.

2.3 Drug-likeness

With the filtering methods described above, the knowledge of medicinal chemists of whether a compound might be a good drug or not is not taken into account. It is desirable that the compounds in a screening library have the typical properties of drugs. Thus, a binary classification, whether a compound is "drug-like" or not, must be performed on all compounds. The challenge regarding this problem is that "drug-likeness" is a property which is not easily evaluated and not related in a simple fashion to other chemical, physical or biological properties. In order to solve the decision problem, the knowledge of medicinal chemists for assessment of "drug-likeness" is used. The implicit knowledge on drug-likeness is inherent in the databases of known drugs and can be extracted by comparison with databases of nondrugs [5, 65, 175].

Implicit information on drugs is contained in the MDDR, WDI and CMC databases (see Section 1.3). Within these databases, not all entries are existing drugs, but the majority of entries were designed by medicinal chemists with the intention of developing a drug. In contrast, databases like the ACD or SPRESI of general organic compounds are supposed to contain very few drugs. A statistical classification technique can be used to extract the knowledge from the databases to decide whether a given compound is a drug or nondrug.

Gillet and Bradshaw [65] used structural features (including number of hydrogen-bond donors and acceptors, number of rotatable bonds, number of aromatic rings, molecular weight) and a shape descriptor. Compounds of the WDI and SPRESI databases were analyzed with a genetic algorithm to derive a weighting scheme, which calculates the drug-likeness of a given compound. Ajay and coworkers [5] used MDL keys (see Section 3.2), in addition. They applied both decision trees and an artificial neural network (ANN) for classification, trained on the MDDR and ACD databases. Sadowski and Kubinyi [175] also used a feed-forward neural network. The classification scheme was trained on atom type descriptors of compounds from the WDI and ACD databases.

Support vector machines (SVM) can also be applied to the drug/nondrug classification problem. In a comparison of SVM to neural networks, Byvatov and coworkers could obtain slightly more accurate classifications on the same data as used in Ref. [175]. Overall, the predictive power of the methods presented so far reaches a typical 80% correctly classified test molecules. Recently, Müller and coworkers [144] were able to reduce the error rate to 7% in a blind-test using SVMs. This performance was achieved by careful model selection after comparison of several learning methods. In summary, the results show that accurate drug-likeness filters can be constructed which use the knowledge on drug-likeness obtained by medicinal chemists over decades.

The technique presented can be tailored to specific screening problems. Thus, it is not the phenomenon of drug-likeness that is assessed, but the likelihood of a drug belonging to a certain class of compounds. Ajay and coworkers [4] used neural networks to classify ligands regarding their CNS activity while Manallack and coworkers [130] used them to screen for candidates binding to kinase and G-protein-coupled receptors. More recently, Briem and Günter [23] presented a SVM method for "kinase-inhibitor likeness". All these target-specific drug-likeness classification techniques have a prediction accuracy of about 80%. Thus, if there is a sufficient number (several hundred) of compounds of a certain class available as training set, machine learning techniques can be trained to predict the likeness to be a certain inhibitor with high accuracy.

2.4 Molecular Diversity

Compound collections, especially those in pharmaceutical companies, contain many series of analogous compounds. It is desirable to screen for only a subset of "maximally diverse" compounds, reducing redundant structural information. This diverse subset is hoped to cover the range of chemical structures and physical properties to a sufficient extent. Unfortunately, there is no generally accepted single definition of similarity or dissimilarity for this purpose [114]. Thus, selecting a set of diverse compounds can be performed in a number of ways. These differ not only in the method, but also in the selection criteria used. These techniques have been reviewed on several occasions [1, 39, 126].

Among the methods for selecting diverse compounds, clustering methods can be considered as the standard technique. For clustering, descriptors (see Section 3.1) are calculated for each compound. Then a cluster analysis algorithm divides a group of compounds into clusters. Compounds within a cluster are similar and compounds from different clusters are dissimilar. After clustering of a library, a representative molecule is taken from each cluster to belong to the diverse compound collection. For clustering of chemical libraries, typically methods generating disjoint clusters are used in which each molecule belongs to a single cluster only. Both, hierarchical [9, 211] and nonhierarchical [213] methods, have been applied. Evaluations of different clustering algorithms demonstrate the better performance of hierarchical clustering methods for several test cases [12, 24, 46]. Naive implementations of hierarchical clustering need an initial $N \cdot N$ similarity matrix, and have space and time complexities of $O(N^2)$ and $O(N^3)$, respectively. By use of the minimum variance method (also called Ward's method) [206] which aims on minimizing the total variance of a cluster, however, a computationally more efficient implementation is possible [146], having space and time complexities of $O(N)$ and $O(N^2)$, respectively. For large numbers of compounds ($N > 10^6$) hierarchical clustering is not applicable. Instead nonhierarchical clustering (e.g. K-means clustering [139]) is used. For these algorithms the time complexity for K generated clusters is $O(KN)$ per iteration for efficient implementations. For descriptions of clustering algorithms, see also Chapters 24 and 27.

A different approach to select diverse compounds is provided by partitioning methods. These use a low-dimensional property space, each property represented by a continuous number that is categorized into a discrete set of value ranges, forming a set of cells in property space [37, 125]. Compounds from a library are then partitioned into these precomputed cells. Two special kinds of descriptors – BCUT descriptors by Pearlman and Smith [155] and pharmacophore keys by Davies [38] – can be used for partitioning chemical property space. BCUT comprises molecular descriptors based on the eigenvalues of a matrix representation of the molecules. These descriptors are designed specifically to define a low-dimensional property space. For the description of the properties, axes are chosen that span property space in such a way that the compounds exhibit maximal variance along the axes and compounds are evenly distributed in property space [155, 156].

Davies [38] developed ChemDiverse, a program using pharmacophore keys for the selection of diverse compound sets. The basic idea is to calculate the pharmacophore key for the first molecule, add the molecule to the diverse compound selection and store the pharmacophore in a list. Subsequently, for the next molecule in the library, the pharmacophore keys are calculated. If this molecule has a pharmacophore key not yet represented in the list, the molecule is added to the selection.

A completely different attempt to find diverse compounds is by dissimilarity-based compound selection. Among them, maxmin by Lajiness [118] is most used. The maxmin algorithm first selects a compound randomly and adds it to the selection. Iteratively, the compound most dissimilar to the already selected set is identified and added to the selection, until a desired number of compounds has been found. A stochastic variant, OptiSim, has been proposed by Clark [32]. The initial random compound is compared to a set of K other randomly chosen compounds. Here, only compounds with a dissimilarity greater than a defined threshold to the already selected compounds are considered. The most dissimilar compound among the *K* compounds is added to the selection. In the next iteration a new set of *K* candidates is generated and the process continues.

Taylor [187] proposed a method based on the stepwise elimination of the most similar molecule from the collection. Initially the similarity matrix between all molecules is calculated. In a stepwise fashion, the two currently most similar compounds are identified, as long as there is more than a single compound left.

While diversity is desired in initial screening runs for identification of hits, once a lead is found, compounds should be similar to the lead, i.e. the library should be "focused". The clustering and partitioning methods can be used directly for generation of focused libraries by switching the selection criteria from one of each kind to all of one kind.

3 Ligand-based VS

The methods of ligand-based VS can be divided into two classes. One class of methods tries to match compounds with identical parts (substructure or pharmacophore) as the active molecule. For these methods, initially, a number of active molecules are analyzed for a common substructure or pharmacophore, which is then used for searching exact matches. The other class tries to find molecules which are "similar" to a known active molecule. The underlying assumption is that if a molecule is structurally similar, it has similar properties, binds in a similar binding mode and exhibits similar activity. This assumption is known as the "similar property principle" [40, 87] or "neighborhood behavior" [153]. Methods for similarity search are applicable if only a single active compound is known. In contrast to substructure and pharmacophore searches, the compounds are not only partitioned with regard to whether they are matching the query or not. Instead, a complete ranking of compounds according to their similarity scores is obtained. Similarity, like dissimilarity, is not clearly defined [114] and there are some remarkable exceptions from the similar property principle [114, 131]. Nevertheless, similarity search is the most widely used method in VS and numerous similarity measures have been developed [181]. Figure 3 illustrates the most common similarity search techniques, detailed below.

The actual methods for defining molecular similarity in this context are quite diverse. Often these methods are classified as 1-, 2- or 3-D, depending on the type of molecular representation used. In this section first we focus on those methods that use the information of a single reference molecule. Then techniques that need a set of input molecules are discussed. The latter are also

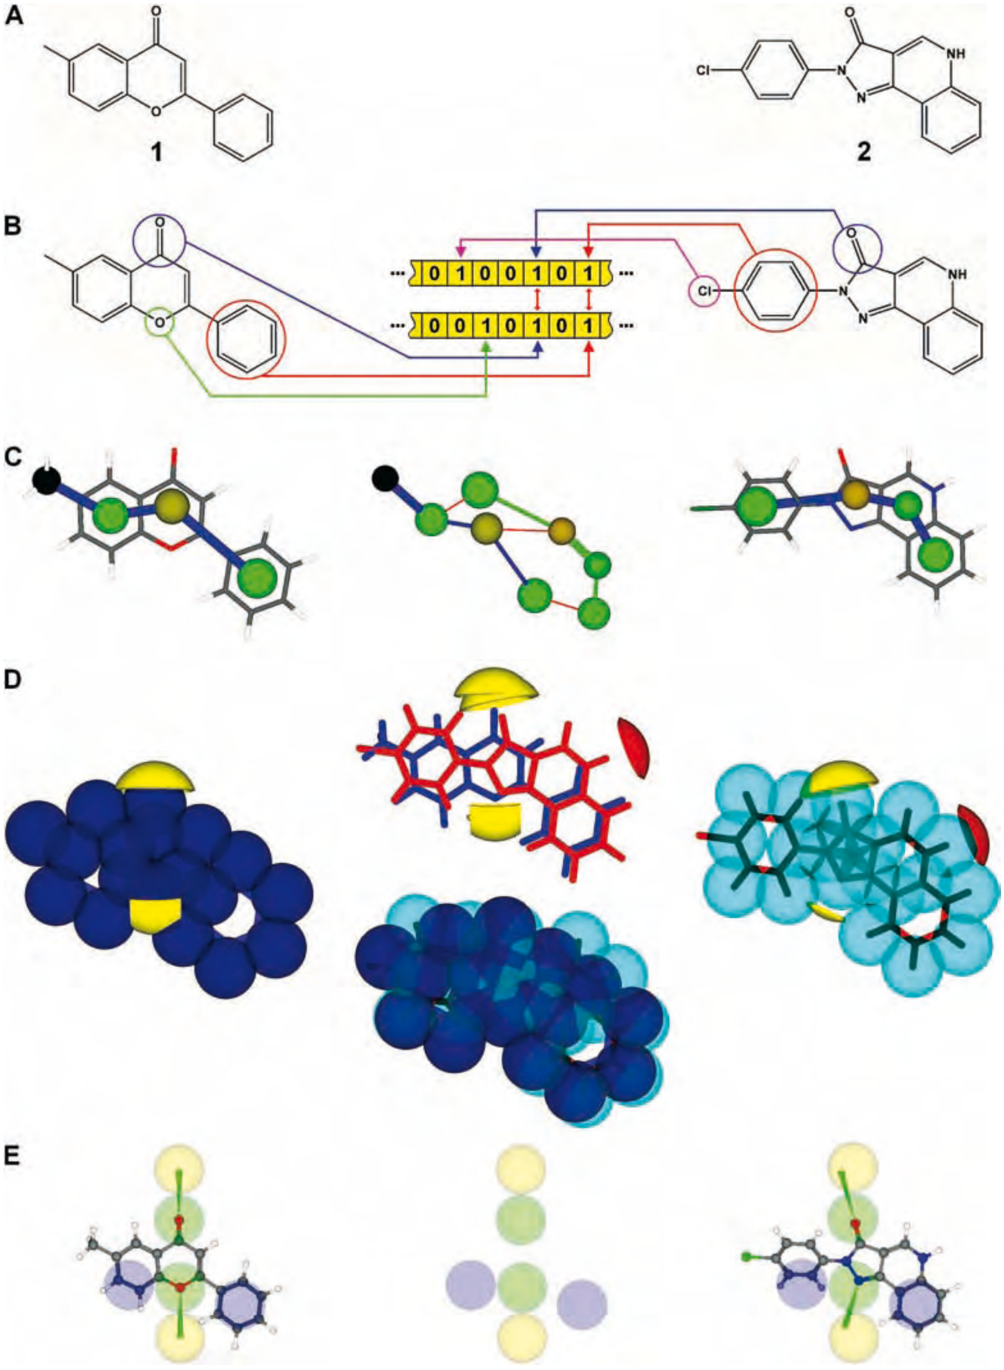

Figure 3 Comparison of common ligand-based screening techniques (see text for details). (A) Example molecules: flavonoid molecule (**1**, test molecule) and a known binder (CGS-9896, **2**, reference molecule) for the benzodiazepine site of the GABA$_A$ receptor [89]. (B) Bitstring generation and comparison. (C) Generation and comparison of feature trees. (D) Comparison by molecular superimposition using FlexS (center top: molecular interaction surfaces, center bottom: molecular volume represented by Gaussian functions. (E) Comparison of both molecules to a pharmacophore model (center).

often used for the selection of compounds from hitlists. These techniques are described in Section 4.

3.1 Descriptor-based Similarity Measures

Similarity search methods have been used for a long time. The field started with counting the numbers of substructures common to a pair of molecules [27,212]. This figure provides an initial effective way of quantifying similarity between molecules with very low computational cost. Since then, it has become a standard retrieval technique for chemical databases.

Methods for calculating quantitative measures for the similarity between a reference molecule and a set of molecules have been studied in detail (see Ref. [211] and references therein). Common to all these techniques is the requirement to provide a set of attributes of the molecules being compared and a similarity coefficient, to provide a quantitative numerical measure for similarity between the molecules. The individual importance of different attributes (e.g. log P, molecular mass, presence of functional groups, etc.) has to be accounted for by definition of a weighting scheme.

Many different similarity coefficients have been proposed in the literature. Some are measures of dissimilarity, while others measure similarity directly. In this chapter, we focus on the most widely used similarity and distance coefficients only, more details can be found in another review [8]. One of the most frequently used distance measures is the Euclidean distance $D_{A,B}^{\text{Euclidean}}$ between two molecules A and B described by properties $x_1 ... x_n$. For continuous property variables, the distance is defined by:

$$D_{A,B}^{\text{Euclidean}} = \sqrt{\sum_{i=1}^{n} \left(x_{i_A} - x_{i_B}\right)^2}. \tag{1}$$

The most often used similarity measure is the Tanimoto coefficient $S_{A,B}^{\text{Tanimoto}}$. This coefficient can be interpreted as the fraction of the number of features present in both molecules divided by the number of features present in at least one of the compounds. For continuous variables it is defined by:

$$S_{A,B}^{\text{Tanimoto}} = \frac{\sum_{i=1}^{n} x_{i_A} x_{i_B}}{\sum_{i=1}^{n} x_{i_A}^2 + \sum_{i=1}^{n} x_{i_B}^2 - \sum_{i=1}^{n} x_{i_A} x_{i_B}}. \tag{2}$$

Willett and coworkers [212] assessed the performance of several distance and similarity coefficients for predicting a measured activity value. The Tanimoto coefficient performed best and, since then, it has become the "standard" coefficient for chemical similarity comparison. Furthermore, this coefficient was shown to be the most appropriate for similarity searches in 2-D databases [212].

In order to compare two molecules in a quantitative fashion, numerical values of attributes of the molecules are needed. The term "molecular descriptor" subsummarizes all numerical representations of chemical information about molecules obtained by a defined mathematical procedure. As example, the molecular descriptor "molecular weight" (*MW*) is defined exactly as the sum of all atomic weights of a molecule:

$$MW = \sum_{i=1}^{n_{\text{atoms}}} m_i. \tag{3}$$

The number of different chemical descriptors which have been proposed for the field of quantitative structure–activity relationships (QSARs) and VS is large (several thousands are described in detail in the handbook by Todeschini and Consonni [189]) and an extensive discussion is out of the scope of this chapter. However, some descriptors have become very important in VS. Among them, $\log P$, *MW* and molar refractivity are typically used in the preprocessing of libraries (see Section 2.2). BCUT descriptors are useful in diversity analysis (see Section 2.4). A second important class of descriptors are bit strings, used in molecular similarity search, as detailed in the next section.

3.2 Bit String Descriptors

For VS the most popular descriptors are based on binary vectors (also called bit strings). The idea of using binary vector representations has its origin in chemical database systems. Bit strings are used in substructure queries to efficiently discard large fractions of the database, before subsequently a much slower subgraph isomorphism algorithm is used. The length of the bit strings varies from roughly 100 bits [218–220] to several million bits [136], depending on the type of information stored. The two most widely used approaches are substructure keys and hashed fingerprints.

Substructure keys [MDL keys available from Elsevier MDL (http://www.mdli.com) and BCI structure fingerprints available from Barnard Chemical Information Ltd. (http://www.bci.gb.com)] represent a description of the substructures present in a molecule (Figure 3B). Within the binary vector, each of the positions is 1, if the corresponding substructure is present in the molecule, 0 otherwise. All substructures for the bit string are predefined in a fragment dictionary. Entries can encode the presence of certain atoms (e.g. there is at least one N present in the molecule) or common functional groups (e.g. ester function). Furthermore, electronic (e.g. *O* with double-bond) and structural features (e.g. six-membered ring) are described by bits.

In hashed fingerprints [Daylight Chemical Information Systems (http://www.daylight.com)], substructure information is encoded by an algorithm. All possible paths of atoms and bonds through the 2-D formula of the molecule, up to a certain certain path length are generated by systematic search, e.g. for a path length of 3 the path C=C–N–C. These patterns are then converted to integer numbers and hashed. The hash code is generated using these numbers as seeds for a pseudo-random number generator, resulting in the fingerprint of this path. The advantage of hashed fingerprints is their applicability to any type of structure without the need of a precomputed fragment dictionary. A disadvantage is the possibility of the same bit string being calculated from different atom paths which may result in false positives, since these hash conflicts are not solved. Unity available from Tripos (http://www.tripos.com) uses a combined approach of substructure keys and hashed fingerprints.

For the use with binary variables, the two similarity coefficients from above can be reformulated. If a denotes the number of bits set (to 1) in molecule A, b for molecule B and c the number of bits set in both molecules, the Euclidean distance becomes:

$$D_{A,B}^{\text{Euclidean}} = \sqrt{a + b - 2c}\,, \tag{4}$$

and the Tanimoto coefficient is given by:

$$S_{A,B}^{\text{Tanimoto}} = \frac{c}{a + b - c}. \tag{5}$$

The substantial advantage of linear descriptions for chemical structures is their speed. The counting of numbers of bits set (a, b, c) can be done computationally very fast, resulting in several hundred thousand molecule comparisons per minute. This allows for fast comparison of millions of compounds in minutes to hours. A disadvantage of the methods described so far is that they cannot detect the similarity between two compounds that behave similar with respect to binding to the target protein, but are structurally quite different [35]. Thus, the techniques cannot find a scaffold different from the scaffold of the reference molecule (scaffold-hopping).

3.3 Feature Trees

Feature trees [166] comprise a class of descriptors in between the classical linear descriptors described in Section 3.1 and molecular superimposition techniques (Section 3.4). In this technique (Figure 3C), a molecule is described as a tree that represents its overall topology. Nodes of the tree represent fragments of the molecule. The nodes are connected by edges if the fragments are also connected by covalent bonds or sharing of atoms. A set of features is assigned to each of the nodes, representing physicochemical properties of the respective fragment. Steric features comprise the number of atoms in the fragment and the approximated van der Waals volume. Chemical features include the interaction profile of the fragment, i.e. whether it acts as hydrogen donor or acceptor, is an aromatic ring, and also represent the hydrophobicity of the fragment.

Similarity between molecules is calculated by matching the two corresponding trees, while preserving their topology. A similarity score quantifies the quality of the fit. The advantage of feature trees provides a more accurate description of chemical properties than by linear descriptors. However, the tree-matching procedure is slower, due to the higher computational complexity of the tree comparison. Typically, thousands of molecules can be compared per minute.

3.4 Molecular Superimposition Approaches

Molecular superimposition techniques structurally align a compound to a reference ligand in 3-D space. During the alignment, matching parts of both molecules are placed on top of each other. The large variety of algorithms for molecular superimposition has been reviewed by Lemmen and coworkers [123]. The application of superposition techniques for VS has also been reported [121].

In general, the molecular superimposition can be achieved in two ways. Either a field-based approach is used, in which properties of the molecules are projected onto a common surface or into three-space. The other method aligns pairs of atoms directly. Early approaches achieved this goal by rigid-body superimposition. Newer programs can handle one or both molecules as flexible on the fly. Nevertheless, the rigid-body techniques are much faster and are thus often preferred. An intermediate technique is to address molecular flexibility by considering a set of alternative conformations of the molecule.

A rigid-body superimposition program reads a reference ligand and a test ligand, then performs an optimization of the position and orientation of the test ligand in space. Early attempts using combinatorial approaches to enumerate efficiently possible matches (correspondences) of chemical features of the two molecules [91, 133] are too computationally intensive. With the program SEAL (Steric and Electrostatic ALignment) [92] and later enhancements [98], for the first time Gaussian functions were used for describing the physicochemical properties of the molecules and a new algorithm was applied to tackle the rigid superpositioning problem efficiently. The description of chemical features by Gaussian functions has several advantages [68]. First, a Fourier transform of a Gaussian is again a Gaussian. Second, there is no boundary which helps in the initial steps of alignment. Furthermore, derivatives can be calculated easily (even symbolically) and, finally, the overlap between two Gaussians increases when their maxima approach each other.

An improvement of the search algorithm was proposed by Lemmen and coworkers [120] in their program RigFit. The optimization is split into two independent optimizations for rotation and translation. Thus, one 6-D search is separated into a sequence of two 3-D searches.

Current state of the art are programs for flexible superpositioning of two molecules. Sheridan and coworkers [180] use distance geometry for superposition, while Itai and coworkers [86] proposed a technique, in which all possible matchings between pharmacophoric points are evaluated in a combinatorial matching. For both techniques, the definition of the pharmacophore is still needed as prerequisite. The combined Monte Carlo and energy-minimization-based technique by McMartin and Bohacek [137] also needs manual intervention. The program GASP [88] was the first method available that was able to handle the structural flexibility of both molecules involved and was not constrained by predefined relationships between functional groups assumed to be similar. GASP is based on a genetic algorithm which mimics the process of evolution. The conformations of each molecule and the correspondences between intramolecular features are coded via so-called chromosomes. In order to modify the superimposition, the chromosomes are subjected to the operations of mutation (local changes) and crossover (splitting and merging of two chromosomes). A population of chromosomes is repeatedly subjected to these modifications and then evaluated with a fitness function. Only the fittest chromosomes survive to the next round. The fitness function used in the selection process of each superposition is calculated by volume overlay, intermolecular matching energy and the conformational energy.

A different technique for superposition, FlexS, uses incremental construction [122]. Here the reference molecule is handled as rigid and the test molecule is flexible. The test molecule is partitioned into fragments which are connected by rotatable bonds. A number of relatively rigid fragments is selected and aligned to the reference molecule. Then the next fragment is attached to the previously placed fragment in all allowed torsion angles. The list of admissible torsion angles is derived by statistical analysis [100] of the Cambridge Structural Database (CSD) [6]. All generated placements are scored by paired intermolecular interactions and overlap, the latter being described by Gaussian functions (see Figure 3D). The best partial solutions are subjected to the next incremental construction cycle until the complete test molecule is build up. The mean computing time is in the order of 30 s per superpositioning for typical test cases.

Krämer and coworkers [107] developed fFLASH, using a fragmentation-reassembly approach. The tool is based on earlier work on FLASHFLOOD [164]. fFLASH describes the query molecule as rigid and the test molecules are handled flexibly. All test molecules are partitioned into fragments by severing rotatable bonds, expanded to a set of conformations, and all conformers stored in a database. Pairs of adjacent fragments are joined and a set of conformations of the fragment pair is generated by varying the dihedral angle at the connecting bond. Molecular interaction features are then calculated and stored in a lookup table. By use of a clique detection algorithm, patterns of features of fragment pairs of the test molecule are geometrically matched on the reference molecule. These matches are subsequently joined, based on the pairwise compatibility of two matches, by a graph algorithm.

3.5 Pharmacophore Searches

A pharmacophore is usually defined as a set of molecular features and their rigid spatial arrangement, which is necessary for ligand–receptor binding [73]. A pharmacophore is typically composed by three to four pharmacophoric centers and their respective distances (Figure 3E). Pharmacophores are applied in 3-D database searches after they have been determined from a set of active ligands. In VS, pharmacophores can also be used as constraints in structure-based screening. Pharmacophores can also act as 3-D descriptors. Often pharmacophores are encoded in the form of bitstrings, known as pharmacophore fingerprints, which are directly applicable for screening (see Section 3.2).

In ligand-based VS, the true pharmacophore is unknown and must be determined first. Pharmacophore perception is closely related to molecular superpositioning, e.g. the program GASP [88] can perform both tasks. Nevertheless, since the programs of both groups are tailored to their specific research areas they are described separately. For automatic determination of a pharmacophore hypothesis a set of active ligands as a training set is needed. The pharmacophore perception is then performed in a number of steps: First, 3-D structures of the molecules must be generated with one of the methods described in Section 2.1. Then the molecules are analyzed in order to identify atoms that can interact with a protein in a characteristic way. Commonly, these pharmacophoric features are acidic and basic groups, hydrogen acceptor and donor sites, aromatic, and hydrophobic groups. In the next step, conformations of the molecules are passed to the pharmacophore perception algorithm. Here, conformations of the molecules are compared in order to identify pharmacophoric features common to all molecules. A number of programs have been developed for pharmacophore identification [73], among them the commercially available tools Catalyst/HipHop [33], DISCO [132] and GASP [88]. For a recent review and a comparison of these three, see Ref. [152]. These programs differ with respect to how the conformations are handled and how the molecules are aligned and compared. GASP uses a genetic algorithm (see Section 3.4) to describe the molecules as flexible. DISCO uses a set of low-energy conformations which are kept rigid throughout the calculation and a clique-detection algorithm is used for rigid-body alignment. Catalyst/HipHop also uses a set of rigid low-energy conformations of the molecules, but then performs a pruned exhaustive search to identify configurations common to all molecules. Once the pharmacophore is identified, it can be used to screen a 3-D database.

An extension of the ligand-based pharmacophores described so far is the use of structural information of the receptor for pharmacophore generation. Two recent examples of these structure-based pharmacophores are the works of Wolber and Langer [214] and Griffith and coworkers [72].

3.6 QSARs

The structure and the physicochemical properties of a molecule can be used to model its biological activity. The mathematical description of this relationship in a quantitative way is the aim of QSAR techniques. In order to model structure–activity relationships, first, for each compound in the library a number of molecular descriptors have to be calculated. In a second step, a quantitative relationship between these descriptors and the activity is derived. This section covers only some selected techniques from the field of QSAR, which has grown in terms of using more and more sophisticated descriptors, and also more sophisticated statistical tools for finding correlations between structure and activity.

The classical technique is Hansch analysis which correlates activity with physicochemical properties by use of regression analysis. Hansch and coworkers [77] described the dependency of the concentration C needed for a certain biological response in terms of the hydrophobicity (expressed by the $\log P$ value) and electronic effects (using the Hammett constant σ) by the equation:

$$\log \frac{1}{C} = k_1 \cdot \log P + k_2 \cdot \sigma + k_3. \tag{6}$$

Here, the k_i are the coefficients to be fitted by the regression. Using this type of QSAR analysis, today, several thousand successful applications have been reported and a database of QSAR equations is electronically available (http://www.cqsar.com/medchem/chem/qsar-db). The descriptors applied include steric, electronic and hydrophobic effects as well as indicator variables. These values are obtained either by computer prediction techniques or experimentally. Due to the large number of descriptors available, the dependency between them has to be studied in order to find the relevant ones. This "feature selection" is usually done based on principal components analysis (PCA) [61] or its extension partial least squares analysis (PLS) [82].

An extension of the classic approach was the introduction of 3-D information of the ligands to reflect the geometry of their binding to receptors, including their chirality. The first of this 3-D-QSAR techniques was the Comparative Molecular Field Analysis (CoMFA) [34] which turned out to be very successful (many examples can be found in Refs. [111–113]). In CoMFA a set of molecules is selected which have an identical binding mode, i.e., they bind to the same site in the same relative geometry. To derive the CoMFA model, for all training set molecules, first, partial charges are assigned and low-energy conformations are generated. Then the molecules are aligned by use of a pharmacophore hypothesis and positioned inside a 3-D grid. For each grid point and for each molecule separately, "field" values (interaction energies) are calculated for charged and uncharged probe atoms. Finally, PLS analysis is used to correlate the fields with biological activity data. The result of this analysis is typically represented as a set of contour maps showing favorable and unfavorable regions for certain substituents. Several techniques have been proposed to obtain better fields. By calculating fields with GRID [71] or HINT [94] more different probes can be used which allows modeling of a wider range of interactions. By replacing CoMFA potentials with SEAL (see Section 3.4) similarity fields (Comparative Molecular Similarity Indices Analysis, CoMSIA [99]) the results become more stable. A frequent problem for PLS can be the high number of noise variables not contributing to the description. With GOLPE (Generating Optimal Linear PLS Estimations) [10] the meaningful variables can be selected and the predictive ability of the model is checked by cross-validation. A cause of error for CoMFA, CoMSIA, GRID/GOLPE and related techniques is the mutual alignment of all molecules. There are methods available that retain the 3-D information, but are independent of the alignment. Examples for these techniques are WHIM (Weighted Holistic Invariant Molecular indices) [188], which uses the moments of atomic properties as descriptors, and the related technique MS-WHIM [21], which uses molecular surface points instead of the atoms as descriptors.

In the classical 3-D-QSAR methods described above, only information on the geometry of the ligands is used. In 4-D techniques multiple conformations or orientations of the ligands are considered simultaneously. It is even possible to include information on the protein structure to which the ligands are bound in the QSAR model. The program Quasar by Vedani and coworkers [195] is a method which constructs a receptor-surface model and bridges between 3-D-QSAR and receptor modeling, taking induced fit into account. Currently, multidimensional QSAR studies are extended up to six dimensions to allow for the simultaneous consideration of different solvation models [194].

3.7 Other Techniques

The interaction of a ligand with a target molecule can be described in terms of the respective molecular surfaces, that have to be complementary with respect to both physicochemical properties and shape. Finding optimal surface complementarity is the main aim of docking procedures (see Chapter 16). Thus, the comparison of different ligands in terms of their molecular surfaces and the properties mapped to them is a valuable similarity criterion.

Among the many techniques of molecular surface comparison, we focus on the recent graph-based method SURFCOMP of Hofbauer and coworkers [79] and the gnomonic projection method [17] as examples. The comparison of two surfaces, each described by a point set in three-space is not an easy task. The problem can only be solved efficiently if the surface model is simplified. In SUFRCOMP, first a representation of the surface via overlapping circular patches is calculated. Then the centers of these patches, representing critical points, are reduced in number using a number of filters and matched via maximal common subgraph comparison.

Blaney and coworkers [17] use gnomonic projection of the molecular surface properties onto equispaced points on the surface of an enclosing sphere. To do so, the points in space at which vectors from the sphere's surface to the "center" of the molecule cut the molecular surface are calculated. The physicochemical properties on the cutpoint farthest from the "center" are then projected onto the sphere. The comparison of the projections of two molecules is then performed after mapping of the property values on two dimensions.

A different type of measuring similarity between molecules is the use of "virtual affinity fingerprints" [124, 208]. In the Flexsim-X method by Lessel and Briem [124] ligands are flexibly docked into a carefully selected reference set of protein-binding sites using the FlexX docking program [165]. The highest-ranking solution of each docking run is selected. The virtual affinity fingerprint of a ligand is then defined as the vector of docking scores obtained for the different binding pockets. Molecules are compared by the Euclidean distance between their affinity fingerprints. The technique was shown to detect molecules with similar biological affinity without prior knowledge of the target protein structure. An extension of this work to calculate similarities of functional groups is Flexsim-R [208].

4 Postprocessing of Hitlists

HTS or VS runs of a compound collection with up to millions of entries results in a huge volume of data. The obtained list of hits is rather crude and needs substantial clean-up. There are a number of computational methods for the postprocessing and analysis of screening data. First, the output is simplified by removing data points where the screening failed (e.g. no docking solution, failure during experiment). Here, also data not needed in postprocessing (e.g. intermediate results, log files) are discarded. Second, the most promising hits have to be selected mostly on the basis of their rank in the hitlists or by criteria based on the scores, in order to reduce the data set to manageable size. To identify leads among the screening data is a challenging problem, addressed by a number of different computational methods. The often concealed information can be extracted by data-mining procedures (Section 4.1). A general problem of screening data consists of false-positive results. Especially for results of structure-based VS runs, some techniques have been developed to identify and discard false positives (Section 4.2). Whenever a combination of different techniques is used in screening, each technique results in a different hitlist. Here, consensus techniques help in picking hits (Section 4.3). Nevertheless, the most important method is still the visual inspection of the results by an experienced medicinal chemist, assisted by visualization tools (Section 4.4).

4.1 Data Mining

A common approach for mining hitlists is the search for families with similar chemical structure among the active compounds. Here active compounds (actives) are those with high affinity, high scores or high similarity after screening. Chemical families can be identified by grouping the compounds with similar chemical structure. A chemical family is characterized by a common scaffold. Substructure search among the results can be applied to identify these families. Roberts and coworkers developed LeadScope [171], a structural classification technique. The method classifies compounds into a collection of predefined chemical families. The predefined families are arranged hierarchically, starting with a major structural class on top, which is subdivided further. For example, a 3-methoxy-pyridine derivative is found in the pyridine → pyridine, 3-R → pyridine, 3-alkoxy class of the hierarchy. For each structural class, activity data and frequency in the data set is depicted in an intuitive bar plot.

As an alternative, techniques for similarity search (Section 3) can be applied to identify families. In this case, the families are defined by a high degree of similarity. For grouping the families, clustering techniques are often used (as described in Section 2.4). Due to the importance of hitlist mining, a number of dedicated clustering techniques have been developed [49, 185].

Another approach to data mining using classification techniques is recursive partitioning (RP) [173,221]. RP is a nonparametric classification technique (as opposed to the many parameters in QSAR models), in which the whole set of compounds is recursively classified into disjoint subsets using statistically determined rules. In this manner, a tree is constructed, in which some terminal nodes (leaves) are enriched with actives, while other leaves contain mostly inactive molecules. If the path from a leaf with actives is traced back to the root node, the molecular descriptors used for partitioning at the inner nodes can be used to characterize or to search for actives.

Nicolaou and coworkers developed a classification method using a phylogenetic-like tree (PGLT) [147]. This tree is constructed using a combination of techniques. Each node has bins for active and inactive compounds. First, all active molecules are stored in the active bin of the tree's root node. Then, in an iterative fashion, a clustering of the molecules of the current leaf is performed, using a criterion based on chemical descriptors. In a next step, cluster level selection is performed to select a set of "natural" clusters. Each of the "natural" clusters is then subjected to a maximum common subgraph (MCS) search. Common substructures are evaluated by a set of rules to evaluate each and to discard all those not providing new knowledge. The rules, for example, discard substructures already found in other nodes, or those identical or subsets of the parent node. Then, for each of the remaining substructures, all molecules from the parent node containing the respective MCS are added to a newly created tree node. Finally, a node is selected at which the iteration proceeds. After the actives have been used to construct the tree, a postprocessing procedure is performed in order to prune the tree and reduce it to contain only nodes with structurally homogeneous families. This is done by adding inactive compounds to the inactive bins of the PGLT using the substructure rules derived with the actives. For each node, the similarity between actives and inactives is calculated and nodes with dissimilarities are eliminated. The technique described has been implemented in the program ClassPharmer [Bioreason (http://www.bioreason.com)].

4.2 Analysis of the Protein–Ligand Interface

A particularly interesting type of strategy that can be applied to results of structure-based screening is the analysis of structural properties of the bound protein–ligand complex. Although this method also belongs to docking techniques (see Chapter 16), we describe it here as a representative example for an important class of postprocessing techniques. Current scoring functions favor the formation of many protein–ligand hydrogen bonds and salt bridges, even if the structures exhibit only limited steric complementarity overall due to holes along the interface or larger parts of the ligand being exposed to the solvent. Stahl and Böhm [184] propose a postprocessing procedure of docking results. For a set of generated docking poses, first, all poses with close contacts between polar atoms that do not take part in hydrogen bonds are discarded. Then the fraction of ligand volume located inside the cavity is calculated. Poses with less than average buried volume are discarded. The size of lipophilic cavities at the protein–ligand interface also acts as filter criterion: poses exceeding the minimum value by more than 25 Å are discarded. Finally, the solvent-accessible surface of nonpolar parts of the ligand is calculated and used for rescoring.

Giordanetto and coworkers [67] also propose the use of solvent-accessible surface areas. These authors perform a classification of all receptor and ligand atoms into classes, depending on the physicochemical properties of hydrophilicity, charge and hybridization. Then descriptors are calculated that describe the energetic cost of burying the atoms. In addition, conformational entropy differences between holo and apo form of the protein are calculated. Here, an amino acid-based conformational entropy contribution of the protein after Murphy and Freire [145] to the binding affinity is used. By use of these techniques, affinity predictions could be improved on the cost of less accurate binding mode prediction.

Results from docking studies can also be analyzed by structural interaction fingerprints as proposed by Deng and coworkers [41]. These interaction fingerprints are a translation of the structural information of a protein–ligand complex into a binary vector. The technique can be applied for identification and clustering of similar docking poses.

4.3 Consensus Techniques

The combination of several different computational methods is another approach to reducing the number of false positives and prioritizing molecules for further study. Some of these methods are only applicable to structure-based techniques, while some use mixtures of different computational methods, including ligand-based techniques. The prototype of the structure-based methods in this field is consensus scoring [28]. Here, one docking program is used to generate a docking pose. Then the highest ranking structure is re-evaluated with different scoring functions. If the compound is not among the top-scoring compounds for all scoring functions applied it is discarded. In a computer experiment by Wang and Wang [205] it has been shown that hit rates improve significantly after consensus scoring if three or four scoring functions are used.

Methods using not only different scoring functions, but different docking techniques go a step further [154]. In the ConsDock approach, docking is performed with three different docking programs and a set of 30 top-ranking poses is stored obtained with each of them. Then a hierarchical clustering is performed on each set and the highest-ranking pose within each cluster is defined as its "leader". Consensus pairs are defined, where two of the docking programs result in similar leaders. Each of these pairs is then described by its mean and clustered again into classes. Finally, the mean pose of the clusters is subjected to re-ranking according to the number of entries in each class.

The use of entirely different computational techniques for investigation of hitlists has been proposed by some groups. Klon and coworkers [102,103] use a combination of docking and machine learning. First, docking of a library is performed with three different docking programs. Then a naive Bayesian classifier is trained on the docking scores of the top-scoring compounds, which are labeled as "good", if their score is better than a threshold. The compounds themselves are described by an extended-connectivity fingerprint as structural descriptor [Pipeline Pilot program available from SciTegic (http://www.scitegic.com)]. Application of the Bayesian classifier for re-ranking the hitlists improved the enrichment in most of the test cases, without any *a priori* knowledge of the activity of the compounds.

Especially in docking, the high-dimensional search space can be explored a bit further to re-rank hitlists. On the one hand, a multiconformer description of the protein can be used [199]. On the other hand, not only the top-ranking pose, but several poses can be used for calculating the score [104].

Ginn and coworkers [66] proposed the use of data fusion for combining molecular similarity measures. In this procedure, a similarity search is performed with at least two different similarity measures i. The rank positions r_i of each individual structure in the hit lists are then combined to a new score. With the fusion rule $\sum_{i=1}^{n} r_i$ the performance is at least as good as the best individual measure.

4.4 Visualization

For the simultaneous display of screening-result data in several dimensions, a number of techniques are available [3, 63, 116]. The techniques have been implemented in several tools for display of screening data using highly sophisticated graphical data representations for visual data mining [DecisionSite (Spotfire; http://www.spotfire.com), ClassPharmer (Bioreason; http://www.bioreason.com), LeadNavigator (LION Bioscience; http://www.lionbioscience.com)]. Results are plotted in multiple dimensions, combining data from different databases. The data points in the plots are linked to the corresponding chemical structures and vice versa. This enables the medicinal chemists to identify patterns within the results. A technique for visualization of the multidimensional screening data is the nonlinear mapping of the data to a lower-dimensional space with just two or three dimensions. The usual technique for nonlinear mapping is multidimensional scaling [110]. This technique aims at keeping points close together in low-dimensional space if they are also close together in the original data-space.

With recent enhancements [2, 216], multidimensional scaling is applicable to large-screening data sets. Despite all the efforts in visualization techniques, it has been pointed out that visual data-mining tools are not applicable to extremely large and complex data sets [147]. Furthermore, due to their "interactive" approach, these tools cannot readily be integrated into fully automated screening procedures.

5 Critical Evaluation of Structure-based VS

Nowadays a large collection of docking/scoring tools is available for high-throughput virtual screening. Out of the flow of information generated over the last 5 years, a computational chemist entering into a VS project will have to make a few decisions about the screening strategy and the tools which are the most suited to their project. Section 5.1 is aimed at pinpointing some good practices in order to avoid classical failures. Section 5.2 will review some recent success stories which could inspire the reader for future work.

5.1 Influence of Parameter Settings

Several input parameters may affect the effectiveness of a VS run. Depending on the computational tool that has been chosen, the number of parameters may vary from around a dozen to over 100. It is therefore crucial to select the best possible input settings, which unfortunately are not always known in advance. However, a few robust guides based on current knowledge can be derived.

5.1.1 Which Library?

As reported above (Section 1.3), several commercially available compound collections are available. There is usually no reason to favor one particular compound collection over another. As most of them are easily accessible [11, 182], the best possible approach for an academic user is to start from a unified and filtered data set [85]. Of course, corporate and focussed/targeted libraries may also be used. They are particularly interesting for screening targets belonging to heavily investigated families (e.g. kinases, GPCRs) and containing a high percentage of true positives.

Whatever the database selected, it is generally advisable to downsize the number of molecules which will be submitted to 3-D docking. Apart from some important filters [chemical reactivity (see Section 2.1), drug-likeness (see Section 2.3), etc.], it is important to remove molecules which do not fulfill simple 2- or/and 3-D pharmacophoric features. This simple strategy aids in dramatically reducing the number of potentially interesting compounds without losing many true positives [51, 129]. If one is simply interested in setting-up optimal screening conditions (e.g. discriminating a few true actives from randomly chosen decoys), it remains important to carefully set-up the test data set in order to avoid artificial enrichments in true actives by making sure that chemical spaces covered by actives and inactives/random compounds largely overlap [197].

5.1.2 Which Ligand Conformation(s)?

Most docking programs only require a single low-energy conformation for each ligand of the data set, provided by automated 3-D converting utilities [157, 176]. For docking tools requiring a multi conformer ligand library, it is important to start from biologically relevant conformations. Several studies agree to conclude that the most reliable conformations are not necessarily produced by the most accurate and CPU-demanding methods. A safe start is to use fast conformer generators like Omega (http://www.eyesopen.com/products/applications/omega.html) or Catalyst [33], which accurately sample the biologically relevant conformational space for a wide array of chemotypes [19, 70, 93, 96].

5.1.3 Which Protein Coordinates?

When screening a high-resolution X-ray structure, several input coordinates might be available describing either ligand-bound (holo) or a ligand-free (apo) structures. A systematic survey over nine enzymes unambiguously demonstrates that the holo form, if it exists, should be the first choice [19]. Furthermore, X-ray structures appear to clearly outperform the corresponding homology models in discriminating known inhibitors from random decoys [134, 150]. However, if the sequence identity (on binding site-lining residues) to the X-ray template is higher than 50%, comparable enrichment rates in true inhibitors can be found [150]. This encouraging result suggests that genomic-scale VS might be feasible, provided that an accurate description of the binding sites can be drawn from existing X-ray templates.

5.1.4 Which Docking Tool?

Starting from the pioneering work of Kuntz and coworkers [115], numerous docking programs based on very different physicochemical approximations have been reported (see Chapter 16). All docking tools combine a docking engine with a fast scoring function and the recent literature is full of benchmarks addressing the accuracy of one or few docking/scoring scenarios. The three following issues are usually investigated: (i) the capability of a docking algorithm to reproduce the X-ray pose of selected small-molecular-weight ligands [93, 105, 159], (ii) the propensity of fast scoring functions to recognize near-native poses among a set of decoys [56, 203] and to predict absolute binding free energies [56], and (iii) the discrimination of known binders from randomly chosen molecules in VS experiments [36, 93, 159]. However, analyzing all these data for a comparative analysis of available docking tools is very difficult. First, many tools are not easily available. Second, independent studies assessing the relative performance of docking algorithms/scoring functions are still rare and focus on the use of few methods. Third, the quality judgment may vary depending on the examined properties (quality of the top-ranked pose, quality of all plausible poses, binding free energy prediction, virtual screening utility). Fourth, most docking programs assume approximation levels that can vary considerably [74] and lead, for example, to very inhomogeneous docking paces ranging from few seconds to few hours. Last, many docking programs have been calibrated and validated on small protein–ligand data sets. Hence, detailed benchmarks (above 100 Protein Data Bank–ligand complexes) are only reported for few docking tools [28, 43, 108, 149, 151, 196]. The most recent validation studies on different data sets agree to conclude that the accuracy of a docking tool is largely target dependent [74, 96, 159, 203] and should be examined on a case-by-case basis. Glide and Gold seem to be the most robust programs for their propensity to generate near-native poses in around 75–80% [96, 159], provided that several solutions are stored. A major problem is that the scoring function does not always predict the correct solution as the most probable one (only in around 40–50 % of the cases). This considerably complicates the analysis of docking results. Numerous reasons explain this limited accuracy [93]. Some are easy to correct (e.g. incorrect atom type for either the ligand or the protein), some are more difficult (e.g. accuracy of the protein 3-D structure, flexibility of the ligand, accuracy of the scoring function) and some are really tricky to overcome (protein flexibility, role of bound water). The accuracy of a docking program to predict the protein-bound ligand pose is reflected in its VS efficacy, i.e. the ability to discriminate true binders from inactives and/or randomly chosen compounds [36,93,159]. However, predicting which docking program will be the most suited for a research project is still problematic. If known ligands are available, a pragmatic approach is to try a systematic combination of docking/scoring parameters and select for productive screening the one that best segregates true actives from true inactives. If no or very few ligands are available, some guides may be followed to choose the tool that seems the most appropriate regarding the physicochemical properties of the protein cavity [93].

5.1.5 Which Scoring Function?

The scoring function still remains the Achilles' heel of structure-based VS. Several recent and independent studies conclude that many fast scoring functions can indeed distinguish near-native poses (RMSD < 2.0 Å from the X-ray pose) from decoys for around 70% of high-resolution protein–ligand X-ray structures [56, 203]. However, when docking is applied to a large database, the corresponding scoring function should be robust enough to rank putative hits by increasing binding free energy values [97]. Unfortunately, an accurate prediction of absolute binding free energies is still impossible whatever the method [36, 56, 204]. Predicting binding free energy changes is possible at the condition that a customized scoring function is applied to a series of congeneric ligands. However, for a database containing a large diversity of compounds, and for targets which have not been traditionally used for calibrating scoring functions, the obtained accuracy is usually limited (around 7 kJ mol^{-1} or 1.5 pK units) [75]. From this observation, two sources of improvement are possible: (i) design more accurate scoring functions [204] or (ii) design smarter strategies to postprocess docking outputs (see next section). Many computational chemists actually favor the second option. The accuracy of scoring functions has leveled off several years ago, for the simple reason that some unknown parameters (e.g. role of bound water, protein flexibility) remain extremely difficult to predict whatever the physical principles used to derive a scoring function.

5.1.6 Which Postprocessing?

Acknowledging that scoring functions are far from being perfect, the easiest way to retrieve true positives from a VS is to first detect false positives. Many strategies are possible. The simplest consists in rescoring poses with additional scoring functions; hoping that a consensus scoring [15, 28] will better identify true hits (top-ranked by several scoring functions) from decoys (see Section 4.3). Comparing hit rates between simple and consensus scoring should, however, be realized on hit lists of comparative size [217]. Moreover, customizing a consensus scoring scheme requires first the knowledge of several and chemically diverse true hits. Such data are not always available. Therefore, for less well-investigated targets, other strategies have to be designed. Topological filters can be used to filter out poses exhibiting steric or electrostatic mismatches between the ligand and its target [184]. Poses can also be minimized by a more accurate force field [90, 186], hierarchically clustered [154] or analyzed by Bayesian statistics [103]. In any case, the postprocessing treatment should be simple enough to be reproducible for a wide array of targets. The influence of different postprocessing strategies on the hit rate and the percentage of true hits recovered is shown in Figure 4 (the top-right corner with a hit rate of 100% and all true hits recovered would be the optimum).

An alternative strategy for postprocessing is to look at enrichment among true hits in pre-computed substructures/scaffolds [147]. This presents the advantage of focusing more on scaffolds and the distribution of docking

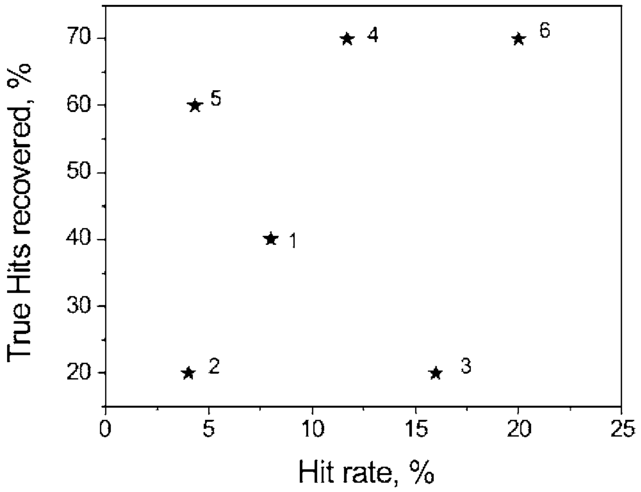

Figure 4 Influence of postprocessing strategies in retrieving true vasopressin V1a receptor antagonists by structure-based screening of a database of 990 randomly chosen "drug-like" compounds seeded with 10 true actives [16]. (1) Top 5% ligands as scored by FlexX; (2) top 5% ligands as scored by Gold; (3) hits common to (1) and (2); (4) ClassPharmer [Bioreason (http://www.bioreason.com)] prioritization of scaffolds for which 60% of the representatives have a FlexXscore lower than $-22\,\text{kJ}\,\text{mol}^{-1}$; (5) ClassPharmer prioritization of scaffolds for which 60% of the representatives have a Goldscore higher than 37.5; (6) ClassPharmer prioritization of scaffolds for which 60% of the representatives have a FlexX score lower than $-22\,\text{kJ}\,\text{mol}^{-1}$ and a Goldscore higher than 37.5.

scores among them, and less on individual molecules. The effect is evident from Figure 4, where the results of such a postprocessing are closer to the optimal corner. Therefore, false negatives may be recovered if they share a scaffold with true positives. Last, but not least, selected hits should be browsed in 3-D target space for the ultimate selection: no algorithms yet outperform the brain of an experienced modeler for such a task!

5.2 Recent Success Stories

Only recent reports from the literature (2003–2005) will be reviewed herein. Most of them still make use of high-resolution X-ray structures. (Sections 5.2.1 –5.2.3). However, encouraging data begin to emerge from homology models (Section 5.2.5) and thus broaden the application of structure-based screening methods to a wider array of pharmaceutically-interesting targets.

5.2.1 **Some Privileged Targets**

Macromolecular targets presenting a well-defined hydrophilic pocket for which the directionality of intermolecular interactions play a key role in ligand recognition are particularly well suited for VS for the simple reason that most docking tools and scoring functions have been calibrated for such situations [56]. Thus, it is no surprise that some protein families (e.g. kinases) are overrepresented in targets for which true inhibitors have been discovered by database docking (Table 1).

Protein kinases have been heavily investigated by structure-based VS [59, 83, 129, 158, 190, 191] to identify novel inhibitors for three major reasons: (i) kinases are among the most relevant target families for the pharmaceutical industry, (ii) a wide array of high-resolution protein–ligand X-ray structures is available for validation purposes and (iii) a canonical hydrogen-bonding to the so-called "hinge region" of the kinase is a typical hallmark of ATP-competitive inhibitors. Two recent studies [129, 191] are representative of the results which might be expected for kinase inhibitors. Vangrevelinghe and coworkers reported a knowledge-based VS protocol for identifying casein kinase II (CK2) inhibitors, in which post-docking filters were designed to downsize the hitlist [191]. Starting from around 400 000 compounds which were docked using Dock4.01 to the 3-D structure of human CK2, 12 000 molecules were first retrieved by score. This primary hitlist was then reduced to 1,592 molecules by selecting only hits which were hydrogen-bonded to the "hinge segment" of the protein and well scored by a consensus scoring function. Visual check of the remaining hits afforded a hit list of only 12 compounds out of which three molecules inhibited the enzyme with an IC_{50} lower than 10 μM.

Pre-docking filters may be useful as well in selecting the most interesting compounds by similarity to known chemotypes present in kinase inhibitors. A good illustration of this strategy has recently been reported by Lyne and coworkers in the discovery of checkpoint kinase-1 inhibitors [129]. A hierarchical screening protocol involving filters of increasing complexity (simple molecular descriptors, 3-D pharmacophore search, FlexX-Pharm constrained docking, knowledge-based consensus scoring) decreases the number of virtual hits from 400 000 to 103, and allowed to identify novel inhibitors in four chemical series. Interestingly, most true inhibitors were not recovered among the top-ranked poses, but by rescoring at least the top 50 poses by a consensus scoring protocol designed from a surrogate kinase (Cdk-2) and a test data set. Post-docking filtering by similarity to well-defined intermolecular interactions may also be a reliable option as it was recently shown to outperform consensus scoring in identifying protein kinase B inhibitors [59]. In the above-cited cases, a precise knowledge-based selection of the most reliable compounds has been achieved thanks to the large information available for related compounds.

The same remark applies to three recent studies aimed at discovering inhibitors of two reductases (dihydrofolate reductase, aldose reductase) [106,

Table 1 Successful structure-based screening data from the recent literature (2003–2005).

Target	Docking	Library	Size	Hit rate[a]	Reference
Chk-1 kinase	FlexX	AstraZeneca	550000	36% @ 68μM	[197]

167, 215], extensively studied in the past. Wyss and coworkers [215] docked a library of 2,4-diaminopyrimidines to the X-ray structure of DHFR from

S. aureus complexed with an in-house inhibitor. In total, 252 out of the 300 top-ranked compounds could be synthesized and tested for DHFR inhibition; 21 % of the proposed compounds inhibited DHFR from either *S. aureus* or *S. pneumoniae* with IC_{50} values lower 10 µM. Remarkably, a structure-based screening protocol was found to be much superior to a ligand-based diversity selection in enriching a hit list in true inhibitors.

Rastelli and coworkers [167] screened a subset of the ACD for inhibitors of the DHFR from *Plasmodium falciparum* which would be insensitive to specific active site mutations. The full data set was first filtered by Catalyst [Accelrys Software (http://www.accelrys.com/products/catalyst)] to retrieve molecules satisfying a set of 3-D pharmacophores generated from known protein-inhibitor X-ray structures and potentially able to bind to some enzyme mutants. Docking the focussed data set using Dock, then selecting the top-ranked molecules interacting with a key residue and clustering by chemotypes afforded a final list of 24 molecules. Twelve compounds truly inhibited DHFR wild-type as well as active-site mutants at micromolar concentrations.

Krämer and coworkers [106] identified, from the ACD, aldose reductase inhibitors by a series of hierarchical filters implying substructure similarity search to known inhibitors, 2-D pharmacophore filtering, FlexX docking and DrugScore scoring. Compounds able to bind to the anionic pocket of the enzyme were prioritized for purchase and experimental evaluation. Out of the nine compounds tested, six exhibited micromolar inhibition of the target. Interestingly, DrugScore values were weighted according to the molecular weight and number of rotatable bonds of the corresponding molecules to favor the selection of lead-like compounds.

5.2.2 **First-in-class Compounds**

Not all targets are suited for experimental HTS. However, if 3-D coordinates are available, VS is still a cheap alternative to HTS. Two recent studies [148, 183] demonstrate the power of VS for quasi-orphan targets (XIAP, Stat3) of interest for discovering new antitumoral drugs. The X-ray structure of XIAP complexed to a peptidic inhibitor was used to identify, within a database of 8000 compounds derived from traditional Chinese medicinal herbs, a non-peptidic micromolar XIAP inhibitor [148]. Likewise, 429 000 compounds from various screening collections were docked to the X-ray structure of Stat3 – a signal transducer and activator of transcription. Rescoring the top 10% scored compounds from each data set with X-score [202] yielded 200 compounds, out of which 100 could be purchased and tested for Stat3 inhibition [183]. As in the previous study, obtained hit rates at micromolar concentrations were rather low (a single hit out of 100 compounds tested), but a totally novel compound could be discovered and used as a basis for further improvement.

Nucleic acids have not been widely investigated in structure-based screening approaches mainly because of the lack of accurate scoring functions. Foloppe and coworkers [58] recently reported the successful discovery of bacterial ribosomal A-site ligands by using a docking tool (RiboDock) specifically designed for that purpose [142]. An electronic catalogue of 1 million commercially available compounds was first filtered to select lead-like compounds and further docked to the crystal structure of the *Escherichia coli* ribosomal A-site. Visual inspection of the top 2000 best-scoring compounds yielded a list of 129 molecules which were evaluated by a FRET binding assay. Five compounds, unrelated to the aminoglycoside series, exhibited an apparent inhibition constant lower than 50 µM. This study is promising by widening the scope of application of high-throughput docking to nonprotein targets and more successful applications are expected in the near future thanks to a better parameterization of common docking tools for predicting ligand binding to nucleic acids [42].

5.2.3 Fragment Screening

Fragment screening by X-ray or nuclear magnetic resonance (NMR) [197] is becoming an increasingly popular method for identifying low-molecular-weight leads, which usually show a greater optimization potential than drug-like compounds [80]. Due to the difficulty in correctly ranking docking poses of small fragments, computational screening of low-molecular weight compounds is still in its infancy. Two recent reports [26, 162], however, indicate that this approach might be promising.

Pickett and coworkers reported the discovery of low-molecular inhibitors of inosine 5′-monophosphate dehydrogenase (IMPDH) by virtual needle screening [162]. A test set of 21 true IMPDH inhibitors and two in-house X-ray structures was first used to select the most adequate docking/scoring combination (FlexX docking/ScreenScore scoring). A corporate database of 3425 low-molecular-weight reagents was then docked to both X-ray structures to retrieve, among top-ranked compounds, 100 virtual hits satisfying a visual check. Out of the 74 compounds evaluated for IMPDH inhibition, three molecules exhibited an IC_{50} lower than 35 µM.

Carbone and coworkers [26], although not explicitly looking for fragments, also discover low-molecular-weight inhibitors of L-xylose reductase by structure-based screening. Hence, this enzyme is characterized by a very shallow active site and most known xylose reductase (XR) inhibitors are short-chain fatty acids. By screening with the Dock program around 240 000 compounds from the NCI data set [National Cancer Institute, Enhanced NCI Database browser (http://129.43.27.140/ncidb2)] against the X-ray structure of XR, a limited number of putative hits (around 1000) could be prioritized by score and known interactions to key catalytic residues. Out of 39 molecules that were purchased and evaluated for XR inhibition, two carboxylic acids (nicotinic acid, benzoic acid) inhibited the target with IC_{50} values under 100 μM.

Chapter 16 discusses methodical aspects of fragment-based drug design.

5.2.4 Lead Optimization

A large majority of structure-based screening projects are aimed at identifying hits. However, lead optimization might be possible under the condition that the binding mode of the starting lead can be unambiguously recovered, and that a rationale exists for selecting the next compounds to synthesize and test. Krier and coworkers [109] recently proposed a straightforward approach for exploring a lead series by enumerating small-sized libraries (a few hundred compounds) in which all combinatorial assemblies of a few linkers and pharmacophoric moieties to a given scaffold are probed. The selection of the best analogs was based on FlexX docking to the X-ray structure of the phosphodiesterase target and topological filtering. A single-round screening campaign on nine synthesized analogs yielded to a subnanomolar inhibitor and a 900-fold improvement in affinity over the starting lead. Lead optimization is discussed in detail in Chapter 19.

5.2.5 Homology Models as VS Targets

All the above-reported applications have used high-resolution X-ray structures to represent the 3-D coordinates of the target under study. However, enzymes for which a crystal or an NMR structure are still missing, but which show enough sequence homology (around 50%) in the active site to a X-ray template, can also be used for database docking approaches with reasonable success [138]. However, there is still a debate whether targets ranging in a much lower homology range (below 30%) might be reliable starting points. This observation is particularly relevant for GPCRs, a target family of utmost pharmaceutical interest for which a single X-ray structure (bovine rhodopsin) might be used for comparative modelling. Several recent reports [13,16,53,54, 192] demonstrated that GPCRs might be suitable indeed for structure-based screening. In all the above-cited successful cases, preliminary knowledge about known ligands was necessary to fine tune the receptor model. Moreover, the choice of a relevant pharmacophore hypothesis was a key factor to downsize the number of molecules for docking. Last, a visual inspection was necessary to ensure that key intermolecular interactions were established with selected hits. Although the derived homology models remain crude with respect to high-resolution X-ray structures, drug-like submicromolar antagonists for rhodopsin-like receptors [13,16,53,54,192] have already been discovered by VS.

5.3 Concluding Remarks

VS of compound libraries by high-throughput docking is nowadays a routinely used computational technique for identifying bioactive ligands with numerous proofs of record. One should, however, keep in mind that the method is highly sensitive to the 3-D coordinates of the target and is likely to generate numerous false positives. As important as the docking itself are the pre- and postprocessing steps, which are key factors to optimize the hit rate. The number of new validated chemotypes amenable to optimization is therefore a better descriptor than the simple hit rate, which varies considerably with regard to the current knowledge on a particular target. VS is a natural complement to traditional medicinal chemistry and particularly well suited for proposing new molecular scaffolds that can be easily converted into focussed ligand libraries of higher values. Both methodological improvements (scoring, hit triage, prediction of ADMET properties) and better screening collections (focussed and targeted libraries) should contribute to improve the value of this powerful tool in a near future.

6 Critical Evaluation of Ligand-based VS

The choice of tools for ligand-based VS is at least as complicated as for structure-based techniques. While for structure-based techniques mainly the "right" docking program has to be chosen, for ligand-based VS also the method itself, e.g. similarity search or pharmacophore search, has to be chosen. The first part of this section will evaluate and compare several methods and give guidance for selecting appropriate methods and/or tools for the screening. The second part will then, as in Section 5, review some recent success stories and, finally, will draw some conclusions on which methods to apply.

6.1 Influence of Parameter Settings

For ligand-based VS the considerations about the choice of the library and its preprocessing are identical to those for structure-based screening (see Section 5). The main selection process is then, which method among those of Section 3 is chosen. This depends mainly on the number of known active ligands available. If at least some (more than five, better more than 20) ligands are known, a ligand-based pharmacophore model can be derived. If additionally their activity is known, QSAR techniques are possible. If, however, less actives are known, only similarity searches can be performed at this stage.

6.2 Recent Success Stories

Here, we review recent studies from the literature (2003–2005) covering the entire field of ligand-based techniques (Table 2), ranging from pharmacophore searching over similarity searching to QSAR studies.

Table 2 Successful ligand-based screening data from the recent literature (2003–2005).

Target	Method	Library	Size	Hit rate[a]	Reference
ERG2	pharmacophore	WDI[b]	48405	55% @ 1 μM	[117]
σ_1 receptor	pharmacophore	WDI	48405	63% @ 1 μM	[117]
Emopamil binding protein	pharmacophore	WDI	48405	73% @ 1 μM	[117]
Kv1.5	pharmacophore	Aventis	NA[c]	6% @ 6 μM	[161]
A_{2A} purinergic receptor	pharmacophore similarity	combinatorial library	192	53% @ 10nM	[179]
mGluR5	pharmacophore similarity	Asinex	194563	33% @ 70μM	[168]
Tat-TAR RNA interaction	pharmacophore similarity	SPECS library	229659	11% @500μM	[169]
H_1 receptor	QSAR	combinatorial library	9000	87% Watanabe[d]	[48]
Trichomonas vaginalis	QSAR	in-house	100	25% *in vitro*[e]	[140]
Kv1.5	similarity	Aventis	NA	1% @ 10μM	[160]
MCH-1R	similarity[f]	24 collections	650000	2% @ 30μM	[30]
D_3 receptor	pharmacophore fingerprints	two collections	255286	40% @100nM	[25]
COX-2	pharmacophore fingerprints	commercial collections	2700000	15% @ 10μM	[60]

[a] Hit rate at a concentration threshold. The hit rate is the ratio of the number of active compounds to the total number of compounds tested.
[b] World Drug Index (http://scientific.thomson.com/products/wdi).
[c] not available
[d] Antihistaminic activity according to the protocol of Watanabe and coworkers [207].
[e] Cytocidal activity of 100% after 48 h at a concentration of 100 μg ml^{-1}.
[f] A combination of 2- and 3-D substructure search 2- and 3-D similarity as well as clustering was used.

The studies of Laggner and coworkers [117] and Peukert and coworkers [161] demonstrate the application of ligand-based pharmacophore models in VS. Laggner and coworkers [117] built pharmacophore models for ERG2, the emopamil binding protein (EBP) and the σ_1 receptor using Catalyst. The training set comprised 23 structurally diverse ligands with a broad activity range from picomolar to micromolar affinity. The pharmacophore models were assessed using cost analysis and randomization tests. Furthermore, on a test set of nine molecules with binding affinities from subnanomolar to micromolar, from 26 measured affinities, 14 were predicted within 1 order of magnitude. The pharmacophore models were then used for VS of the WDI. From the WDI, previously known binders were found as expected, but also a number of new hits. Among them, 11 were experimentally tested and hit rates between 55 and 75% were obtained for the three targets. Subsequently, the pharmacophore models were altered to perform a search in a subset of the KEGG database of 3525 metabolites. Peukert and coworkers [161] described the discovery of novel blockers of the Kv1.5 potassium ion channel based on pharmacophore search. The authors used DISCO for pharmacophore elucidation using a training set of seven known Kv1.5 blockers. The pharmacophore model obtained was consistent with published SAR data and was able to retrieve 58% of a testset of 423 known Kv1.5 blockers. A 3-D search was performed on the Aventis compound collection resulting in 1975 hits after filtering. In a subsequent clustering, 27 clusters were obtained and representatives of 18 clusters were screened *in vitro*. One active compound was found with an IC_{50} of 5.6 μM belonging to a new class exhibiting a favorable pharmacokinetic profile.

Schneider and Nettekoven [179] demonstrated the use of a topological pharmacophore similarity model named CATS [178]. This approach was applied to the prediction of selective purinergic receptor (A_{2A}) antagonists from a virtual combinatorial library. From a preliminary SAR model an ANN [self-organizing map (SOM)] was trained. Molecules were encoded by the CATS descriptor and the features were mapped from 150-D space onto the plane of a SOM. Each field of the SOM has thus certain pharmacophore features in common. With this technique, the library was reduced from 192 to 17 combinatorial products. These 17 molecules exhibit 3-fold higher binding affinities and 3.5-fold higher selectivities than the initial library. The most selective antagonist displays 121-fold selectivity and an affinity of 2.4 nM. The CATS3D descriptor, a 3-D extension of the CATS approach, was used by Renner and coworkers [168] to identify metabotropic glutamate receptor 5 (mGluR5) modulators. From the original library of 194 563 molecules, first, the 20 000 most "drug-like" compounds were selected and screened by similarity of the CATS3D vectors with each of seven active molecules. Of the obtained 27 top-scoring molecules, nine exhibited an activity below 70 μM. The authors validate that the method used allows for pharmacophore-based similarity searching with "scaffold-hopping". This descriptor was also reported to be successful for identification of new inhibitors of the Tat–TAR RNA interaction [169]. In addition, a "fuzzy" pharmacophore approach (SQUID) was also used. Again, the 20 000 most "drug-like" compounds of an initial library of 229 658 compounds were screened. In the VS the similarities were calculated by the Manhattan distance for the CATS3D and a similarity score for the SQUID, respectively. Both techniques revealed 10 hits, with one molecule overlap. Two molecules among them had IC_{50} values of 500 and 46 μM, respectively.

A screening for antihistaminic compounds blocking the H_1 receptor was performed by Duart and coworkers [48] using a QSAR model based on molecular topology descriptors. From the initial virtual library of 9000 compounds, 236 molecules were predicted as active. Of the selected seven most promising compounds, experimental testing exhibited antihistaminic activity in 87%. The discovery of trichomonacidal compounds was reported by Meneses-Marcel and coworkers [140]. A linear discrimination analysis (LDA) QSAR model was trained to classify molecules using atom-based quadratic indices as descriptors. Since validation of the model revealed 88% good classification, a virtual screening was performed. Biological assays of eight compounds selected by screening gave good classification. Two molecules maintained their efficacy against *T. vaginalis* even at 10 μg ml^{-1} and one of them did not show cytotoxic effects in macrophage cultivations.

A 2-D similarity search with Unity was performed by Peukert and coworkers [160] for blockers of the Kv1.5 ion channel. Using a compound with an IC_{50} of 0.1 μM as reference molecule, 75 compounds with a similarity value of 0.8 or greater were found in the Aventis compound library and experimentally tested. In this step a moderately active compound (IC_{50} = 9.5 μM) was discovered. Although this compound was rejected due to problems with its stability and properties, a compound with similar side-chains, but a different scaffold (naphthene spacer replaced by a biphenyl group), was identified as lead (IC_{50} = 4.8 μM).

Clark and coworkers performed substructure and similarity searches, both in 2- and 3-D, among other techniques, for discovering MCH-1R antagonists. As query compounds 11 known MCH-1R antagonists were selected. The combined hits from all searches were selected (3015 molecules) and assessed for drug-likeness, synthetic tractability and molecular properties. After duplicate removal, 1490 compounds remained which were clustered using Daylight fingerprints. After final visual inspection, 795 compounds were purchased and biochemically screened, resulting in 19 compounds with IC_{50} values below 1 μM and the best having an IC_{50} of 50 nM. Clark and coworkers analyzed, which of the searches revealed which of the 19 compounds. Six compounds were found by 3-D similarity search with FlexS only, also six were found by 3-D substructure search only, two were found by a clustering approach only and one was revealed only by 2-D similarity search. Just four compounds were discovered by more than a single technique. The hit rates were in the range of 0.0 (2-D substructure) to 5.6% (2-D similarity).

6.3 Comparison of Structure- and Ligand-based Techniques

Recently groups at Roche [14], Aventis [52] and Argenta Discovery [30] compared structure- and ligand-based techniques for VS for GPCR targets. Bissantz and coworkers [14] performed a comparative evaluation of the techniques for searching 5-HT$_{2C}$ agonists, while Evers and coworkers [52] performed the comparison on four different biogenic amine-binding GPCRs (α1A, 5-HT$_{2A}$, D2 and M1 receptors), and Clark and coworkers [30] used a number of ligand-based techniques (see above) and compared them to structure-directed pharmacophores.

In the work of Bissantz and coworkers, the results of docking into homology models with FRED were compared with results from Daylight fingerprints, feature trees and the program Phacir. The performance was assessed by hit rate, enrichment factor and the diversity of the structure retrieved. The test database was a collection of actives and inactives from the Roche compound depository, with high similarity between actives and inactives. Four molecules were used as reference for the three similarity search programs (so in total 12 similarity searches were performed) and the top 20% of the ranking lists were analyzed. Each of the 207 actives was retrieved with at least one of the methods by combining the results for each of the reference molecules. When looking at the 12 screening runs, in each individual search many compounds were not retrieved or, even worse, not a single compound with some of the scaffolds was found. Furthermore, the results show that the success of the methods depends strongly on the choice of the reference ligand. While all three similarity measures obtained hit rates of at least 4.8% and enrichment factors of 2.3 or greater for one of the ligands, for another reference ligand the best hit rate was only 2.8%. Some combinations of method and reference ligand did not perform better than random selection. For comparison, the docking program FRED was applied using different scoring functions. The hit rate was between 3.0 and 4.5% and the enrichment factor between 1.5 and 2.2. Thus, while the top-performing ligand-based techniques reached better hit rates than docking, docking always performed better than half of the ligand-based screening runs. Furthermore, the compounds retrieved by structure-based techniques were more diverse on average than those from ligand-based screening. The authors conclude that the results of structure-based screening are more stable than those of ligand-based screening. The latter can yield higher hit rates, but only for some of the reference ligands. Based on these results, the authors propose to combine at least one similarity search with a docking technique.

Evers and coworkers [52] also compared docking into homology models to ligand-based protocols. For the latter, ligand-based pharmacophores, multiple feature trees (MTrees) as well as 3-D similarity by FlexS and QSAR models were applied. Pharmacophore and MTree models were compared on two different reference ligands (one for each class of ligand molecules) for each GPCR. In this study, ligand-based pharmacophore, MTrees and 2-D-QSAR techniques received higher enrichment factors than docking into the homology model with GOLD and FlexX-Pharm. However, the results with GOLD were still satisfying. The authors conclude that docking into GPCR homology models can be useful if no or only a few active ligands are known. In this study the hit rates obtained with FlexS are worse than those obtained from the other virtual screening techniques applied. This is in contrast to results of other studies (e.g. Ref. [30], see above and below) where FlexS gives respectable results. Evers and coworkers conclude that a "fair" comparison can be made only by using several reference structures for the queries.

Clark and coworkers [30] compared a set of different ligand-based methods (see above) to searches using structure-directed pharmacophores. The pharmacophores were generated by docking one ligand into a homology model, then aligning nine other molecules with GASP on the docked conformation and refining the complexes by simulated annealing. Based on this alignment, three different pharmacophore hypotheses were derived and used as queries, but none of them gave rise to a hit.

Ligand- and structure-based VS has not only been compared for GPCR targets. Another group at Aventis used a number of techniques for the search for Kv1.5 ion channel blockers. Apart from the ligand-based work (ligand-based pharmacophore and 2-D similarity, see above) a structure-based screening was also performed in which a protein-derived pharmacophore based on a homology model was used [163]. The structure-based VS gave a higher hit rate (7.8%) than the screenings based on ligand-based pharmacophore (5.5%) and similarity searches (2.7%). Furthermore, the structure-based technique yielded more active compounds and more chemotypes. Even more important is the result that there was no overlap between the hit lists obtained by ligand- and structure-based approaches.

6.4 Concluding Remarks

From the large number of successful applications of ligand-based VS, two general and simple rules can be derived. These rules help to reduce the false-negative rate (ligands being active but not found) of the screening.

(i) *Use as many query ligands as possible.* Several authors have reported that some ligands perform very poorly, not giving any hits at all, while with other reference ligands many hits were found. Unfortunately, it cannot be determined in advance, which of the ligands will be successful.

(ii) *Use as many different techniques as possible.* While some of the hits are "easy" to find by many different techniques, often valuable compounds (e.g. unique scaffolds) are found only by one of the techniques. Again, it cannot be predicted which of the techniques will be successful. It is important to note that not necessarily the most sophisticated techniques yield the most hits. In some cases a very simple search technique can find an interesting compound.

Comparing ligand- and structure-based techniques is difficult since the effectiveness of ligand- and structure-based techniques depends strongly on the screening project. For some targets the ligand-based techniques perform better than structure-based methods, while for other targets they perform worse. From this finding, a third rule can be derived:

(iii) *Use both ligand- and structure-based techniques if possible.* In this combined scenario the maximal benefit of the different starting points can be obtained, and the best compromise between the strengths and limitations of the various methods can be obtained. In other words, make use of the complementarity between ligand- and structure-based techniques [14].

Acknowledgments

The authors are grateful to Matthias Rarey (Hamburg) and Andreas Steffen (Saarbrücken) for valuable suggestions. A large part of this chapter is based on the course "Computer-aided Drug Design" taught by A. K., and he would like to thank the Max Planck Institute for Informatics and the Center for Bioinformatics of Saarland University for the opportunity to give this course.

Efficient Strategies for Lead Optimization by Simultaneously Addressing Affinity, Selectivity and Pharmacokinetic Parameters

Karl-Heinz Baringhaus and Hans Matter

1 Introduction

The increasing pressure on efficiency and cost of research in the pharmaceutical industry has caused a technological paradigm shift [1, 2] in order to bring promising candidate molecules earlier to the market [3, 4]. The total research and development costs for a novel compound to enter this market have recently been estimated as US$600–800 million [5, 6], while continuously increasing expenses are mainly attributed to the high attrition rate in later development phases. The major reason for failure in phase II and III of clinical trials is inadequate understanding of pharmacokinetic behavior of drugs [7–9] and what constitutes a pharmacokinetic profile for candidate drugs. This again underscores the necessity to improve on the success rates in order to maintain economic viability of the pharmaceutical drug discovery process on longer terms.

Several technological advances [10] along the drug discovery value chain have entered the field and become indispensable tools for identifying novel lead compounds. However, the advent of technologies like combinatorial chemistry [11, 12], automated synthesis technologies and high-throughput screening (HTS) [13] also caused an exponential increase in the number of single data points for analysis, while it is debatable to what extent these technologies contributed to the launch of new chemical entities (NCEs) to the market [2, 3, 14, 15]. The current challenges in drug discovery are related to increased regulatory hurdles, more effective integration of technological advances, the extraction of relevant information and knowledge from primary data to support data-driven decisions, and – at the same time – the cost pressure, prompting for increased efficiency and lower attrition rates.

Improving on the low success rates requires a balanced compound progression driven by clearly defined knowledge-based decisions to advance or discontinue particular lead series as early as possible. Any failure to identify promising lead series has severe implications on time and resources within a disease-related program in a pharmaceutical company. A clear process,

Bioinformatics – From Genomes to Therapies Vol. 2. Edited by Thomas Lengauer

ISBN: 978-3-527-31278-8

and rigorous and relevant metrics for compound progression are essential here [2, 16]. This requires early attention to stringent quality criteria for compound series, reflecting the complex multitude of biological, pharmacological, pharmacokinetic and physicochemical parameters that a project team has identified as key drivers for the chemical optimization and for candidate selection.

Although, at first glance, the stage of lead optimization is not very spectacular, the efficient conversion of molecules with promising biological activity into viable drug candidates fulfilling a multitude of requirements appears to be one of the most challenging steps [17, 18] with a very high impact on the successful continuation of efficient drug discovery programs [2]. Conversion of a biologically active chemical compound into an effective and safe drug adds substantial value in the drug discovery process. Consequently, the improvement of a compound profile toward a clinical candidate is one of the essential skills in integrated drug discovery teams. Those candidate requirements include not only desirable selectivity against related or diverse "antitargets", but also favorable physicochemical and pharmacokinetic properties, leading to oral administration and an acceptable half-life of the final candidate. Hence, to arrive at candidates with suitable pharmacodynamic and pharmacokinetic properties requires a simultaneous optimization of multiple parameters in carefully planned iterations. Here, it is interesting to note that recent comparisons of molecular properties of launched drugs revealed only limited differences compared to the original lead compound as starting point [19].

The necessity to shorten the discovery process has prompted for an early integration of pharmacokinetic and drug development efforts to rapidly identify those molecules that are unlikely to become drugs and those lead series with significantly lower chemical optimization potential. It is of great importance to initiate lead optimization programs only for those molecules that intrinsically have the potential to be converted into drugs. Hence, this lead optimization stage has entered into a new phase of complexity caused by advances in modern technologies like protein crystallography, assay technology, absorption, distribution, metabolism and excretion (ADME) assays, medicinal chemistry automation, etc. Although rational approaches during this phase to manipulate molecules are typically guided by quantitative structure–activity relationships (QSARs) and structure-based design, it now becomes a tight interplay between various disciplines: medicinal chemistry, structural biology, pharmacology and pharmacokinetics. It is vital for success to conceive lead optimization as simultaneous multidimensional optimization rather than to address one parameter at a time (Figure 1).

This chapter focuses on a discussion of novel strategies, processes and computational tools with an impact on improving the poor industry success

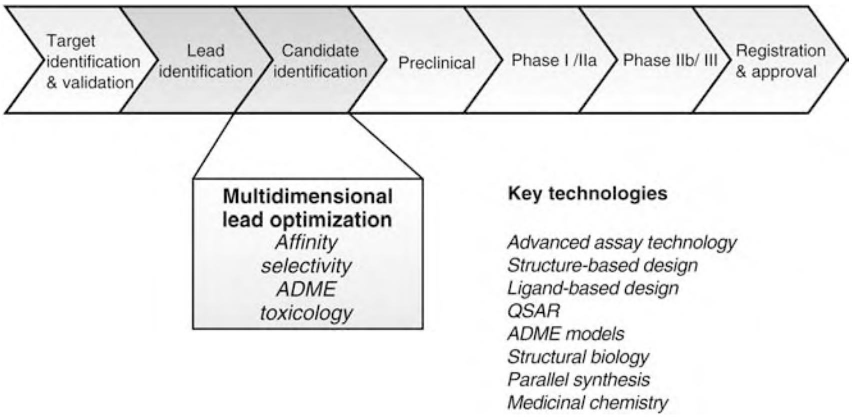

Figure 1 Drug discovery value chain, and selected key technologies and activities [2]

rates during the chemical optimization phase of lead series. The ultimate goal of any chemical optimization program is to convert quality lead structures into high-value drug candidate molecules prior to clinical development (Figure 1). First, the starting point for lead optimization is analyzed, i.e. the origin of lead and current selection criteria for the promising series. Knowledge-based decisions are essential at this stage to circumvent time and resource investments for later stages. The emphasis of subsequent sections is to discuss several components in this lead optimization process toward refinement of series with improved drug-like properties. This includes a summary of the understanding and predictive models for biological affinity, selectivity versus closely related targets as well as clearly defined antitargets and pharmacokinetic problems.

Traditionally, in this optimization process, the affinity is optimized first, while pharmacokinetic and ADME issues are investigated later in this process [20, 21]. This approach, however, showed only limited success, as optimizing for affinity only can result in chemical classes, where subsequent optimization for ADME properties becomes difficult, if not impossible. The efficiency of the drug discovery process is expected to improve if both aspects are considered simultaneously (Figure 2). Hence, we discuss different approaches and case studies on lead optimization using such a tight integration of different parameters by means of simultaneous optimization of a variety of relevant molecular properties, sometimes referred to as *multidimensional optimization* (MDO) [2, 16, 22]. Consequently, we will use this term throughout the following discussion. This multidimensional optimization requires a clear risk assessment prior to initialization of a resource-intensive research program to optimize compounds toward a balance of such a multitude of properties [23]. General considerations for multidimensional lead optimization are discussed

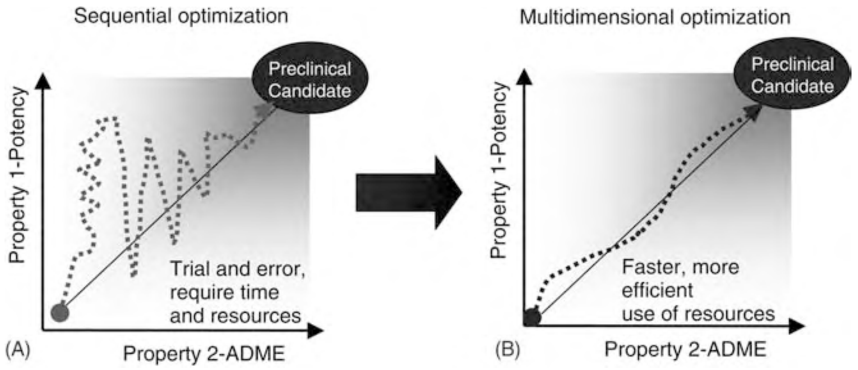

Figure 2 Different drug discovery strategies: (A) Sequential optimization (historic approach) – first optimization of affinity, while ADME properties are treated at a later stage. (B) Multidimensional scenario – combined optimization of affinity and ADME properties, simultaneously monitor changes in relevant properties [20]

with an emphasis on computational approaches to assist in this simultaneous task. Data integration is mandatory for extraction of knowledge and reuse in following iterations in the design cycle, while *in silico* approaches to estimate ADME parameters are crucial to focus only on promising molecules to address the increased complexity in lead optimization. These concepts will be illustrated using literature and in-house examples (Figure 2).

2 The Origin of Lead Structures

This section summarizes strategies to identify lead structures with a particular emphasis on modern technologies complementing HTS in the pharmaceutical industry, while Bleicher and coworkers discuss some aspects in detail [22], and provide a summary of the individual processes and interfaces between disciplines involved within a pharmaceutical setting [16].

The success of many drug development projects seems to be fundamentally limited by the nature of the target. Experience in medicinal chemistry and historic drug discovery programs suggests that small-molecule organic compounds can modulate more readily some privileged protein target classes. Hence, the selection of tractable targets in addition to careful selection following therapeutic requirements is essential to guide drug discovery at an early stage. All drugs that are currently on the market are estimated to modulate less than 500 targets, like nucleic acids, enzymes, G-protein-coupled receptors (GPCRs) or ion channels [9]. Consequently, the “druggability” of protein targets including small-molecule binding sites has been discussed [24] following the completion of the Human Genome Project, with an attempt to estimate a reasonable number of targets that indeed provide an opportunity for future therapeutic intervention. While earlier estimations discuss a total of 5000–10 000 potential targets according to the number of disease-related genes [9], a focus on properties of orally bioavailable, small drug molecules that could potentially interact with those targets results in a lower number of targets (600–1500) [24]. Those physicochemical properties of "drug-like" molecules include the well-established "Rule of Five" [25] or related knowledge-derived guidelines [26]. Those summarize simple, intuitive parameters for medicinal chemists to give a warning for compounds that are unlikely to be orally absorbed via the passive intestinal route. Hence, the increasing understanding of drug-like properties might additionally refine our understanding of complementary properties for drug targets.

Hit finding for a selected target typically starts with a collection of actives from HTS [13, 27, 28], which today is the most widely applicable technology, while quality of results is critically dependent on assay type and quality [16]. In addition, recent years have witnessed an emerging number of complementary biophysical and *in silico* hit-finding approaches like fragment-based SAR-by-nuclear magnetic resonance [29–31], surface plasmon resonance binding [32], high-throughput X-ray crystallography [33, 34], protein structure-directed *de novo* design [35], and structure- and ligand-based library design and virtual screening [36, 37].

The costs associated with hit identification using diverse assay systems and technologies as well as, alternatively, biophysical methods and approaches, are regarded as minor compared to the finally required clinical development of novel candidate molecules [38]. The validation and exploration around lead series is significantly more resource-intensive and dependent upon the selection criteria to progress on promising series. Hence, the series of hits are thoroughly evaluated and validated as early as possible for collecting as much information on individual structures and entire structure classes. Any systematic method to evaluate and validate results from hit finding requires a clear understanding of which terms and criteria to monitor in order to decide upon the fate of a series [2, 16].

Several criteria for selecting promising lead structures and tailoring focused libraries have been proposed in the literature. The early awareness of liabilities within a lead series with respect to the desirable compound profile in terms of selectivity, physicochemical and ADME properties is important for choosing the series with potential for starting a successful lead optimization program; however, none of these knowledge-driven decisions can prevent unpredictable problems like animal toxicity and others. Generally speaking, it is the overall characteristics of a particular compound class, considering a multitude of properties including synthetic feasibility and patentability, which make it attractive for starting a lead optimization program. This potential, however, has to be systematically explored within the frame of a limited synthetic program dedicated to exploring the SAR as well as obtaining as much information on key drivers in order to identify those series with improved drug-like properties.

Recent comparisons of physicochemical properties of lead structures to drug molecules also enhanced the understanding of which criteria to apply for selecting a promising series. Those studies were reported by Oprea and coworkers [39–41] based on a data set of 96 lead-drug pairs and a variety of calculated physicochemical properties. Lead structures tend to exhibit lower molecular weight, lower number of rings and rotatable bonds and lower log P, suggesting that the subsequent process of lead optimization in medicinal chemistry tends to add complexity, mainly by means of less directional hydrophobic interactions.

The impact of molecular complexity on the probability to detect hits was studied by Hann and coworkers [42] on the basis of statistical arguments. Using simple models of ligand–receptor interactions, the probability of useful binding events of increasing complexities (number of potential protein–ligand interactions) was estimated. Low-complexity compounds have an increased probability of being detected as hits in screening and thus might offer better starting points for drug discovery. If systems become more complex, the chance of observing a useful interaction for a randomly picked ligand falls dramatically, based on statistical reasons.

One possible route to increase binding affinity of low-complexity fragments is to link two fragments binding to different subpockets. From an analysis of high-resolution X-ray data for fragments and corresponding larger molecules, the loss of rigid-body translational and rotational entropy, which forms a significant barrier of protein–ligand recognition, was estimated as 15–20 kJ mol^{-1}, i.e. 3 orders of magnitude in affinity at 298 K [43].

These studies consistently suggest that less-complex lead structures are better to detect and exhibit a favorable optimization potential, which might influence attempts to design more “lead-like” [44] compound libraries for screening. They have also lead to alternative lead-finding strategies directed toward the initial discovery of small fragments as starting points for optimization [45]. Recent examples include the discovery of DNA gyrase inhibitors by means of three-dimensional (3-D) structure-based fragment screening combined with biophysical assays and protein structure-based optimization [46] and the discovery of inosine 5′-monophosphate dehydrogenase (IMPDH) inhibitors [47] from a virtual screening protocol tailored to discover small, alternative warheads to known phenyloxazole anilines.

The combination of alternative screening approaches, virtual screening and parallel medicinal chemistry in combination with an early profiling on the multitude of relevant compound properties will hopefully generate an improved basis for proper decisions about which promising lead series to take forward.

3 Optimization for Affinity and Selectivity

3.1 Lead Optimization as a Challenge in Drug Discovery

This section summarizes several approaches with and without knowledge of the target protein 3-D structure to optimize lead structures for affinity and selectivity as one prerequisite for multidimensional optimization. The lead optimization phase to efficiently convert the lead structures with promising biological properties into clean drug candidates fulfilling a multitude of criteria is a challenging task [17, 18] with a high impact on the successful continuation of efficient drug discovery programs [2]. Consequently, the improvement of a compound profile toward a clinical candidate is one of the essential skills in integrated project teams. Those candidate requirements include not only desirable selectivity against related or diverse “antitargets”, but also favorable physicochemical and pharmacokinetic properties, leading to oral administration and an acceptable half-life of the final candidate. To arrive at candidates with suitable pharmacodynamic and pharmacokinetic properties thus requires a simultaneous optimization of multiple parameters in carefully planned iterations.

Due to the lower dimensionality of the ADME space, ADME properties should be easier to predict than biological receptor affinity [48], although in practice this is more difficult, as many experimental screens for ADME properties are multi-mechanism rather than single mechanism systems. In contrast, biological assays for the majority of pharmacological targets are typical single-mechanism systems, for which computational models to correlate structural descriptors are easier to develop and resulting predictions tend to be more robust. Many experimental screens for these ADME properties include multiple-mechanism systems, however. Computational models, on the other hand, for data with multiple underlying mechanisms tend to get worse if more data for structurally more diverse compounds are experimentally obtained and included into the training set. This is mainly due to the fact that the increase of assay data relates to an increase of underlying mechanisms on which those data have been obtained and the noise level rises for each individual mechanistic component [48]. For smaller, structurally and, thus probably, mechanistically homogeneous data sets, acceptable correlations are obtained, while the ability of descriptors to capture a more diverse experimental data set is limited. Although the same descriptors might still have some statistical significance and thus explain global trends for less homogeneous data, their predictivity is often too low for a valid *in silico* prediction. This only offers the possibility to construct statistically significant rules or filters based on descriptors and property distributions and ranges. Hence, it is mandatory to carry out high-quality single-mechanism ADME experimental data and use them to derive single-mechanism models [48]. In contrast, assays and models to correlate structural properties to biological activity for a biomolecular target are mainly based on a single mechanism, i.e. favorable protein–ligand interactions upon the molecular recognition event.

Although the present chapter does not summarize the pharmacophore [49, 50] and 2-D/3-D-QSAR [51–55] approaches toward ligand-based optimization in the absence of any 3-D receptor structure, these methods are extremely important in today's lead optimization settings, as for the majority of targets it might be difficult to obtain relevant X-ray structures of protein–ligand complexes. This is true for membrane-bound proteins, like ion channels, GPCRs and others. Hence, validated methods in ligand-based design to extract knowledge from molecules in a series, build statistical models and use them for further design are useful. The focus here is on the use of 3-D protein structure information *per se* and of the tight integration of ligand- and structure-based design approaches toward a more reliable affinity prediction and understanding of selectivity. However, both ligand- and structure-based design approaches require the close monitoring of ADME and physicochemical properties of ligand series for successful optimization.

3.2 Use and Limitation of Structure-based Design Approaches

Over the past few years, there has been an exponential increase in the number of available 3-D structures in the public domain [56, 57], which is increasingly being used within the drug discovery process in the lead-finding and lead optimization phase. However, there are still other factors that add up to the complexity of guided lead optimization by structure-based design [58–62]. The reality of protein–ligand interactions at the molecular level is still far too complex to provide a correct *in silico* approach for accurate affinity prediction, either based on the knowledge of the target protein 3-D structure or even without that information. The effect of entropy and the dielectric constant are only two examples that are controversially discussed within the literature. Other challenging factors in structure-based design are the existence of multiple ligand-binding modes [63, 64], the accessibility of conformational states for both ligand and receptors [65, 66], the influence of structurally conserved water [67], pH [68], and others. One important point to address is the well-documented protein flexibility [65] as a direct consequence of the chemical properties of amino acids. Furthermore, it is of critical importance in the structure-based design process to reflect the limitations of the use of X-ray protein structures [69], which also is partially due to significant errors in some reported structures [70, 71] and experimental limitations that are difficult to overcome. These complicating influences turn the reality of lead optimization for affinity into a difficult task.

Some important reviews summarized the current status of our understanding of protein–ligand interactions [72, 73]. This knowledge prompted some groups to derive scoring functions for guiding flexible docking algorithms and rank-ordering series of docked molecules. Several publications indicate the substantial progress made in both fields of docking and scoring, respectively. A variety of methods exist to estimate how strongly a ligand interacts with a protein-binding site, while today's existing functions belong to three main categories: force field-based methods, empirical scoring functions and knowledge-based methods [62, 73–77]. In an intersection-based consensus scoring approach, Charifson and coworkers [78] and Clark and coworkers [79] combined a range of different functions to rank protein–ligand geometries, which resulted in an increased performance with respect to hit rates. The first paper [78] also discusses one of the possible limitations for earlier scoring functions, i.e. that those are derived from X-ray structures of extremely potent ligands, while information about less-active analogs is often not available.

3.3 Integration of Ligand- and Structure-based Design Concepts

The global scoring functions described above are derived from a more or less balanced collection of protein–ligand complexes from the public domain, leading to empirical functions that might be able to globally provide some guidelines on whether a compound could potentially bind to a particular binding site. However, their accuracy in ranking compounds on the basis of experimental binding affinities is typically limited. This caused studies to tailor scoring functions in lead optimization stages using a narrow training set for only the protein target of interest. In addition, this need in lead optimization prompted others toward a tight integration of ligand- and structure-based design approaches to model and understand biological affinities by means of 3-D-QSAR methods, which are based on an alignment rule derived from reliable docking modes.

Gohlke and coworkers developed the AFMoC procedure [80] to derive tailored scoring functions for protein–ligand complexes based on DrugScore [81] knowledge-based pair-potentials, which are adapted to a single protein-binding site by incorporating ligand information (Figure 3). The formalism is similar to comparative molecular field analysis (CoMFA) [82, 83], while the fields in their approach originate from the protein environment and not from the ligands alone. A regular-spaced grid is placed into the binding site and knowledge-based pair-potentials between protein atoms and ligand

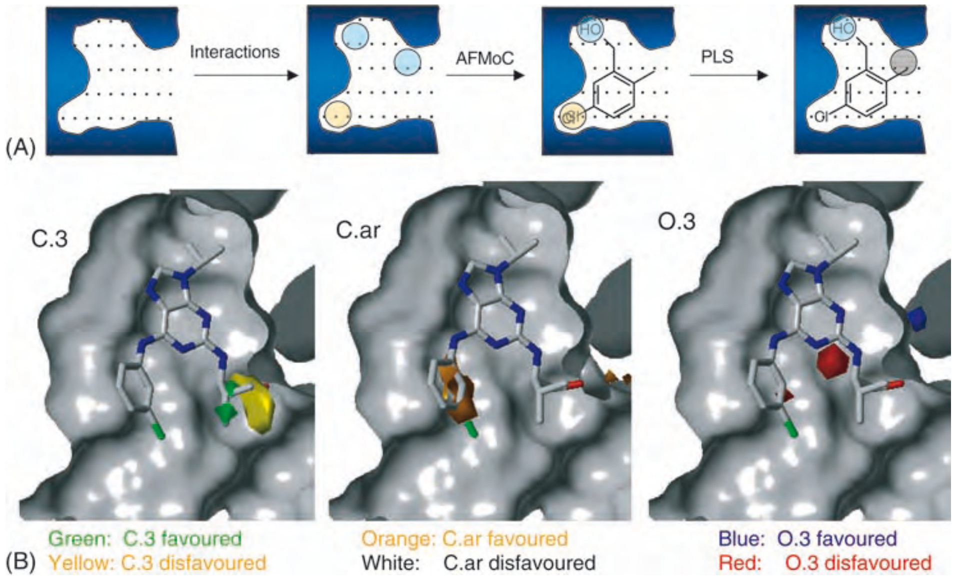

Figure 3 (A) Deriving a tailored scoring function using AFMoC [80], which integrates protein- and ligand-derived descriptors and produces a statistical model on protein–ligand interactions relevant for affinity. On a predefined grid, favorable protein interactions with ligand atom types are computed. These are adapted by incorporating actual information from a series of docked or crystallized ligands. A statistical analysis led to a model with favorable and unfavorable contributions. (B) AFMoC interpretation for 86 substituted purines as CDK-2 inhibitors. The underlying PLS model (q^2: 0.521, r^2: 0.800, 5 PLS components) indicates favorable and unfavorable regions for atom types, as shown for C.3, C.ar and O.3, and the CDK-2/purvalanol A complex (PDB 1CKP). The CDK-2 binding site is represented as a MOLCAD solvent-accessible surface.

atom probes are mapped onto the grid intersections resulting in "potential fields". In a partial least square (PLS) [84] analysis, these atom-type specific interaction fields are correlated to the actual binding affinities of the docked or experimentally known ligands, resulting in individual weighting factors for each field value. They described significant improvements of the predictive power for affinity prediction compared to global knowledge-based potentials by considering a sample set of only 15 known training ligands.

The conceptually similar COMBINE approach was developed by Wade and coworkers [85] on the basis of the analysis of force-field energy contributions per amino acid to describe interaction differences to a congeneric set of ligands. The resulting predictive regression equations were also reported for applications in structure-based design projects [86–88].

Other approaches are based on tailor-made empirical functions, consisting of additional descriptors and weights for these, plus the known terms using appropriate statistical methods based on a training set of several ligands exhibiting a range of biological affinities to only one protein cavity. Approaches to understand the SAR in chemotypes by a determination of the importance of weights of different coefficients of individual terms in scoring functions are described by Rognan and coworkers [89] and Murray and coworkers [90], both using the ChemScore global scoring function [91] as a start.

Structure-based design is focused on understanding protein–ligand interactions but does not always lead to predictive models for ligand series. In contrast, 3-D-QSAR with acceptable statistics does not always reflect topological features of the protein structure, as those are not necessarily built using alignment rules that reflect the bioactive conformation. Hence, several groups have successfully combined both approaches. On the basis of the protein X-ray structure and a series of analogs with a potentially similar binding mode, consistent and highly predictive 3-D-QSAR models were derived, which could be mapped back to the protein topology. This leads to a better understanding of important protein–ligand interactions, and provides guidelines for ligand design and a predictive model for scoring novel synthetic candidates. Docking calculations based on already available 3-D structures often might result in an alignment for all other compounds by superimposing them onto the template and relaxing them within the cavity for consistent 3-D-QSAR models.

These receptor-based 3-D-QSAR models represent a strategy to integrate ligand- and structure-based design approaches. CoMFA [51, 82, 83] and comparative molecular similarity index analysis (CoMSIA) [92] are used to derive relationships between molecular property fields and biological activities. Electrostatic and steric interaction energies are computed between each ligand and a probe atom located on predefined grid points for CoMFA, while for CoMSIA those interaction fields are replaced by fields based on similarity indices between probe atoms and each molecule. The PLS [84] method is used to derive a linear relationship, while cross-validation [93] is used to check for consistency and predictiveness. The resulting contour maps from 3-D-QSAR models enhance the understanding of electrostatic, hydrophobic and steric requirements for ligand binding, guiding the design of novel inhibitors to those regions where structural variations altering steric or electrostatic fields reveal a significant correlation to biological properties. The 3-D-QSAR results then allow focusing on those regions where steric, electronic or hydrophobic effects play a dominant role in ligand–receptor interactions.

One of the earlier and most influential applications of receptor-based CoMFA studies was carried out by Marshall and coworkers on a series of HIV protease inhibitors [94, 95]. The bound conformation of several ligands was known from X-ray crystallographic studies, and was shown to provide the most consistent and predictive QSAR models, while the authors also pointed out that conformational energy and entropic effects are not adequately included within these data sets. Hydrophobic field types used within CoMSIA [92] or HINT [96] might be partially useful to overcome the second limitation. Other successful applications include estrogen receptor ligands [97], acetyl cholinesterase inhibitors [98], and (from the authors' own work) receptor-based QSAR models for matrix metalloproteinase [99, 100], CDK-2 [101] and factor Xa inhibitors [102]. These models collectively found applications in lead optimization projects, as they provide an enhanced understanding of important effects in protein–ligand interactions and reliable affinity predictions.

3.4 The Selectivity Challenge from the Ligand's Perspective

Protein target families are the fundamentals to build a framework for matching biological motifs with chemical scaffolds. Many structurally related targets find implications in different therapeutic areas, while exhibiting similar protein–ligand interactions. A key issue for this interdisciplinary field is how to generate and efficiently use this information to guide drug design across targets [2]. The knowledge of structurally related proteins for a particular target is of interest in early drug discovery stages to identify leads by analogy within a target family [2, 22] from focused libraries enriched with privileged motifs of importance for that family [103] or by annotation-based similarity searching across target families [104, 105]. This latter approach allows us to perform similarity searching to identify appropriate ligands for new targets within the same target family by linking chemical structure databases, biological target sequences and structure activity data (screening results).

However, selectivity toward only a single biological target is an essential requirement for drug candidates to minimize side-effects. Hence, it is mandatory to involve selectivity considerations early in the drug discovery process, and to monitor experimentally and by *in silico* approaches closely related or structurally unrelated "antitargets" for the potential drug candidate. The following section will briefly summarize methods to take this requirement into account from both the perspective of the ligand and the protein 3-D target structures, if available.

While most chemistry-driven approaches rely on trial and error, often 2- and 3-D-QSAR approaches have been used to correlate biological affinities against both target proteins in order to identify those structural determinants or favorable spatial regions around the ligands gaining selectivity on the target enzymes. This approach requires a series of biologically characterized chemical analogs, which are typically available at this stage within the drug discovery value chain.

Some earlier examples on the use of 3-D-QSAR to understand selectivity differences include the work of Wong and coworkers to unveil structural requirements for selective binding of ligands to the diazepam-insensitive (DI) benzodiazepine receptor [106]. The chemical interpretation of the resulting CoMFA model on a larger series of 1,4-benzodiazepines highlighted the marked influence of particular substitutions in only a few scaffold positions on the ratio of affinities against the DI and diazepam-sensitive (DS) benzodiazepin receptor-binding site. Interestingly, individual 3-D-QSAR models have been derived for binding affinities against both individual sites as well as against the ratio, defined as $K_\mathrm{i}(\mathrm{DI})/K_\mathrm{i}(\mathrm{DS})$, as an additional dependent variable for statistical analysis. The use of K_i values for this mathematical transformation is preferable due to their independence on concentration effects, while IC_{50} values for closely related targets or sites at one receptor are often practically determined at very similar conditions, thus also allowing the use of similar ratios as dependent variables for statistics. However, PLS can also be used for two (or more) dependent Y-variables in only one model [84].

A similar approach has been taken to explain selectivity differences between the matrix metalloproteinases MMP-8 and MMP-3 [100] and the serine proteases factor Xa and thrombin [107]. However, in both cases, the availability of experimental 3-D protein structures also allowed the interpretation of selectivity differences by careful inspection of protein-binding site requirements and additional statistical models tailored to highlight key differences in potential protein–ligand interactions from binding sites only [100, 101, 107, 108]. In both cases, the selectivity differences from the analysis of ligand series nicely correspond to binding site requirements. Furthermore, the availability of 3-D structures for both the target and the closely related “antitarget” might lead to the use of structure-based design approaches to qualitatively identify amino acid differences, which might allow for a more focused interaction toward only one target. The combined use of both types of information greatly enhanced the understanding of selectivity requirements for these series of target enzymes.

Other quantitative approaches to address selectivity rely on generating and consistently interpreting individual statistical models, which again provide very detailed information on desirable scaffold substitution patterns and spatial areas around superimposed ligands, which allow them to selectively interact only with one binding site. There are multiple interesting applications of this concept in the literature (e.g. Refs. [109–112]).

3.5 Selectivity Approaches Considering Binding Site Topologies

The availability of protein 3-D structures considerably simplifies the search for selective ligands, as these structures allow the comparative analysis of favorable protein–ligand interactions with a particular focus on those that are only possible in one member of a protein family. There are several computational tools that assist in an unbiased characterization of protein–ligand interactions, e.g. the force field-based approach GRID [113], and the knowledge-based approaches SuperStar [114, 115] and DrugScore [81, 116]. In the recent consensus principal component analysis (GRID/CPCA) approach [108], the GRID descriptors derived for multiple protein binding sites are analyzed using CPCA [117] as a statistical method, which allows the identification of possible modifications in potential ligands in a straightforward way to improve their selectivity toward a chosen target. This statistical analysis evaluates the relative importance of individual molecular interaction fields from particular probe atoms for the final PCA model. As the input data matrix is structured in chemically meaningful blocks, hierarchical and consensus multivariate analysis tools like CPCA provide information about the relative importance of individual blocks on the stage of an intermediate level of the analysis, while the final model is identical to a regular PCA. Plotting of the individual PCA and CPCA scores then allows visualization of selectivities between different members of the protein family, while the structural reason in terms of potential protein–ligand interactions that allows discrimination can be deduced from CPCA loadings plots and interactive variations thereof. Those "active plots" help to focus ligand designs toward binding site residues, which are essential for discriminating between subfamilies.

This approach was first applied toward an understanding of discriminating interactions in the serine proteases factor Xa, thrombin and trypsin [108], and provided selectivity information for all important serine protease subpockets, which are in agreement with experimental selectivities of typical protease inhibitors. This approach was complemented by a 3-D-QSAR selectivity analysis on a series of 3-amidinobenzyl-1H-indole-2-carboxamides [107], which points, from the viewpoint of the ligands, to similar main interactions driving selectivity between key enzymes in the blood coagulation cascade: factor Xa and thrombin. Other applications of GRID/CPCA include the interpretation of structural differences in human cytochromes P450, 2C8, 2C9, 2C18 and 2C19 [118] from homology models using the mammalian CYP2C5 X-ray structure [119], matrix metalloproteinases from X-ray and homology modeling [120], the classification of Eph Kinases [121], and a comparison of the binding characteristics of the family of lipid-binding proteins [122]. For these cases, the selectivity regions were in good agreement to available experimental information and inhibitor structure–activity relationships. Recent extensions include FLOGTV toward a simplified visualization of differences between related receptor sites based on a trend vector analysis [123].

Many structurally related protein targets find implications in different therapeutic areas, while exhibiting similar protein–ligand interactions. It is essential to efficiently use this information to guide drug design across targets. This encompasses both the knowledge about selectivity regions in binding sites, while, on the other hand, a general entrance by less-specific interactions into such target family is of particular interest for shaping a compound library at the lead-finding stage. To this end, GRID/CPCA was successfully applied to arrive at the "target family landscape" concept [101] to study features for general interactions to an entire target family and to identify determinants for interactions to only one member, which was of particular interest for broader sets of kinases [101] and serine proteases [107] with experimentally known 3-D crystal structures. The applications to major protein target families produced models in agreement with in-house ligand SAR models and thus provide guidelines toward rapid optimization in a library format for family-specific scaffolds.

To use a set of consistent descriptors for docking and selectivity studies, the replacement of the force field GRID by DrugScore-derived [81, 116] knowledge-based potentials was successfully investigated on the factor Xa/thrombin/trypsin problem [124] as well as for matrix metalloproteinases. It was shown that this change produces models of qualitatively similar interpretation. Predictive submodels for all protein pockets (S1, S2, S4) were obtained. Here, CPCA scores discriminate factor Xa from thrombin and trypsin on PC1 in Figure 4 (Cl probe for S2 submodel). Differential plots reveal the structural reason for this discrimination: the piperidinyl moiety in the thrombin selective inhibitor NAPAP can only favorably interact with this subsite in thrombin. The detailed interpretation for other pockets is consistent and in agreement with internal series.

Lapinsh and coworkers [125] developed the proteochemometrical strategy combining ligand and protein information for a comparative analysis of series of receptors and ligands. Proteochemometrics exploits affinity data for series of diverse organic ligands binding to different receptor subtypes, correlating it to descriptors and cross terms derived from the amino acid sequences of the receptors and the structures of the small ligands. Statistically valid models resulted in all cases with good external predictive ability, while evaluation of these models gave important insight into the mode of interactions of the GCPRs with their ligands. This method was successfully applied to other GPCR receptor subtype analyses without experimental knowledge of binding site topologies, i.e. melanocortin receptor subtypes [126], serotonin, dopamine, histamine, adrenergic receptor subtypes [127], and α_{1a}-, α_{1b}- and α_{1d} -adrenoceptors [125]. This approach combining information from ligands and receptors provided more detailed information about receptor–ligand interactions and determinants for receptor subtype selectivity than ligand-based QSAR studies on individual ligand series alone.

These presented examples of quantitative descriptions of protein–ligand interactions remain to be a very promising area to address affinity and the selectivity challenge in the future. Those approaches are collectively seen

as interesting for a more integrated lead optimization on a simultaneous consideration of numerous balanced descriptors and models for optimization.

4 Addressing Pharmacokinetic Problems

4.1 Prediction of Physicochemical Properties

Pharmacokinetics and toxicity have been identified as important causes of costly late-stage failures in drug development. Hence, physicochemical as well as ADMET properties need to be fine-tuned even in the lead optimization phase. Recently developed *in silico* approaches will further increase model predictivity in this area to improve compound design and to focus on the most promising compounds only. A recent overview on ADME *in silico* models is given in Ref. [128].

The physical properties of a compound also determine its pharmacokinetic and metabolic behavior in the body. Poor biopharmaceutical properties are often linked to poor aqueous solubility, as summarized by Lipinski [129]. Thermodynamic solubility measurements consider the crystal packing energy of the solute as also its cavitation and solvation energy. The crystal packing energy accounts for disruption of the crystal to bring isolated molecules into the gas phase. The cavitation energy is the energy required to disrupt water for the creation of a cavity in which the solute is to be hosted. Finally, the solvation energy is the sum of favorable interactions between solvent and solute. Solubilization is largely kinetically driven, and the effects of crystal packing energy and polymorphic crystal forms are lost.

Currently available solubility models based on turbidimetry as well as nephelometry are not very predictive and are limited in their broad applicability, because they make use of training data from different laboratories determined under varying experimental conditions [130]. However, access to many aqueous solubilities measured under standardized conditions is expected to greatly improve currently available models.

Figure 4 DrugScore/CPCA for ligand selectivity in structure-based design. The binding sites of serine protease X-ray structures (factor Xa/thrombin/trypsin) are profiled using DrugScore for favorable interactions of six atom types (C.3, O.2, N.am, C.ar, O.3 and Cl). Individual CPCA models are derived for each subsite, allowing the identification of regions for discrimination. The interpretation for the S2 pocket and NAPAP as thrombin-selective inhibitor (PDB 1ETS) highlights yellow regions, where hydrophobic groups increase thrombin selectivity, while blue regions should favorable effect factor Xa selectivity. The interpretation is in good agreement with internal SAR data.

4.2 Prediction of ADME Properties

Poor intestinal absorption of a potential drug molecule can be related to poor physicochemical properties and/or poor membrane permeation. Poor membrane permeation could be due to low paracellular or transcellular permeability or the net result of efflux from transporter proteins including MDR1 [P-glycoprotein (P-gp)] or MRP proteins situated in the intestinal membrane. Cell lines with only one single efflux transporter are currently engineered for *in vitro* permeability assays to obtain suitable data for reliable QS models. In addition, efforts to gain deeper insight into P-gp and the ABC transporter on a structural basis are ongoing [131, 132].

Discrimination of efflux, active or passive transport is already feasible by suitable *in vitro* experiments. For instance, the PAMPA assay detects passive transport only, while Caco-2 cells include transporters. A comparison between transport in PAMPA and Caco-2 cells by a calibration plot reveals compounds with greater or lesser transport in Caco-2 cells than in PAMPA. These compounds should be tested in uptake and efflux transport assays in order to gain a deeper insight into absorption fate.

Several *in silico* models for prediction of oral absorption are available [133–136]. Simple models are based on only few descriptors like $\log P$, $\log D$ or polar surface area (PSA), while they are only applicable if the compounds are passively absorbed. In case of absorption via active transporters or if efflux is involved, prediction of absorption is still not successful.

GastroPlus [137] and iDEA [138] are absorption-simulation models based on *in vitro* input data like solubility, Caco-2 permeability and others. They are based on advanced compartmental absorption and transit (ACAT) models in which physicochemical concepts are incorporated. Both approaches were compared, and shown to be suitable to predict the rate and extent of human absorption [139].

Problems related to poor systemic exposure are also tied to volume of distribution, which is indirectly related to plasma protein binding. Human plasma contains more than 60 different proteins of which the major components are serum albumin (HSA, 60%) and glycosylated proteins (AGP). Eighteen different variants arising from single amino acid mutations have been identified, accounting for different protein binding. Allelic variation makes data consistency difficult and hence modeling of the resultant data less reliable [140].

Prediction of bioavailability from molecular structure is quite difficult, since bioavailability depends on absorption and first-pass clearance [141]. By applying "fuzzy adaptive least squares", Yoshida and Topliss generated a QSAR model using $\log D$ at pH 7.4 and 6.5 as input for physicochemical properties and the presence/absence of certain functional groups as structural input.

They achieved a classification of drugs into one of four bioavailability categories with an overall accuracy of 60% [142].

First-pass clearance can be tracked to gut stability or metabolism by phase I and then either direct clearance or clearance of the metabolite by phase II enzymes or biliary, renal or plasma clearance. Metabolite stability by phase I enzymes includes inhibition, induction, regiospecificity, lability or affinity toward several cytochrome P450 enzymes or flavin monooxygenase (FMO). Inhibition might cause drug–drug interactions and can be related to competitive, noncompetitive, uncompetitive or mechanistic inhibition [143]. Metabolite-based inhibition of the P450 enzymes also needs to be considered if toxicity aspects are related to these enzymes. Assays for differentiating these various types of mechanisms of inhibition are necessary and need to be applied for a reasonable number of compounds in a series in order to apply molecular modeling techniques to help in designing proper molecules with the preferred inhibition properties. Typical fluorimetric assays do not differentiate substrates that can be competitively bound or those that can covalently modify and inactivate the P450 enzymes. Only by different experimental approaches (time, substrate concentration, inhibitor concentration, NADPH-dependent inhibition) can these types of compounds be identified. Sometimes, the identification of metabolites helps to decipher the binding modes in the cytochrome P450 responsible [144]. Despite these problems, some successful applications of modeling to reduce drug–drug interactions, especially for CYP2D6 and CYP2C9, have been reported (see below).

Assays for FMO and most phase II enzymes are typically not included as part of a standard eADMET profile and, therefore, modeling related to clearance by phase II enzymes has not been attempted, although structural information for some sulfotransferases is available [145].

In silico methods to predict metabolism are based on QSAR, 3-D-QSAR or protein and pharmacophore models [146]. Early predictions of metabolism within a particular compound are now feasible. One approach by Korzekwa and coworkers uses, for example, reaction energetics to develop a predictive model for CYP3A4-mediated metabolization [147]. Sheridan and coworkers [148] described a model to predict likely sites of CYP3A4-mediated metabolism based on the energy necessary to remove a hydrogen radical from each site, as estimated by AM1 semiempirical molecular orbital calculations and the surface area exposure of the hydrogen atom. The development and validation of a general quantitative structure–property model of metabolic turnover rates in human S9 homogenate based on uniform biological data of 631 diverse compounds proprietary to GlaxoSmithKline has also been described [149]. This model was able to classify 83% of test compounds correctly for their metabolic stability. Other approaches are based on databases to predict metabolism, e.g. MetabolExpert (Compudrug), META (MultiCASE), Meteor (Lhasa) and the MDL database Metabolite [150].

4.3 Prediction of Toxicity

Approximately 20–40% of drug failures are attributed to toxicity problems. Hence, *in silico* predictive toxicology tools are necessary to reduce attrition. Most of the current software packages available deal with carcinogenicity and mutagenicity [151], and are based on available public domain toxicological data. *In silico* tools for other important end-points such as hepatotoxicity, QT prolongation [152] and phospholipidosis are emerging, and are expected to improve the design and optimization of novel compounds.

4.4 Physicochemical and ADMET Property-based Design

Property-based design supplements successful activity-based strategies to produce drug candidates [153]. Property screening in parallel with activity screening allows medicinal chemists to simultaneously optimize both biological activity and drug-like properties, which is a widely accepted and implemented approach within the pharmaceutical industry. ADMET filters are now applied even at very early stages of drug design, e.g. in virtual screening. The first generation of predictive ADMET tools allows focusing on compounds with a high potential of the required pharmacokinetic and safety criteria, and should reduce compound attrition. However, all currently available models are based on a limited set of data and are therefore restricted in their applicability. Hence, a continuous improvement and refinement of these models is required by taking into account more data that is also of high quality. Thereby, ADME might be considered as "automated decision-making engine" in the early discovery paradigm and as ADME in the regulatory phase [154].

5 ADME/Antitarget Models for Lead Optimization

5.1 Global ADME Models for Intestinal Absorption and Protein Binding

This section will provide an overview of ADME models from our group to illustrate our approach to building predictive models on structurally diverse training sets. Data sets for intestinal human absorption and human serum albumin binding are discussed, while models for other relevant ADME properties have also been obtained. Those models, however, do not stand alone, but are used in combination with those models tailored for affinity and selectivity in the frame of multidimensional lead optimization.

Recently, a set of alignment-free 3-D descriptors named VolSurf was developed by Cruciani and coworkers [155], referring to molecular properties extracted from 3-D molecular interaction fields of various probe atoms. VolSurf transforms the information present in GRID-derived [113] 3-D fields for particular probes into quantitative descriptors (Figure 5), which carry information related to pharmacokinetic properties like polarity, hydrogen bonding, lipophilicity, size, polarizability and others. The descriptors are easy to understand and to interpret, thus providing guidelines for chemical optimization after a linear model has been established. In most cases, the GRID water, hydrophobic (DRY) and carbonyl oxygen probes were utilized,

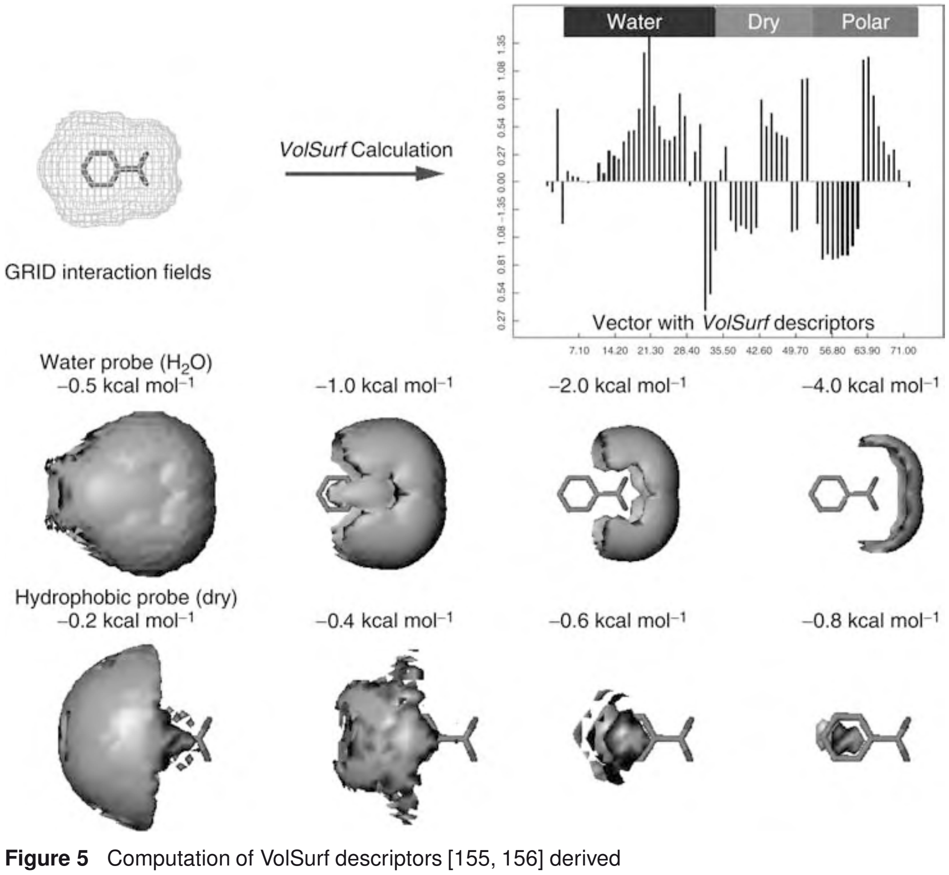

Figure 5 Computation of VolSurf descriptors [155, 156] derived from GRID molecular interaction fields. Interactions of the example molecule with a water and dry probe at different contour levels are used to compute a vector of 72 volume-, size- and surface-based descriptors.

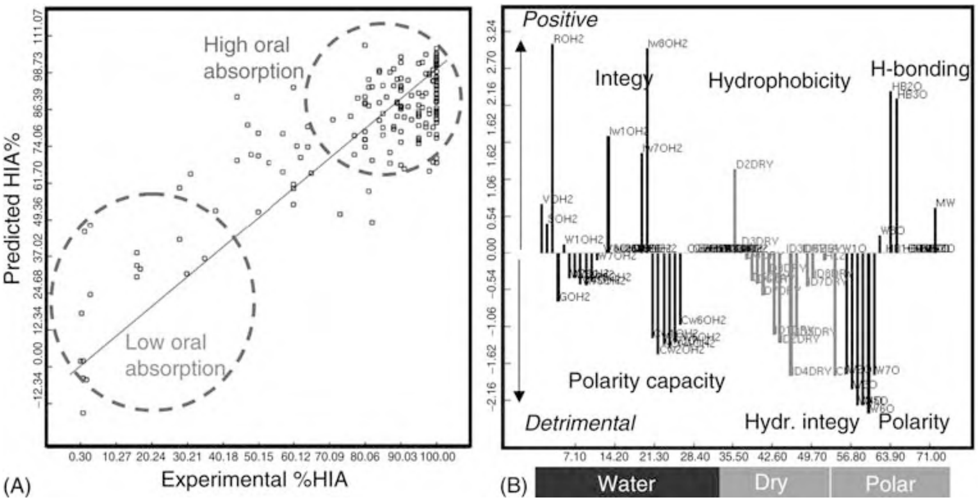

Figure 6 Correlation of VolSurf descriptors with human intestinal absorption for 169 drug molecules. (A) Predicted versus experimental percent HIA (human intestinal absorption) from the final PLS model with q^2: 0.662, r^2: 0.709 and 4 PLS components. (B) PLS loadings for a four-component model showing the importance of individual VolSurf descriptors to the prediction of human intestinal absorption.

as interaction of molecules with biological membranes is mediated by surface properties like shape, electrostatic forces, hydrogen bonding and hydrophobicity.

These descriptors have been reported in the literature to correlate with bioavailability, blood–brain partitioning, membrane transport and other properties [156–159]. They are also correlated to relevant physicochemical properties, and were successfully applied to many internal and public data. For example, we derived PLS models [160] using 72 VolSurf descriptors for HSA binding using 95 drugs on a data set from Colmenarejo and coworkers [161] ($r^2 = 0.76$, $q^2 = 0.67$, 6 PLS components) and for human intestinal absorption using data of 169 drugs compiled by Zhao and coworkers [133] ($r^2 = 0.71$, $q^2 = 0.66$, 4 PLS components). Those models were obtained using a canonical 3-D structure of neutral molecules.

As an example, the correlation of VolSurf descriptors to the human intestinal absorption for 169 drugs is shown in Figure 6. The conclusions for factors influencing permeability and absorption are in agreement with earlier findings, pointing to the positive impact of hydrophobicity, integy moment, shape and hydrogen bonding, while polarity derived using the GRID water and carbonyl O probes as well as the capacity factors from polar interactions on the entire surface are detrimental for intestinal absorption. However, because of the nature of these descriptors, this approach led to an enhanced understanding of the physicochemical requirements for a pharmacokinetic

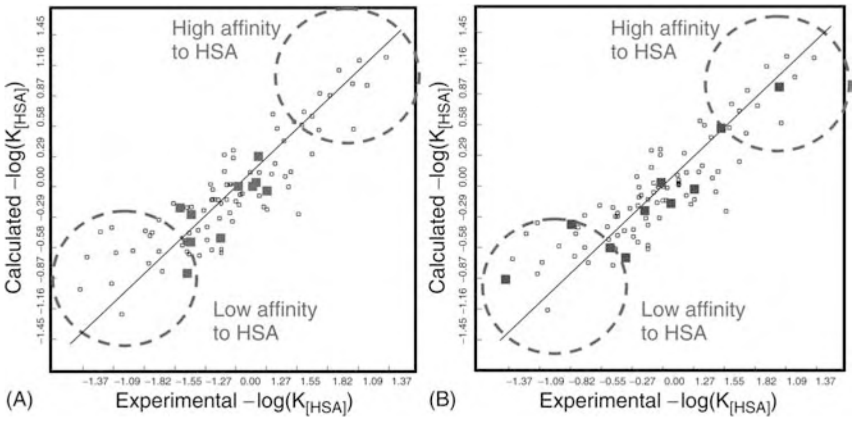

Figure 7 Correlation of VolSurf descriptors with HSA binding affinity. Two submodels indicate their predictive ability to external test sets. Ten compounds were removed by either experimental design on PCA scores (A) or literature proposals (B). Model A: q^2: 0.668, r^2: 0.763, 6 PLS components, SDEP for prediction 0.223 for 10 cpds. Model B: q^2: 0.646, r^2: 0.745, 6 PLS components, SDEP for prediction 0.274 for 10 cpd.

effect. For example, the balance between lipophilic and hydrophilic parts in combination with size, volume and other effects guides the design of new compounds.

The interpretation for HSA binding affinity is also in accord with literature findings and X-ray information on warfarin binding to the first drug binding site in HSA [162]. For instance, hydrophobicity, volume, shape and molecular weight increase HSA binding, while factors like polarity, integy moment, hydrogen bonding and favorable interactions to water are detrimental. Typically, hydrophobicity and geometrical factors like shape are reported as essential in the literature [161]. These models are always validated by external test data sets, as is schematically shown in Figure 7, where 10 compounds have been removed from the HSA training data set by two different approaches and predicted using two only slightly differing models. In both cases, the agreement between experiment and prediction was very good.

Alifrangis and coworkers [158] reported a structure–property model for membrane partitioning for 20 peptides with data from two chromatographic systems with phospholipides as the stationary phase, immobilized artificial membranes (IAM) and immobilized membrane chromatography (ILC). The relationship between these measures and three different sets of calculated descriptors (molecular surface area, MolSurf and VolSurf) were analyzed using PLS, showing that VolSurf-derived models are superior to both others [158]. In particular, the VolSurf critical packing descriptor to describe interactions of amphiphilic molecules with membranes is important to explain the membrane partitioning ability. This agrees with internal VolSurf models derived for PAMPA membrane transport [163] to understand passive transcellular transport across membranes. One of our internal models based on 29 compounds characterized by immobilized artificial membrane chromatography by Salminen and coworkers [164] shows $r^2 = 0.81$ and $q^2 = 0.70$ for two PLS components derived using VolSurf descriptors. This is one of the rare examples where ionized starting molecules led to slightly better PLS statistics, while the general chemical interpretation was not affected.

VolSurf was also successfully applied in the literature to predict absorption properties [156] from experimental drug permeability data of 55 compounds [165] in Caco-2 cells (a human intestinal epithelial cell line derived from a colorectal carcinoma) and Madin-Darby canine kidney (MDCK) cell monolayers. In this interesting case, it was shown that models including counterions for charged molecules clearly show significantly better quality and overall performance. The final model was also able to correctly predict, to a great extent, the relative ranking of molecules from another Caco-2 permeability study by Yazdanian and coworkers [166].

5.2 Selected Examples to Address ADME/Toxicology Antitargets

For ADME and toxicology properties, which are related to a particular target protein, approaches similar to those for affinity and selectivity are used in our group, while most of the ligand-based studies have recently been augmented by X-ray structures and/or validated homology models. Again, both approaches led to significant results in combination, when applied in the context of lead optimization in internal projects.

The K^+ channel encoded by the human ether-à-go-go-related gene (hERG) is one of the many ion channels that are crucial for normal action potential repolarization in cardiac myocytes [152]. This hERG channel is connected to drug-induced long QT syndrome causing cardiac toxicity of a wide range of pharmaceutical agents. This undesirable side-effect for noncardiac drugs has caused recent withdrawals of drugs from the market and stimulated many studies to establish a structural hypothesis for hERG and a structure–activity relationship of hERG channel blockers. Given the wide range of chemical structures that act as hERG inhibitors and the observation that different compounds are reported to bind to different states (open or closed) of the channel, multiple binding sites have been proposed [152]. On the basis of a homology model of the closed form of the tetrameric pore derived from the X-ray structure of the bacterial K^+ channel KcsA [167] combined with site-directed mutagenesis studies, several amino acids were identified as important for high-affinity binding of the methansulfonanilide MK-499 and thus provided a structural basis for drug-induced long QT syndrome [168]. Interestingly, two aromatic residues, Tyr652 and Phe656, lining the inner pore as a unique structural motif in hERG compared to other K^+ channels (except EAG) are proposed to interact with aromatic groups in ligands.

Perlstein and coworkers [169] describe the status of previously developed hERG structure–activity *in silico* models. While some of the models are intended to be used as early filters in compound design [170], only the 3-D-QSAR studies of Cavalli and coworkers [171] and the combination [172, 173] of 3-D-QSAR from consistent biological data with homology models of the closed and open form of hERG built from the low-resolution crystal structure of the MthK K^+ channel [174] allow us to understand structural reasons for hERG blocking, and thus provide sufficient details to apply them during the multidimensional lead optimization of a candidate molecule. These models have been internally derived from consistent biological data on literature compounds and close analogs, while they are constantly updated using novel molecules and biological data from lead optimization programs. Many internal applications have proven the value in using such a combined approach. The essential elements of the hERG pharmacophore, the 3-D-QSAR and the homology model are as follows. (i) The hydrophobic feature optimally consists of an aromatic group that is capable of engaging in π-stacking with Phe656. Optionally, a second aromatic or hydrophobic group may contact an additional Phe656 side-chain. (ii) The basic nitrogen appears to undergo a π-cation interaction with Tyr652. (iii) The pore diameter and depth of the selectivity loop relative to the intracellular opening, act as constraints on the conformation-dependent inhibitor dimensions [172]. However, undesirable structural features for hERG are not sufficient in the context of a lead optimization project. It is important to understand which variations influence hERG binding, but are still tolerated by the desired biological target. Both properties were used as lead optimization parameters by Friesen and coworkers [175] for PDE-4 inhibitors in a systematic approach to identify structural features that only affect hERG binding.

Toxicity caused by drug–drug interaction also resulted in withdrawal of several drugs from the market. Compounds that are potent inhibitors of the major metabolizing enzymes can potentially affect the metabolism of other molecules and thus lead to toxicity. Early information on cytochrome P450 inhibition thus is useful to develop structure–activity relationships and minimize the potential toxicity of development candidates. Inhibition of CYPs can be substrate dependent, which especially is reported for CYP3A4 with a very large active site that is able to bind multiple substrates in different orientations [176]. The growing knowledge about CYP substrates has increased the understanding of active-site requirements either by protein- or ligand-oriented studies [177]. However, understanding the nature of substrate specificity of each CYP requires knowledge of the interaction of drugs with each CYP active site. A detailed analysis of substrate-binding affinities and selectivities for the CYP2 family is given elsewhere [118, 178].

Pharmacophore-based models for many cytochrome P450 isoforms have been reported for CYP2B6 substrates [179], CYP3A4 substrates [180] and inhibitors [181], CYP2C9 inhibitors [182], and CYP2D6 inhibitors [183]. A 3-D-QSAR model for CYP2C9 inhibitors for prediction of drug–drug interactions was reported by Rao and coworkers [184] and compared with appropriate homology models. Afzelius and coworkers [185] used alignment-independent GRIND descriptors implemented in the program Almond [186] to obtain qualitative and quantitative predictions of CYP2C9 inhibitors for a series of structurally very diverse molecules. De Groot and coworkers reported a combined protein and pharmacophore model approach to understand and predict CYP2D6-mediated drug metabolism [187, 188]. A model for 40 different CYP2D6 substrates (hydroxylation, *O*-demethylation) was obtained by combination of pharmacophores, protein models and molecular orbital calculations. This model was extended by a second pharmacophore explaining 14 less-common *N*-dealkylation transformations. The final model was in agreement with additional substrate and site-directed mutagenesis data. Zamora and coworkers developed an interesting novel approach named MetaSite to predict the metabolization site of substrates in CYP2C9 on the basis of a combined application of alignment-independent descriptors to describe the protein binding site taken from a CYP2C9 homology model and a distance-based representation of individual substrates [189].

The recently solved X-ray structures of rabbit microsomal CYP2C5 in complex with diclofenac [190] and a sulfaphanazole derivative [191] provided additional evidence on how the molecular recognition of structurally diverse substrates takes place. Comparisons of the complex with apo CYP2C5 [119] indicates that the protein closes around the substrate and prevents open access of water from bulk solvent to heme Fe. Multiple substrate-binding models of the sulfaphenazole derivative are in agreement with the experimentally derived ligand electron density maps and the finding that the substrate is not tightly constrained in the active site. For diclofenac, a single binding mode is consistent with the observation of a highly regiospecific hydroxylation at the distal ring in 4′ position. This large active site and the striking enzyme flexibility upon binding of both ligands underlines the ability of the drug-metabolizing enzymes to work on structurally diverse substrates of different sizes.

This work was complemented by the X-ray structure of human CYP2C9 in complex with warfarin by Williams and coworkers [192] (Figure 8). This report provides the first human CYP protein structure, while the warfarin-binding mode reveals previously unanticipated interactions in a new binding

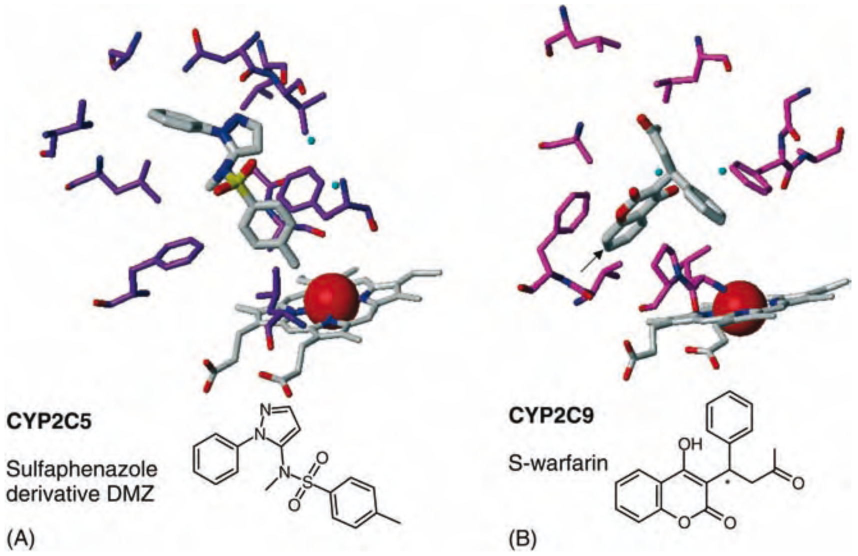

Figure 8 Experimental ligand interactions with the cytochrome P450 2C family. (A) X-ray structure of the sulfaphenazole derivate DMZ in rabbit CYP2C5 at 2.3-Å resolution (PDB 1N6B) from Wester and coworkers [191]. Only one of the two ligand orientations for DMZ in accord with electron density is shown placing the benzylic methyl group 4.4 Å from the heme Fe. (B) X-ray structure of S-warfarin in human CYP2C9 at 2.55-Å resolution (PDB 1OG5) from Williams and coworkers [192]. The substrate is situated in a predominantly hydrophobic pocket. This binding mode places the 6- and 7-hydroxylation sites 10 Å from the iron (arrow).

pocket. From the binding mode, the authors conclude that CYP2C9 may undergo an allosteric mechanism during its function and that two molecules for warfarin could be accommodated in the very large CYP active site. Collectively, these X-ray structures provide insights into relevant protein–ligand interactions for particular human CYP subfamilies, and thus can be used for docking studies and building scaffold-specific 3-D-QSAR models driven by a protein-derived alignment rule. Those models provide guidelines on where to optimize a molecule with a CYP liability. Hence, a higher-resolution picture of drug–CYP interactions begins to emerge for some subfamilies, allowing the use of this information as one optimization parameter in multidimensional optimization projects.

6 Integrated Approach

6.1 Strategy and Risk Assessment

While previous sections discussed computational approaches towards the understanding and analysis of individual properties like affinity, selectivity and ADME parameters, here we show how those tools should be combined to arrive at a lead optimization strategy that is able to manage and design for multiple properties in lead optimization cycles. While in early phases of discovery without knowledge of multiple analogs for a particular hit, "global" models for ADME properties are applied for library design and selection of promising hits, this focus is shifted toward "local" models based on information about analogs during the subsequent optimization phase. The lack of consistent publicly available data on properties like oral absorption prompted us to optimize pharmacokinetic properties based on consistent biological data for one series.

Any significant improvement of the lead optimization process requires predictive *in vitro* assays, models and computations for ADME and toxicological properties to be incorporated into the iterative cycle of compound design and synthesis. In this manner, compounds can be optimized in parallel by a multidimensional optimization strategy, which integrates the evaluation and optimization for affinity, selectivity, physicochemical and ADME properties. This approach, however, requires a proper experimental design of compounds related to a specific chemotype prior to any synthesis. Such a design should take into account a broad coverage of the chemotype-specific chemical space. The reliability of any subsequent statistical model strongly depends on the information content of the training set data. If experiments are planned inefficiently, resulting in higher numbers of experiments, less information and sometimes misleading data are generated. The systematic variation of one factor at a time is only appropriate if the response surface is not influenced by interactions between factors, while cooperative effects may require advanced design approaches [193]. Thereby, appropriate chemotype-specific local models can be built and subsequently applied in the design of new compounds.

Needless to say that reliable experimental data based on a single mechanism should be preferred. Such single-mechanism data provide not only a deeper understanding of the underlying molecular mechanisms, but also allow us to derive better, less noisy and thus more predictive *in silico* models with information on directions to be taken for further design. Furthermore, this approach allows early identification of properties to be improved in lead optimization and, in addition, whether two, three or more variables can be optimized in parallel. For example, if the optimization of the biological properties $Y1$ and $Y2$ requires increasing hydrophobicity for better activity, while this descriptor is detrimental for the improvement of a third property $Y3$, a detailed statistical assessment is necessary whether it is possible at the end to optimize all three dependent variables in parallel to derive a compound with a suitable target product profile.

In particular, parallel optimization of affinity/selectivity and pharmacokinetic properties are difficult to achieve, especially if several pharmacokinetic parameters need to be optimized (e.g. absorption and volume of distribution). The number of variables to be optimized as well as their optimization potential should always be assessed in order to deal with a minimal set of properties to work with. It is our experience in multiple lead optimization projects that as more variables need to be addressed in parallel, the more difficult, time consuming and exhaustive a particular lead optimization will be. In general, the probability of a successful lead optimization of a certain chemotype resulting in a development candidate decreases substantially with

Cpd4	z	z	z	z	z	z

Figure 9 Individual components of multidimensional optimization. This approach requires experimental compound profiling against key properties, which should be performed on a designed compound subset to maximize information with a minimum number of molecules. These data are used to derive models for key properties, which are applied during the next design cycle. The results then led to augmented models. The process is characterized by a tight integration of *in vitro* and *in silico* tools for profiling compound series to guide chemical optimization.

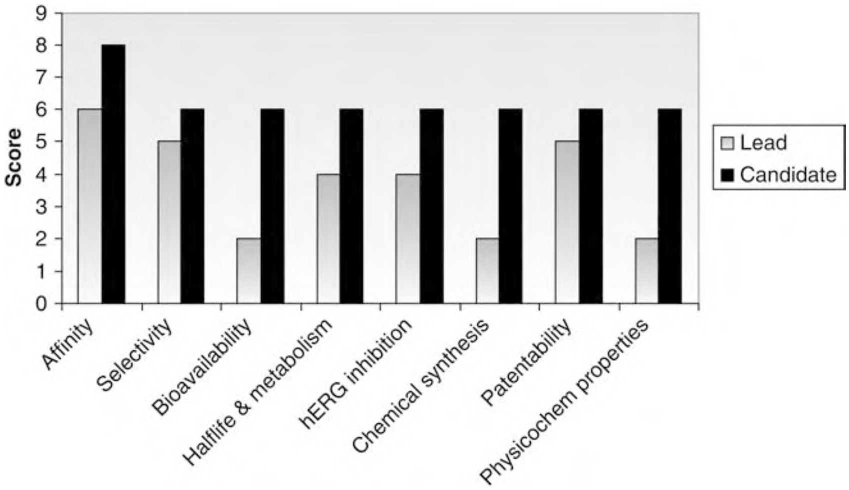

Figure 10 Example for multidimensional optimization on relevant properties during the lead optimization phase from leads to a development candidate. After some iteration, compound properties are either improved or show no further optimization potential.

the need to improve more than three properties in order to fulfill the target property profile.

This requires risk estimation by an early assessment of the optimization potential for any novel chemistry series in order to obtain early information on ADME and antitarget properties as well as potential toxicity issues, which are known to become increasingly important for drug failures. Unfortunately, only a few ADME antitargets have been addressed already (e.g. hERG activity, see above), while others need to be improved. Toxicity, however, is quite often not related to a single mechanism and therefore very difficult to address [194]. Certainly, more reliable and more predictive SARs for target affinity as well as for antitarget and pharmacokinetic properties will strengthen the multidimensional optimization of compounds. The integration of these tools into connected processes will certainly raise modern drug discovery to a new level (Figure 9).

6.2 Integration

The ideal case during lead optimization is to use a consistent set of descriptors for multiple biological variables. This concept is followed wherever applicable, although this is not always possible from a practical point of view. If such a single set of informative descriptors, e.g. VolSurf, to model binding affinity in structure- or ligand-based design and ADMET properties at the same time [21] is used to build appropriate models for all dependent

(Y) variables, an early assessment of the optimization potential is feasible. The approach described by Zamora and coworkers [21] is the promising integration of both binding affinity and passive pharmacokinetic properties on the descriptor level.

However, if different models and descriptors are used and applied, certain criteria, decision trees or scoring functions need to be used to deal with the multidimensional optimization. Decision trees refer to approaches similar in spirit to the well-established "Rule of Five" and are often project-specific variations and improvements thereof. The chemical meaning and interpretability of the descriptors is essential here. Scoring models, as a slightly different approach, condense each *in silico* estimated compound property into a range between 0 and 1 based on project team-specific thresholds. Some degree of uncertainty could be considered by introducing a linear increase in this score contribution from 0 (undesirable) to 1 (desirable) within a narrow area around the threshold. Those individual scores are compiled into a weighted sum and used to evaluate novel synthesis proposals, often biased by the knowledge of the protein 3-D structure (Figure 10). Step-by-step application of decision trees or a set of single models, however, might ultimately sort out almost all compounds depending on the sequence used and are therefore less valuable. Scoring functions, however, offer the opportunity to fine-tune the function in terms of the most important variables without neglecting any of the other properties. The thoughtful integration of *in silico* tools in this multidimensional optimization process will certainly improve candidate quality in the next decade.

6.3 Literature and Aventis Examples on Aspects of Multidimensional Optimization

Although the optimization of promising lead compounds toward clinical candidates is one of the essential skills within the pharmaceutical industry, there are not many reports on the entire multidimensional optimization strategy or selected aspects. Here, we discuss examples from the medicinal chemistry literature and projects at Aventis in which either the chosen optimization strategy or the computational tools are interesting and agree with the proposed multidimensional optimization strategy and its requirements. Important prerequisites for lead optimization that are essential to successfully manage a drug discovery program include the early assessment of the optimization potential for a lead series, the risk assessment of how many parameters have to be optimized in a multidimensional context while all the others should remain in the positive range, where they have been from the beginning. The literature reports address one or only a few additional parameters in addition to biological affinity at the target enzyme to progress a series. This could be seen as typical examples for one single optimization cycle within multidimensional lead optimization.

Linusson and coworkers at AstraZeneca described the application of statistical molecular design for planning and analysis of a parallel synthesis lead optimization library of thrombin inhibitors [195]. This structurally well-characterized serine protease is involved in the blood coagulation cascade and was targeted by many industrial drug discovery projects. The report described how building blocks were selected for a central scaffold with three vectors directed toward individual thrombin subpockets S1, S2 and S4. This was done on the basis of a quantitative statistical analysis of known experimental information such as biological affinities for related thrombin inhibitors at AstraZeneca. The focus of the planned library was to replace benzamidine, which provides important polar interactions within the protease S1 pocket, while it has been recognized for a while that benzamidine substituents are detrimental for oral bioavailability, mainly due to their low intestinal membrane permeability, which could be attributed to their high pK_a value. Hence, parameters like pK_a and membrane permeability are seen as equally important in the planning phase for multidimensional optimization. There are many reports on benzamidine-based thrombin inhibitors, which are all end-points in lead optimization, and lead to potent inhibitors in terms of affinity, selectivity and anticoagulation effect, while significant oral bioavailability could not be demonstrated, except for prodrugs like ximelagatran [196]. Considering this property for a development candidate very late in the discovery phase, however, often results in a significant loss of affinity when replacing the S1 benzamidine. These considerations led the authors to include topologically similar S1 directed substituents with a potential for lower pK_a into their statistical selection procedure of appropriate building blocks. The resulting parallel synthesis library was analyzed with respect to affinity, membrane permeability, pK_a and trypsin selectivity. To this end, the authors derived multivariate QSAR models for all key biological data (affinity, selectivity, pK_a, permeability). As the library has been carefully designed, the final models, although only based on a limited series of molecules, are significant and predictive, and might guide the direction for further optimization. The SAR information for key properties, which was only found using statistical molecular design in combination with multivariate analysis, could now be applied to focus a second follow-up library. This interesting study combines the concepts of multidimensional optimization and suggests statistical approaches to obtain informative models. As this study presents only one cycle in lead optimization, it is only a "snapshot" in the search for a development candidate.

Sugano and coworkers studied the membrane permeation of 51 benzamidine-based thrombin inhibitors in a rat everted sac permeability model [197]. They reported significant membrane permeabilities in this *in vitro* model, which they attributed to passive paracellular transport – a different absorption mechanism to transcellular permeability. On the basis of their evaluation and our internal predictive VolSurf model [160] for this series (r^2: 0.81, q^2: 0.60, 4 PLS components), it can be concluded that factors like size and shape, which had previously been reported to affect paracellular permeability, are indeed important in the VolSurf PLS model to explain the local structure–permeability relationship of one particular scaffold. Hence, local statistical models provide a qualitative ranking of candidates and thus are valuable for optimization of pharmaceutically relevant compounds, especially if combined with additional models to understand affinity, selectivity or any particular pharmacokinetic behavior.

Burgey and coworkers at Merck described their approach toward metabolism-directed optimization of 3-aminopyrazinone-based thrombin inhibitors [198] to result in an orally bioavailable series. Several research groups have now successfully replaced the benzamidine moiety in S1 by less-basic or non-basic substituents with different protein–ligand interactions to overcome the specific benzamidine problems described above, resulting in series with increased oral bioavailability and pharmacokinetics. Starting from an aminopyrazinone–acetamide scaffold with moderately basic 2-aminopyridine as an S1-directed benzamidine mimetic (Figure 11), they discovered three main sites of metabolism, which they related to the observed insufficient pharmacokinetic behavior. The optimization was dictated by metabolic considerations in concert with required target affinity. On the basis of the available experimental information on binding modes for this chemotype and the detailed drug metabolism and pharmacokinetic studies to unravel the mechanistic origin of metabolic instability, they were able to design a series of metabolically more stable variations of the original lead structure with similar enzyme affinity and selectivity. The introduction of metabolically more stable substituents at this scaffold led to a final compound with improved pharmacokinetic properties. Two key observations are essential in this and other successful studies: (i) the careful balance of decreasing thrombin affinity by metabolically more stable substitutions in one subpocket by compensation within another pocket, which could have been achieved only using the wealth of structural knowledge and understanding of thrombin protein–ligand interactions, and (ii) the careful correlation of *in vivo* pharmacokinetic observations to their *in vitro* origin and the subsequent monitoring of each metabolically less labile substituent in appropriate *in vivo* dog pharmacokinetic studies.

In a second contribution from the same group, a subsequent optimization cycle for the previous scaffold was directed toward improving solubility while reducing the number of chemical steps in the overall synthesis of S1 replacements. The readily available S1 directed building blocks then led to

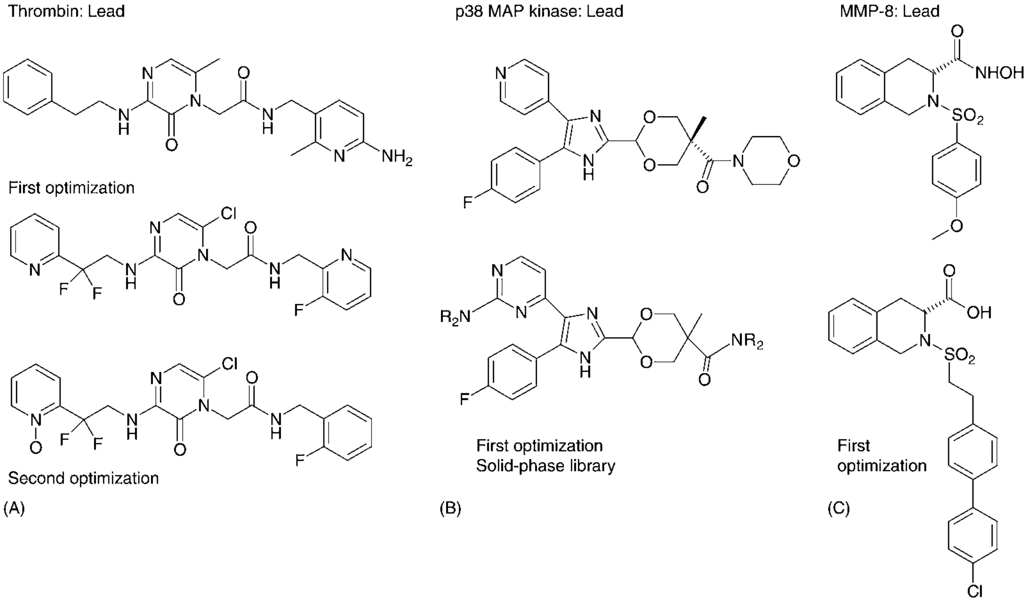

Figure 11 Selected examples for lead optimization under consideration of multiple parameters simultaneously: (A) thrombin inhibitors, (B) p38 mitogen-activated protein (MAP) kinase inhibitors and (C) MMP-8 inhibitors.

establish the structure–activity relationships of three key parameters besides thrombin affinity, i.e. oral bioavailability, half-life and human liver microsome stability. Hence, the optimization strategy of the S1 subpocket was again guided by pharmacokinetic considerations, which were related by *in vitro* solubility assays. Finally, the introduction of S4 pyridine *N*-oxides with increased solubility led to a new orally bioavailable series. An expedited investigation of the P1 SAR incorporating several S1 *N*-benzylamides with respect to oral bioavailability, plasma half-life and human liver microsome stability subsequently revealed an interesting candidate for advanced pharmacological evaluation after careful monitoring and optimization of a variety of affinity, selectivity, physicochemical and pharmacokinetic parameters.

Hasegawa and coworkers from Roche [199] described a local model to understand structure–pharmacokinetic relationships for 107 benzofurans as *N*-myristoyltransferase inhibitors, based on cassette-dosing pharmacokinetic studies and rat elimination half-lifes as dependent variables. They obtained a relatively simple, yet effective, statistical model, which they describe as useful and which gives a direction for designing new inhibitors having good pharmacokinetic profiles. Similar local QSAR models for relevant pharmacokinetic properties could be used in combination with affinity prediction models or docking and scoring calculations, if applicable, to select novel synthesis candidates from a series of feasible proposals in a multidimensional fashion.

McKenna and coworkers at Aventis described the design and synthesis of a solid-phase library to optimize a pyridine-imidazole-based p38 MAP kinase inhibitor toward target affinity and rat oral bioavailability [200]. The authors describe a computational approach toward the design of a library with 570 analogs on two attachment points. Those are selected using a Monte Carlo monomer selection (MCMS) strategy on the basis of combinatorial synthetic efficiency on one hand, while maximizing the estimated bioavailability, as considered by *in silico* descriptors like PSA and a modified "Rule of Five" definition. MCMS applies a scoring function controlled by a series of weights for individual components to drive monomer selection toward solutions that satisfy the design constraints [201]. From this focused lead-optimization library, 10 relatively structurally diverse compounds with improved potency and acceptable bioavailability and pharmacokinetic parameters were rapidly identified as follow-up to the previous candidate.

In their search for nonbenzamidine-based inhibitors of the serine protease factor Xa, Choi-Sledeski and coworkers [202] described the discovery of an orally efficacious inhibitor that incorporates a neutral substituent directed toward the protease S1 pocket as a result of an optimization strategy guided by structure-based rational design and a qualitative consideration of bioavailability. The conflicting and nonconclusive SARs of initial derivatives on that scaffold could only be resolved by X-ray structure analysis of a relevant protein–ligand complex [64]. The X-ray structure revealed a strong preference for a neutral substituent directed toward this S1 pocket for the explored ketopiperazine scaffold, which offered a new perspective on designing nonbasic novel factor Xa inhibitors with increased potential for oral bioavailability. This striking preference for neutral S1 substituents was earlier reported for bioavailable thrombin inhibitors as well [203]. By minimizing the size and lipophilicity of the S4-directed substituents and by incorporating hydrogen-bonding groups on the N-terminus or on the 2-position of the S1-directed ring system, a series of active thrombin inhibitors with good bioavailability profiles was reported that showed a unique binding mode after X-ray structure analysis in thrombin. Both optimizations on serine protease inhibitors were supported by structure-based design techniques, while the latter, including favorable protein–ligand interactions, alone is not sufficient to arrive at bioavailable inhibitors. Here, the careful analysis of available X-ray structures helps to identify substituent positions that will not affect enzyme activity, but will modulate other properties favorably. Replacing a high-affinity substituent requires, on the other hand, a careful monitoring of the loss of affinity, possible substituents in other areas that might compensate for this loss and the favorable change in the desired ADME or pharmacokinetic property.

A similar situation was experienced in the search for potent and bioavailable inhibitors of the matrix metalloproteinase MMP-8 [99, 204]. For the explored tetrahydroisoquinoline scaffold, hydroxamic acids for zinc binding in 3-position are essential for matrix metalloproteinase affinity in early inhibitors, while those showed insufficient pharmacokinetic properties and low oral bioavailability. Driven by X-ray and 3-D-QSAR, alternative zinc-binding groups like carboxylates were investigated, while the expected loss in binding affinity could be compensated by optimally filling the proteinase S1′ pocket close to the catalytic zinc. The design and SAR for this series is in good agreement with those protein requirements and, moreover, monitored multiple properties including selectivity against the undesirable MMP-1 [204]. For several MMP-8 inhibitors, the oral bioavailability from rabbit *per os* studies could be correlated again to VolSurf descriptors (r^2: 0.65, q^2: 0.42, 4 PLS components), which led to a semiquantitative model [160], used in conjunction with structure-based docking and scoring, 3-D-QSAR-based affinity and selectivity predictions, and *in silico* ADME models to estimate membrane permeability, solubility and other key properties for the optimization process in this series (Figure 12). Hence, in this as well as in other series, multiple models are collectively utilized to rank and prioritize novel synthesis candidates, and focus virtual libraries.

In the search for bile-acid resorption inhibitors (BARI), a predictive 3-D-QSAR pharmacophore model for the ileal Na^+/bile acid cotransporter was derived, which enhanced the understanding of binding and transport properties [205]. This model was then also successfully explored to search for potential substitution sites, which are not relevant for the SAR of this series, while they allow the addition of additional substituents to minimize the oral uptake of inhibitors.

The approach discussed to use VolSurf derived *in silico* models to understand structure–pharmacokinetic relationships for pharmacokinetic properties was also applied to one series of selective cardiac KATP channel blockers [160]. It was found that compounds fulfilling the predefined selectivity profile exhibit only less-optimal pharmacokinetic properties because of a short plasma mean residential time (MRT). Consequently, the MRT for 28 compounds from rabbit intravenous studies for one series was used as the dependent variable to derive a VolSurf PLS model in addition to ligand-affinity SAR data. The chemical interpretation of the VolSurf model ($r^2 = 0.89$, $q^2 = 0.76$, 3 PLS components) reveals hydrophobic interactions and the hydrophobic integy moment to be strongly correlated to MRT. This model was then used to prioritize a novel set of promising synthesis candidates from a virtual library of potential products accessible via parallel synthesis.

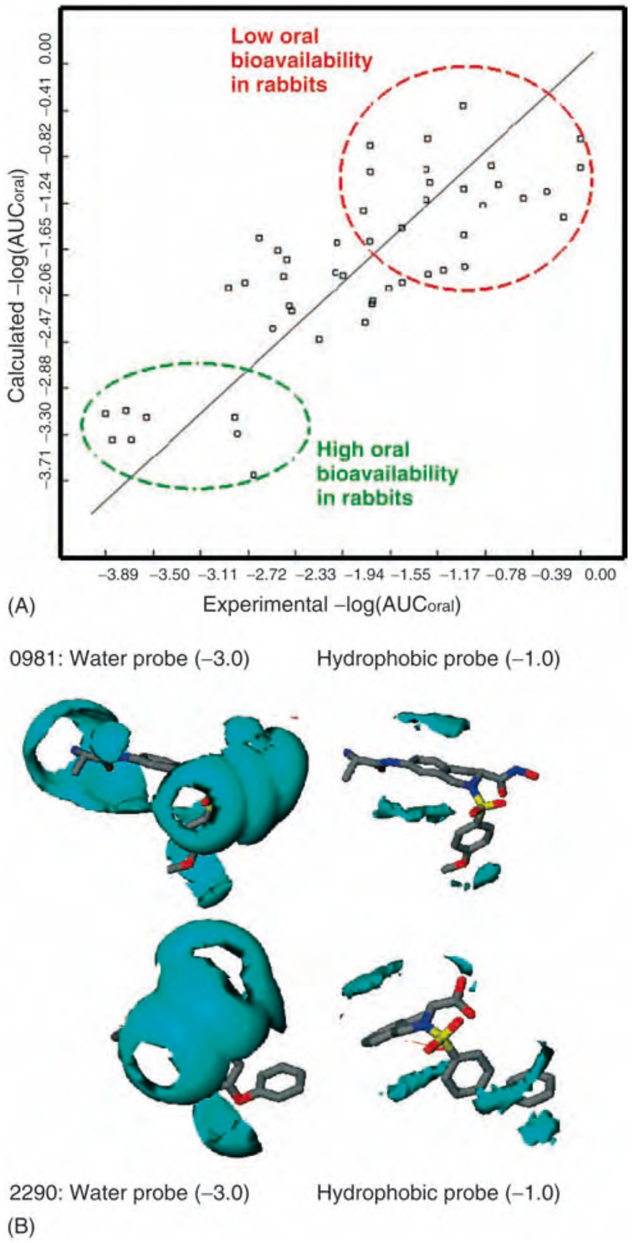

Figure 12 VolSurf model to correlate 49 matrix metalloproteinase inhibitors with different zinc-binding functionalities to rabbit oral bioavailability for metabolically stable compounds. (A) Semiquantitative PLS model (q^2: 0.424, r^2: 0.646, 4 PLS components) to rank novel synthesis candidates. Main factors influencing absorption, i.e. lower polarity, capacity factors and increased hydrophobicity, are in agreement with global models for human intestinal absorption. (B) Distribution of polar and hydrophobic surfaces for two molecules with low (0981) and higher (2290) rabbit AUC from oral pharmacokinetic studies.

Those examples illustrate typical workflows, i.e. the use of a few predictive models in parallel to rank order very focused synthesis proposals that have been derived on the basis of chemical feasibility and ligand SAR data. Each iteration and biological testing of a well-defined, information-rich set of compounds enriches our knowledge about the problem and is, of course, used to update the statistical models in order to guide the next optimization cycle. On the other hand, it might also happen that models for different properties reveal that key parameters influence different properties in opposite directions. This indicates that optimization might be extremely difficult, if not impossible, because of the very narrow balance and possibilities in the design of novel analogs.

7 Conclusions

Optimization of early lead compounds into promising drug candidates for pharmaceutical development is one of the key technologies in today's drug discovery efforts. Several medicinal chemistry approaches have been successfully applied to this problem, while the flexible integration of approaches to form an adaptive project team strategy is essential. The high complexity of this task prompts for an early identification of critical success factors and a risk assessment before individual series are progressed. High throughput alone, in this phase, does not provide a solution, as only the scientific understanding of critical success factors will enable a project team to focus on the most promising series. Therefore, a clear understanding of factors controlling affinity, selectivity, ADME and physicochemical compound properties of lead structures is essential to direct the medicinal chemistry strategies.

This chapter discussed approaches to simultaneously consider multiple aspects in optimization with the challenging goal to improve the efficiency of the drug discovery process. Some literature case studies on lead optimization illustrate the value of tight integration of parameters by means of simultaneous optimization. Data integration is mandatory for reusing the knowledge in subsequent design cycles toward an enhanced lead optimization and drug candidate selection process. Typical problems are, in particular, the improvement of affinity at the desired target, sufficient selectivity against closely related proteins, and ADME and toxicology antitargets (e.g. hERG). Furthermore, a parallel optimization of compound properties toward favorable physicochemical and related ADME/pharmacokinetic properties is essential. In the end, it is important to realize that no single approach will solve all problems for a series, but the challenge lies in the effective integration of these concepts depending on the individual problem. Only flexible and data-driven integration of those tools will enable drug discovery project teams to process interesting lead series and cancel less promising ones early and less cost-intensively.

The paradigm shift from critical activities from later drug development to earlier discovery phases some years ago has effectively led to a change in lead optimization and added a new dimension of complexity, while it is envisioned that from a multidimensional, data-driven process more suitable candidates in accord with the therapeutic target product profiles may emerge for the treatment of currently unmet medical needs.

Acknowledgments

The authors would like to thank Thorsten Naumann, Roy Vaz (Aventis Pharma), Gabriele Cruciani (University of Perugia) and Gerhard Klebe (University of Marburg) for stimulating discussions on several aspects of this chapter.
